PREFACE

After the earthquake of World War II and the spell of prostration which succeeded it, we are now facing the onset of an inevitable tidal wave of scientific publication. It will be some time before proper appraisal of this period is ossible, and all that can be done by the author of a text book is to select such xamples as represent, in his opinion, either current trends or well-established vances. For the ultimate benefit of reviewers, however, I shall not give in is preface a list of the main new features, but leave the matter to their dis-ernment.

Despite a good deal of pruning of older matter and compression of the new, some increase in size has been unavoidable: part of this is due to the inclusion of 60 new figures. These are:—Figs. 30, 31, 32, 51, 55, 62, 85, 89, 90, 101, 102, 103, 104, 114, 142, 172, 197, 199, 208, 213, 214, 241, 254, 265, 266, 295, 296, 297, 298, 299, 300, 301, 302, 303, 385, 395, 397, 398, 402, 406, 423, 427, 455, 456, 492, 499, 516, 534, 541, 543, 566, 567, 586, 586a, 595, 609, 618, 636, 637, 638.

I wish to convey my best thanks to authors and publishers, all of whom are duly acknowledged in the figure legends, for their permission to copy some of these figures; the remainder of the figures have been specially produced for is book. I have again to thank Professor H. Hartridge, F.R.S., for revision f the chapters on "Special Senses".

In accordance with the fashion in the various Services of Government, and erhaps as an omen of the shape of things to come, there has developed in late ears a considerable use of abbreviations in the form of initial letters. Although I do not like these, and have generally avoided their use in the text, I have bowed, or at least nodded, to the inevitable by giving a table of some of the common ones on p. xi.

I have to thank several readers for pointing out errors and misprints in previous editions and many workers in all parts of the world for valuable reprints which have helped to provide material or to shape my outlook.

My best thanks for reading galley proofs and for many suggestions are due to Dr. M. de Burgh Daly, Dr. Sheila Howarth, Dr. H. Ellis Lewis, Dr. O. C. J. Lippold and Dr. A. Schweitzer. To Dr. M. Grace Eggleton I once more express my gratitude for her reading of all page proofs, for many valuable suggestions and for preparation of the Index. I also wish to thank my Secretary, Miss Sybil Reid, for her competent and zealous work over many months in pre-aration of manuscript and in checking all proof corrections.

It has been a pleasure to work with the staff of Messrs. J. & A. Churchill, td., and I would especially record my gratitude to Mr. J. Rivers and to Ir. A. S. Knightley. The usual high standard of their artists and printers has een maintained.

SOME COMMON ABBREVIATIONS

A.C.H. = Adrenal cortical hormone.
A.C.T.H. = Adrenocorticotropic hormone.
A.D.P. = Adenosine diphosphate.
A.N.T.U. = Alpha-naphthylthiourea.
A.P.E. = Anterior pituitary extract.
A.T.P. = Adenosine triphosphate.
B.A.L. = British Anti-Lewisite (= 2 : 3 dimercaptopropanol).
B.M.R. = Basal metabolic rate.
B.P. = Blood pressure.
C.10 = Bistrimethylammonium decane diiodide, or decamethonium iodide.
C.R.O. = Cathode ray oscillograph.
D. = Diodrast.
D.B.T. = Dry bulb temperature.
D.C.A. or
D.O.C.A. = Desoxycorticosterone acetate.
D.O.P.A. = Dihydroxyphenylalanine.
D.P.N. = Dipyridino nucleotide.
D.T*m*. = Diodrast transport maximum.
E.C.G. = Electrocardiogram.
E.E.G. = Electroencephalogram.
E.T. = Effective temperature.
F.F. = Filtration fraction.
F.S.H. = Follicle-stimulating hormone.
G.F. = Glomerular filtrate.
I.U. = International unit.
I.C.S.H. = Interstitial cell-stimulating hormone.
L.H. = Luteinizing hormone.
M.Eq. = Milli-equivalent.
M.E.V. = Million electron volts.
M.L.D. = Minimal lethal dose.
M.T. = Methyl testosterone.
N.T.P. = Normal temperature and pressure.
P.A.H. = Para-amino hippuric acid.
P.G.A. = Pteroylglutamic acid.
P.F. = Plasma flow.
P.M.S. = Pregnant mare's serum (similar to F.S.H.)
P.U. = Pregnancy urine or chorionic gonadotropin.
P.R. = Pulse rate.
R.H. = Relative humidity.
R.Q. = Respiratory quotient.
S.D.A. = Specific dynamic action.
S.T.P. = Standard temperature and pressure.
T.Ac. = Testosterone acetate.
T.E.A. = Tetraethylammonium chloride.
T*m*. = Transport maximum.
T.P. = Testosterone propionate.
T.P.R. = Total peripheral resistance.
U.S. = Unconditional stimulus.
V.D.M. = Vaso depressor substance.
V.E.M. = Vaso excitor substance formed by kidney.
W.B.T. = Wet bulb temperature.

SOME UNITS AND CONSTANTS

Prefixes used in nomenclature, in addition to usual ones :—

Micro = 10^{-6} *i.e.*, one-millionth (μ).
Milli = 10^{-3} *i.e.*, one-thousandth, etc. (m.)
Centi = one-hundredth. (c.)
Kilo = 10^3 *i.e.*, one thousand. (k.)
Mega = 10^6 *i.e.*, one million, etc.
E.g., 1 Kilo calorie = 1 Calorie = 10^3 calories.
1 Micro calorie= 10^{-6} calories.

The following abbreviations and signs are employed for units :

mile	mi.	milligram	mg.
kilometre	km.	microgram (= 0·001 mg.)	μg. (or γ)
metre	m.	kilogram-metre	kg.m.
centimetre	cm.	gram-centimetre	g.cm.
millimetre	mm.	cubic metre (1,000 l.)	cu.m. (or
micron (10^{-3} mm.)	μ	litre	l.
millimicron (10^{-6} mm.)	mμ.	millilitre (= 1·000027 c.c.)	ml.
Angstrom unit (10^{-7} mm. or		cubic centimetre	c.c.
10^{-4} μ.)	A.U. or Å.	cubic millimetre	c.mm.
millionth micron (10^{-9} mm.)	μμ.	hour	hr.
square metre	sq.m. or m².	minute	min.
kilogram	kg.	second	sec.
gram	g.	millisecond (0.001 sec.)	msec. (or
centigram	cg.	microsecond (0·001 msec.)	μsec.

1 farad (F) = an electrical capacity which holds 1 coulomb when charged to 1 volt
microfarad = μF.

1 Microcurie (μC) = radioactivity of $3{\cdot}7 \times 10^4$ disintegrations per second.

1 Roentgen (*r*) = radiation producing 1 electrostatic unit of ions of both signs in
air at 0° C. and 760 mm. Hg.

1 cal. $\begin{cases} = \text{heat to raise 1 gram of water through } 1^\circ \text{ C.} \\ = 4{\cdot}2 \times 10^7 \text{ ergs} = 42{\cdot}7 \times 10^3 \text{ gram cms.} \end{cases}$

1 micro cal. = 42 ergs = $42{\cdot}7 \times 10^{-3}$ gram cms.

1 Cal (or 1 kilo cal.) = 1,000 cal. (= 4 B.Th.U. or 0·00004 Ther

Kinetic C.G.S. unit of force = 1 dyne = force which, acting on mass of 1 gram, ca
it to move with an acceleration of 1 cm. per second, per second.

Gravitational unit of force = 1 gram weight = 981·5 dynes.

Kinetic unit of work = 1 erg = 1 dyne-cm. = $23{\cdot}84 \times 10^{-9}$ calories = 10·16 ×
gram cms.

Gravitational unit of work = 1 gram cm. = 981·5 ergs = 23·4 micro cals. 1 kg.m
2·34 cal. (= 0·468 c.c. O_2 at 5 Cal/l.).

Kinetic Unit of Power = 1 erg. per second.

1 kilowatt = 10^3 watts = 10^{10} ergs per second.

Gravitational Unit of Power = 1 gram-cm. per second.

1 horse-power = 0·746 kw = 457 kg-m. per minute.

Mole (M) = 1 g. molecule = 6×10^{23} molecules. Molar = 1 g. molecule per l.

Millimole (mM) = M × 10^{-3} : Millimolar = 1 mg. molecule per l.

Micromole (μM) = M × 10^{-6}.

Osmotic pressure of molar solution (undissociated) = 22·4 atmospheres.

Osmotic pressure of binary electrolyte (whose degree of dissociation = δ) in
solution = $(1 + \delta) \times 22{\cdot}4$ atm. = $(1 + \delta) \times 22{\cdot}4 \times 760$ mm. Hg.

CHAPTER 1

INTRODUCTION

HE name "physiology," derived from a Greek root with the Latin equivalent *Physiologia*,* and originally connoting "natural knowledge," was first used n 1542 by Fernel,† but was not generally adopted until the 19th century. It now signifies the study of the phenomena presented by living organisms, the lassification of these phenomena, and the recognition of their sequence and elative significance, the allocation of every function to its appropriate organ, and the study of the conditions which determine each function.

Life is the indefinable of biological science, as time and space are indefinables or the physical sciences. By this is meant that we cannot even approximately define life without the idea itself being implicit in our definition. Our business s, given living things, to study their phenomena.

The fundamental phenomena of life are essentially identical in all living organisms. The interest of mankind was, however, naturally awakened in connection with his own body, and the science, growing up as ancillary to medical studies, has always taken man as its chief type of study. Further, the choice of the higher animals in general receives justification from the fact that, whereas morphology must proceed from the lowest to the highest organisation, the science of function presents its problems in their clearest form in the most highly differentiated organisms. In the unicellular animal all the essential functions of living beings are carried out, often simultaneously, in one ittle speck of protoplasm. It is only when, as in the higher animals, the chief parts of the body have highly specialised functions that it becomes possible to peer into the details of these functions with some chance of understanding them.

Organisation. What are the fundamental phenomena which distinguish iving things ? Their distinctive feature is perhaps *organisation*, and in the higher members this organisation becomes more and more distinct. This greater complexity of organisation runs parallel with increasing range and power of adaptation, attained by the setting apart of special structures (organs) or the performance of definite functions. The parallelism between the development of function and structure justifies us in the assumption generally, though often only tacitly, made by physiologists, that the structure is the determining actor for the function. Further, as living animals show progressively increasing differentiation of structure in all their parts, and with this an increased power f adaptation of each part, so by increasingly delicate co-operation between heir various parts, they display a progressive advance in *integration* which urther augments the powers of the individual to adapt itself to its surroundings.

Energy Expenditure. When dealing with the higher animals, we are nclined to lay stress on the phenomena involving a discharge of energy. The fe of a man in the ordinary sense of the term is made up of those movements hich place him in relationship with his environment. For these movements, s for the maintenance of a constant body-temperature, a continual expenditure f energy is necessary. Experience teaches us that these movements come to n end in the absence of food or of oxygen, and that an increased call on the nergies of the body must always be met by an increased demand for air and od. Two further processes must therefore be included among those making o our conception of life, viz. the function of assimilation (the taking in and digestion of food), and the function of respiration, by which oxygen is absorbed and carbon dioxide is excreted into the surrounding atmosphere.

---

* FULTON. *Yale J. Biol. Med.*, 1930, **3**, 59 ; *Science*, 1933, **78**, 109.

† SHERRINGTON, The Endeavour of Jean Fernel, 1946. (Cambridge Univ. Press.) *Arch. néerl. de Physiol.*, 1947, **28**, 369.

The substances which make up our foodstuffs are all capable of oxidation. In this process of oxidation there is liberation of heat. In the body a similar oxidation occurs, and energy is thus set free which is available for the activities of the living organism.

Before we can make any accurate investigations of the conditions which determine these activities, we must know whether the laws of the conservation of mass and the conservation of energy hold good for the processes within the living body. Thousands of experiments have been made, both on man and on animals, in which the total income of the body, viz. food and oxygen, has been weighed, and compared with the total output, viz. carbon dioxide, water, and urea, etc. In every case complete equality has been obtained.

In the determination of the equation in the case of the total energy of the body we have, in the first place, to measure the material income and output of the body, and to determine the total heat which would be evolved by the oxidation of the foodstuffs ingested to the carbon dioxide, water, etc., that are given out. We must then compare the figure so obtained with the *actual* output of heat by placing the animal in a specially constructed calorimeter, described in Chapter XLI. Rubner * thus measured in dogs the energy income and output of the body, and more elaborate experiments were made on men by Atwater and Benedict, a summary of whose results are given below :

INCOME AND OUTGO IN MAN DURING 143 DAYS
(Atwater and Benedict) †

Number of subjects used.	Condition.	Total number of days of experiment.	Average daily net income (calculated potential energy of material oxidized). Calories.	Average daily net outgo (energy given off by body). Calories.	Percentage difference.
4	Rest	41	2,246	2,246	0·0
3	Work	66	4,682	4,676	− 0·1
3	Special diet	26	2,290	2,305	+ 0·7
2	Special diet and work	10	3,719	3,702	− 0·5

The important deduction to be drawn from these observations is that the foodstuffs which are oxidised in the body develop in this process exactly the same amount of energy as when they are burnt outside the body.

From one aspect, therefore, the animal body may be looked upon as a machine for the transformation of the potential energy of the foodstuffs into kinetic energy, represented by the warmth and movements of the body as well as by other physical changes. In the living organism, however, it is not easy to distinguish between the source of energy and the machinery. When we endeavour to trace the foodstuffs after their entry into the body, we lose sight of them at the point where they apparently form an integral part of the living tissues. During activity there is a discharge of the products of oxidation of this living matter, which therefore becomes reduced in mass. This disintegration of the living matter, associated with activity, is always followed by a period of increased integration by the assimilation of more food. Our conception of life must therefore involve the idea of a constantly recurring cycle of processes.

---

* RUBNER. *Ztschr. f. Biol.*, 1894, **30,** 73. Gesetze des Energieverbrauchs bei der Ernährung. (Deuticke, 1902).

† ATWATER and BENEDICT. *U.S. Dept. Agricult. Bull., No.* **136,** 1903, p. 194.

one of *anabolism*, repair, or assimilation, and the other, associated with activity, of *katabolism* or dissimilation. Together they are called *metabolism*.

In the process of assimilation substances of high potential energy are formed, and this energy is obtained either from that imparted to the system at the moment of assimilation, as *e.g.* in the assimilation of carbon from carbon dioxide under the influence of the sun's rays, or from that contained in the foodstuffs themselves. In animal cells it is the latter method which is adopted and a foodstuff therefore connotes some substance which can be taken in by the cell and can serve it as a source of chemical energy. In assimilation there may also be a synthesis of more complex from less complex compounds, without their necessary entry into the structure of the living molecule. Assimilation requires the ingestion of food into the organism, and then its digestion, *i.e.* its solution in the juices of the cells. These two processes are often succeeded by an actual growth in the living material. Digestion is effected in most cases by the production of solutions containing *enzymes*, *i.e.* agents which have the power of hydrolysing the different foodstuffs.

In the process of dissimilation in most organisms the energy for their activities is derived from oxidation. A necessary condition therefore is the presence of oxygen. As a result of this oxidation, products are formed which are of no further value and are therefore *excreted*, *i.e.* turned out of the cell. The chief of these are carbon dioxide and water. There are also many substances resulting from the oxidation of nitrogenous substances which have to be excreted.

Although the need for oxygen is so general a quality of living protoplasm, its presence does not seem to be necessary for all kinds of life. Indeed, most cells can survive for a short time in its absence, and can even carry out oxidative processes by indirect reactions. Further, many bacteria are known which are anaerobic, *i.e.* exist only in the absence of oxygen. Examples of such are bacillus tetanus and the bacillus of malignant œdema.

The activities of a living cell or organism can be regarded in every case as dependent originally on environmental change, and are of such a nature that they tend to preserve the organism intact. The property of reacting in such a manner to changes in the environment is fundamental to all protoplasm and is spoken of as *excitability*, and any change which will influence an organism and cause a response in it is known as a *stimulus*. Stimuli may be of various kinds. Thus mechanical, thermal, chemical, electrical changes, light and so on may act as stimuli. The reactions which they evoke in every case involve changes in the metabolism of the cell. Sometimes this change may be assimilatory in character, or at any rate a reduction of dissimilation. In such a case the stimulus is spoken of as inhibitory, because it diminishes or prevents the output of energy by the organism. The frequent result of a stimulus is an increased output of energy, which may appear in the form of movement, heat, or chemical change.

A common feature of all dissimilatory changes evoked by the application of a stimulus is that the energy of the response is many times greater than the energy represented by the stimulus, the excess, of course, being supplied at the expense of the potential energy of the material of the living protoplasm.

In unicellular organisms and single cells, definite classes of motor reaction to stimulus have been described. Among the primitive reactions of cells perhaps the most important in the life of higher animals are those grouped under the term *chemiotaxis*. Thus, the movements of the white corpuscles of the blood are largely determined by their chemical sensibility, and various substances can be divided into (*a*) those which exercise positive and (*b*) those which exercise negative chemiotactic influence on the leucocytes. The introduction under the skin of an animal of a capillary tube containing a solution of substances of the first class, such as peptone, "leukotaxin," or the chemical products of certain bacteria, leads to an accumulation within the tube of leucocytes which pass to it from all the surrounding tissues. Other substances, such as quinine, exert a negative chemiotaxis. Tubes filled with these, after introduction into the subcutaneous tissue of a mammal, will be found many hours later to contain no leucocytes at all.

Growth, Reproduction. If the anabolic process predominates, we obtain growth. Closely associated with growth is the power possessed by all living organisms of repair, *i.e.* the replacement by newly formed healthy material c parts which have been damaged.

The process of growth does not, in the individual, proceed indefinitel At a certain stage in its life every organism divides, and part of its substanc is thrown off to form one or more new individuals, each of them endowed wit the same properties as the parent organism. In all the higher forms the paren organism begins to undergo decay, until finally death takes place.

Adaptation. All these phenomena, viz. organisation, assimilation respiration, the discharge of energy, growth, reproduction, and death itself are bound up in our conception of life. All living organisms have one featur in common, viz. they are endowed with the power of *adaptation.* Adaptatio is " the continuous adjustment of internal relations to external relations." living organism is a highly unstable system which tends to undergo disintegration if its average environment is changed beyond certain narrow limits. The real environment of the living cells is the tissue fluid in which they live ; this *internal environment* tends to be altered by changes in the general environment in which the animal is placed. It is evident that the condition for survival of the organism must be that changes in the environment are counteracted so that, whatever the general environment may be, the internal environment stays within viable limits. This is what is meant by adaptation.

We have no knowledge of how living things first came into existence, but having once arisen in a primitive form, the " adaptation," *i.e.* the reactions of the primitive living material to changes in its environment, must become ever more and more complex, since only by means of increasing variety of reaction is it possible to provide for the stability of the system within greater and greater range of external conditions. The difference between higher and lower forms is therefore one of complexity of reaction, or of range of adaptation.

Organism and Environment. Though it is a philosophical point on which there is no need to dwell, it should be emphasised that organism and environment must be viewed as a whole. But so far as possible the organism adjusts itself to any changes in its environment or " adjusts its internal to its external relations."

This " adjustment of internal to external relations " is possible only within strictly defined limits, limits which increase in extent with rise in the type of organism, and in the complexity of its powers of reaction. Among the chief of them are temperature, and the presence of food material, water and oxygen. Many organisms are killed by the alteration of only a few degrees in the temperature of their environment. In the higher animals a greater stability in face of such changes has been accomplished by the development of a heat-regulating mechanism, so that, provided sufficient food is available, the temperature of the body is maintained at a constant level. In the primitive condition, the food material must be of a given character and form a constant constituent of the surrounding medium. In the higher forms, the development of a complex digestive system has enabled the organism to utilise many different kinds of food, while the storage of excess as reserve material provides for a constant supply of food to the cells of the body, even when it is temporarily wanting in the environment. Moreover, but few cells of the higher organisms are called upon to face the vicissitudes of light, temperature, chemical composition, etc., of the general environment : instead, most of the cells of the body live in darkness and in contact only with that inner environment, the blood and tissue fluid, the composition and temperature of which are kept constant by wonderfully adapted arrangements. The name *homeostasis* (homoiostasis) is given by Cannon to the condition of uniformity which results from the adjustments of living things to changes in their environment.

To sum up. Our objects in the study of physiology include the description of the chief reactions of the body to changes in its environment, the analysis of these reactions into the simpler reactions of which they are made up, and the assignment to each differentiated structure of the organism its part in every reaction. We must determine the conditions under which each response takes place, so that we may learn to evoke it by application of the appropriate change of environment.

In attacking this problem our methods cannot differ fundamentally from those of the physicist and chemist. In every case our experiments will consist in the observation and measurement of processes of one kind or another which we shall hope to interpret in terms of mass or energy. Physiology, if it could be completed, would therefore describe the *how* of every process in the body. It would state the sequence of events and would summarise these as so-called "laws." These laws would, however, no more explain the phenomena of life than does the "law of gravitation" explain the fact that two masses attract each other with forces directly proportional to the product of their masses. Nor can we hope to explain physiological phenomena by reference to the laws of physics and chemistry, since these themselves are only expressions of sequences, and not explanations. With every growth in science, however, its generalisations become wider and its laws summarise ever more extensive groups of phenomena. The principle of adaptation is the only formula which will include all the phenomena of living beings. This principle must provisionally be accepted as fundamental by the biologist, as the physicist accepts the first law of thermodynamics.

The consciousness of the inadequacy of our explanations, which must be experienced with great force the more deeply the physiologist endeavours to peer into the processes within the living cells, at one time led some to the assumption of a special quality in living organisms which was designated as "vital activity." Such views are classified together under the term "*vitalism.*" As a working hypothesis it must be sterile because there is no evidence that the introduction of vitality enables the known laws of nature to be overruled in any way: whatever the living thing accomplishes, it may do so with the aid of quite orthodox phenomena. That the presence of life does, however, result in an orderly marshalling of these orthodox phenomena, and that in a quite peculiar way, could hardly be questioned. This again, is a philosophical point and need not detain us further than to note the apt remark of Claude Bernard, that "vital force directs phenomena which it does not produce; physical agencies produce (in living things) phenomena which they do not direct." In many cases, however, the terms "*vitalism*" and its antithesis "*mechanism*" are used unjustifiably. The phenomena of living matter are not arbitrary, and since the conditions are infinitely complicated, they are incapable of arbitrary simplification when compared with those concerned with the study of non-living matter, and are hence more difficult to analyse or to control. The physiologist, basing his belief in the principle of adaptation must reject vitalistic "explanations" and seek to discover by experiment the conditions which determine the appearance of phenomena in living things. But he must equally reject an arrogant and superficial doctrine of "mechanism" which would suppose that life can be the outcome of any chance encounter of physical and chemical phenomena, and here again the principle of adaptation must be his guide in refusing to accept the suggestion that physiology is nothing more than applied chemistry and physics. Holding these aims always before him, he must abide by the answer he receives from his experiments as to the ways and means of adaptation, and can hope for little more.

Throughout this chapter we have admitted no necessary dividing line between the different classes of phenomena in the conceptual universe, although in the present state of our knowledge we are far from being able to include the whole of them under the same general laws. It might be objected that in taking up this attitude we have left out of account one supreme fact, viz. the existence of *consciousness* in ourselves. As a comparative and objective study, however, physiology is concerned, not with the study of consciousness, but with the conceptions in consciousness of the *phenomena* presented by living beings.

THE METHOD OF PHYSIOLOGY. Physiology derives most of its inspiration from observations incidental to the phenomena of our daily life and from those made in the course of medical practice. In the prosecution of his enquiries the physiologist often must make appeal to other sciences, but especially to chemistry and physics. In the first place the chemistry and physics of the various separate organs of the animal body must be investigated. This involves first an accurate knowledge of the gross and minute structures, and hence requires the aid of anatomy and histology. Here very frequently, too, comparative anatomy and histology furnish valuable clues to function.

Then the chemical, physical and physico-chemical build must be taken into consideration with a view to the determination of the changes which these exhibit under altered conditions of environment, chemical or physical in nature.

In this way analytical physiology is built up, by experiments, carried out on living animals, or on separated parts of them surviving for a time under suitable conditions ; knowledge of the properties and functions of the various structura parts is obtained. Then, in synthetic physiology, we attempt to find how, by integrative processes, the functions of the body as a whole are synthesised from the co-operative activity of the various parts, and how the organism as a whole reacts, by appropriate adjustment of its individual organs, to changes in its external environment.*

"*Mechanisms*" *in Physiology.* In his physiological studies the student will often meet with the word "mechanism," *e.g.* "the mechanism of gastric secretion"; ". . . of walking"; ". . . of reflex action," etc. This rather overworked word need not be taken too seriously, because as a rule it has no more significance than the equally busy and now notorious adjective "marked." "Mechanism of" really means, as a rule, "the phenomena concerned in . . ." as *e.g.* "the mechanism of bone formation," though in other instances, which the reader can readily find as *e.g.* "The mechanism of speech," the word is more literally employed.

The Normal. Individuals of the same species resemble one another more or less closely in structure and in their physiological properties, and this tendency of biological characters towards a standard type is an expression of the approximate harmony between the organism and its environment. The resemblance is greatest between animals born of the same parents at the same time. As species further apart are considered the differences become greater, and, between the extremes of the animal kingdom, are so great that comparisons become vague.

Yet, even when the relationships between individual animals are of the closest kind, *e.g.* in the human race, these do show differences from one another. It is a duty of human physiology to study the normal human individual, since this provides an important baseline for the study of disease ; yet it is far from easy to state what is the normal of any given character. Further, in all physiological experiments the results must show a good deal of apparently arbitrary variation depending on the individual animals used. Hence the importance of proper controls, and the decision of what constitutes a significant result, cannot be overestimated. Often, in order to be certain that representative results are being considered, it is necessary to repeat experiments many times. The error of observation which is usually slight in the exact sciences, is often great in the biological ones, on account of the variability introduced by the use of varying individuals. The results are, however, capable of being treated by the application of the same laws of probability as are employed in other sciences, *i.e.* they can be treated statistically. Caution is especially necessary in drawing conclusions from a limited number of experiments, as to whether the results obtained differ from those of a control series or not. Thus if a given result happens 4 times out of 8 in one series and 7 times out of 16 in another, we are not justified in concluding that it happens more often under the conditions of the first, because chance could easily account for the difference. But 4 out of 8 in one series and 3 out of 16 in the second would be a significant difference.

It is a common practice to speak of averages, that is, of arithmetic means, as one way of overcoming the difficulty, *e.g.* we can say that the average number of red cells per cubic millimetre of blood in a given community of men is 5·2 millions. Such a method, though the simplest and the one most commonly used, is often unsatisfactory, because it does not tell us how great or how relatively frequent are the departures from the mean, so that we should have no means of knowing in the example quoted whether 4·5 millions was within the normal range or not. There is consequently a growing practice of using more accurate means for the expression of statistical results.

One of the methods employed is the use of the *frequency diagram*, an example of which is given in Fig. 1, which illustrates data regarding the stature of a large number of individuals. These have been divided into frequency groups differing in stature by 1 inch. The height of each rectangle is proportional to the number of individuals having the height shown at the abscissa, the grouped figure being called a histogram. A smoothed curve, or frequency curve, drawn from this, shows the frequency with which any stature between the given limits occurs.

---

* As an example of essays in synthetic physiology may be quoted J. Barcroft's "Features in the Architecture of Physiological Function," Cambridge, 1934.

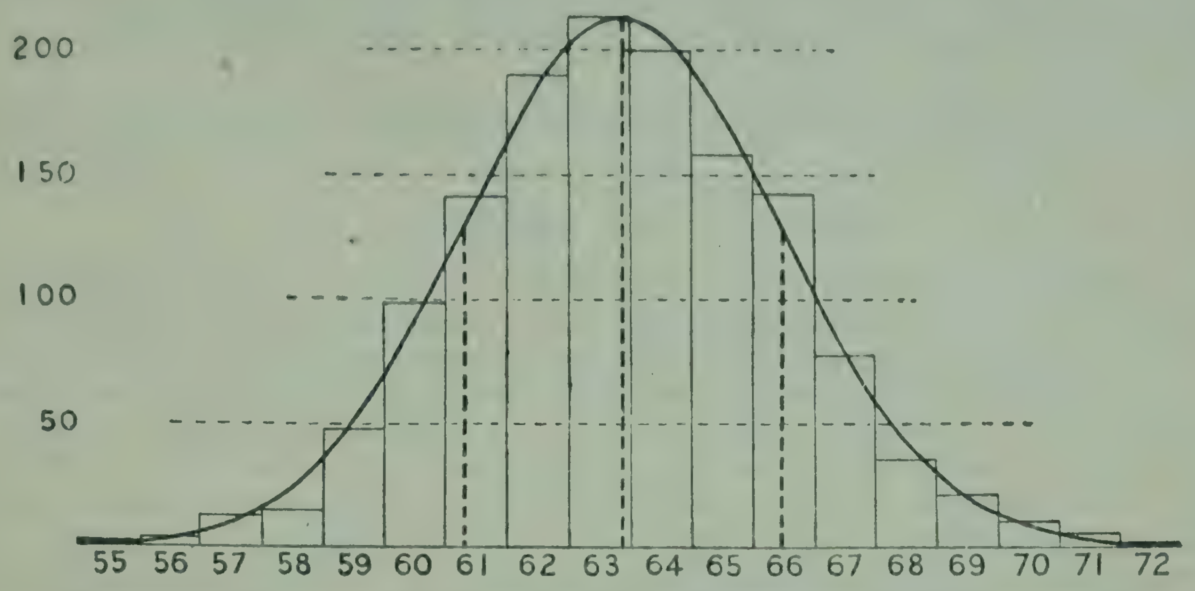

FIG. 1. Frequency diagram of distribution of stature of 1,375 women, in groups differing by one inch. (Pearson and Lee.) (From Fisher's "Statistical Methods for Research Workers." London. Oliver & Boyd.)

(Other examples are given in Chapter XXIX showing distributions for blood counts, and in Chapter XXXIII showing blood pressures.)

The *standard deviation* or mean error, is one of the means of improving the value of results; it measures the amount of variation in the individual figures from which the average was obtained. The accuracy of an average result depends on the square root of the number of observations made, so that, in a series of n determinations with individual differences summed up as Σd, it can be shown that the standard deviation of a single observation is $\pm \sqrt{\frac{\Sigma d^2}{n-1}}$, while the standard deviation of the average is given by the formula $\pm \sqrt{\frac{\Sigma d^2}{n(n-1)}}$.

To take an illustration given by Burn, we may consider the investigation of the lethal dose of a drug, as determined on a series of five cats, which gave the result as 17·44 ± 1·67 c.c. The figure 1·67 is the standard deviation of the average, and means that, "if a number of determinations of the average lethal dose be made, each time on five cats, then twice out of three times the difference between the value obtained and the true value will be less than 1·67, and once out of three times this difference will be greater than 1·67." If we take twice the standard deviation, and call the result 17·44 ± 3·34 c.c. the report will probably be wrong only once in twenty-two times; or if three times the S.D. or 17·44 ± 5·01 c.c., then it will probably only be wrong once in 370 times.

A difference between two series of similar experiments with standard deviation $= \sigma$ may be considered to be significant if, the two series having given results of $x_1 \pm \sigma_1$, and $x_2 \pm \sigma_2$, the ratio $\frac{x_1 - x_2}{\sqrt{\sigma_1^2 + \sigma_2^2}}$ is greater than 3.

The *probable error* of a mean is given by the formula $\pm\ 0{\cdot}6745\ \frac{\sqrt{\Sigma d^2}}{n\,(n-1)}$ or, by the more convenient approximation of Peters, the probable error of the arithmetic means of a series of observations $= \pm \frac{0{\cdot}8455\ \Sigma(+\,d)}{n\sqrt{(n-1)}}$ where $\Sigma\,(+\,d)$ is the sum of the deviations of every observation from the mean, their sign being disregarded. The probable error determines the degree of confidence we may have in using the mean as the best representative value of a series.*

HISTORY OF PHYSIOLOGY

As it is impossible to realise the present position of any science without some knowledge of the history of its development, the serious student of physiology should acquaint himself with the outlines of its history. By way of introduction, some very brief historical notes, dealing with the development of various branches of physiology, are given here and there in this volume. As regards the growth of the subject as a whole, it must be remembered that no part of scientific knowledge can develop alone, but that all parts depend on each other. For instance, until a reasonable body of anatomical knowledge had been established, no physiology, as we understand it, was possible; and until physics and chemistry had reached a certain state of development, much of the early physiology could be but tales of mystery and imagination.

Starting, then, with the foundation of modern anatomy by the publication, in 1543, of the *Fabrica Humani Corporis* of Andreas Vesalius, we may put down the following names of key men whose work enabled expansion of our subject to take place in one direction or another. They form important landmarks.

Name.	Life.	Important publication.	
		Date.	Significance.
Vesalius	1514–64	1543	Start of modern anatomy.
Galileo	1564–1642	c. 1600	Start of modern physics.
Harvey	1578–1667	1628	Experimental method in biology.
Boyle	1627–91	1660	Experimental method in chemistry.
Malpighi	1628–94	1661	Microscope used in biology.
Mayow	1645–79	1668	Application of chemistry.
Newton	1642–1727	1687	Development of modern physics.
Boerhaave	1668–1738	1708	Application of chemistry and physics.
Haller	1708–77	c. 1760	Important text-book on physiology.
Lavoisier	1743–94	1775	Combustion and respiration related.
Joh. Müller	1801–58	c. 1834	Important text-book.
Schwann	1810–82	1839	Cell theory established.
Bernard	1813–78	1840–70	Great experimentalist.
Ludwig	1816–95	1850–90	Great experimentalist. Introduced graphic method.
Helmholtz	1821–94	1850–90	Applications of physics.

The first journal devoted to physiology, first appeared in 1795; the English *Journal of Physiology* in 1878, and the *American Journal of Physiology* in 1898. The first English chair of physiology, as distinct from anatomy, was founded at University College, London, in 1874, and the first in the United States of America, at Harvard, in 1876.

It is thus seen that the subject of Physiology, in anything like the form we now know it, began to take shape little more than a century ago, and so is a young subject. Biochemistry is still younger, and has mainly developed in the lifetime of many not yet old, as an outgrowth of physiology.

A. STRUCTURAL PRINCIPLES

CHAPTER II

THE STRUCTURAL BASIS OF THE BODY*

THE CELL

A cell is a small mass of protoplasm containing a nucleus. Since the formulation of the *cell theory* of life by Schwann and Schleiden about 1840, it has been customary to regard the function of any organ, or indeed of the whole body, as the sum of the functions of its constituent cells. The cell is therefore a physiological as well as a structural unit.

Many of the lower forms consist only of a single cell. In this cell are represented all the adapted reactions which we associate with life.

The general characteristics of cells present important similarities, whether they form the whole of an organism or but an infinitesimal part of a highly developed animal.

In the multicellular animals there are cells of many different kinds of structure and function. In this way there is a division of labour. The organism, biologically, is something more than the mere sum of its component cells, since it directs the growth and functions of these to its own ends, just as a nation is, biologically, something more than a large number of individuals. We must regard the organism also as a biological unit of definite significance.

Every cell, so far as we have been able to ascertain, is derived from some pre-existing cell, by a process of division, and every nucleus similarly from a parent nucleus. These important laws, so significant in the study of heredity, were expressed by Virchow (1855) and Flemming (1882) in the dicta "*omnis*

---

* The matter of this chapter will be familiar to students who have studied Histology, Cytology, and Embryology, and only gives such broad outlines as to recall the importance of those subjects to Physiology.

cellula e cellula" and "*omnis nucleus e nucleo*" respectively. As a necessary consequence it follows that the cytoplasm of the cell is also derived from the previously existing cytoplasm of the cell from which it arose.

The term "protoplasm" generally implies any material which we can regard as endowed with life. This material is very complex and of very varied composition. The organisation and reactions of every cell are the resultant of the molecular structure of the matter of which it is built up. The limited methods of the chemist show him that the composition of the muscle cell is entirely different from that of a leucocyte. The finer methods of the physiologist show him that every sort of cell has its own peculiarities of reaction to changes in its surroundings, and the reactions of the whole organism are but the sum of the reactions of its constituent cells.

Even in a single cell there is more than one kind of protoplasm, since the nucleus differs widely from the cytoplasm. Both are necessary for the life of the cell and both must be considered as "living." In the cytoplasm itself we find structures or substances which we must regard as on their way to protoplasm or as products of the breakdown of protoplasm (Fig. 2); but in many cases it is impossible to say whether a given material is to be regarded as living. Even in a single cell we may have differentiation among its different parts, one part serving for the process of digestion while others are employed for the purpose of locomotion, etc.

METHODS EMPLOYED IN THE STUDY OF MINUTE STRUCTURE

The relations between structure and function are so intimate that physiology would be incomplete if it did not take considerations of structure into account. Moreover, there has grown up recently an important branch of physiological investigation, namely, the enquiry into the physiology of individual cells, in which methods of histological research are in constant use, and are supplemented by a variety of instrumental techniques.

Routine histological technique has its limitations. We are often in doubt as to how far the structures we see in fixed and stained preparations have any real existence in the living cells. A method of fixation which produces minimal change of structure and physicochemical arrangement is to dry the tissue while in a frozen state.* A further difficulty is that the power of the microscope to resolve details has been developed to the uttermost limit, namely, to enable us to see structures whose dimensions are 0·25 μ, equal to half the wave-length of light. Some further resolution can be got by using light of shorter wave-lengths; more detail will be seen with green illumination than with yellow light, and by photomicrography with invisible ultra-violet light details down to 0·1μ can be made out. A further result of using ultra-violet light has been to show that certain structures, *e.g.* chromosomes, are more opaque to it than others, though both types may be equally transparent to the visible rays; hence not only finer structures, but actual new structures, may be revealed.

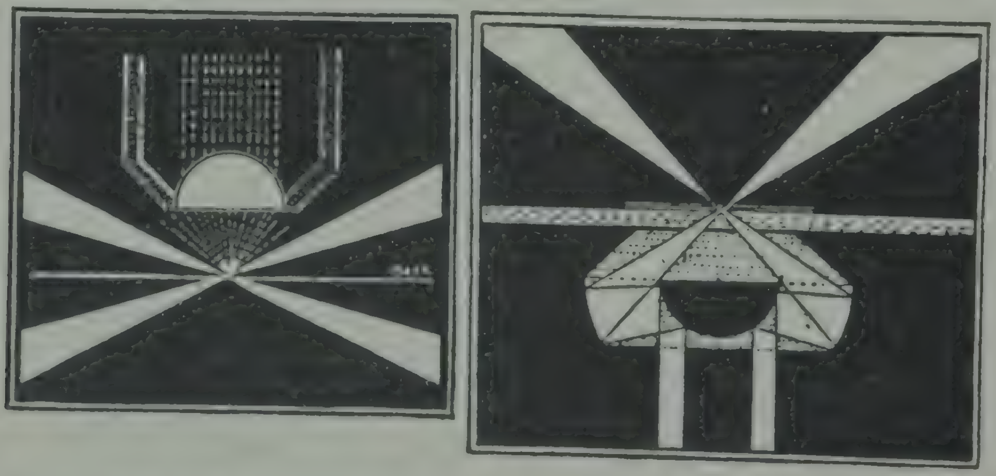

FIG. 3. To illustrate the principle of dark-ground illumination, and the method by which this is obtained with the use of a special substage condenser. (Courtesy of Messrs. R. and J. BECK.)

A further refinement is by the use of the principle of the ultra-microscope in what is called *dark-ground illumination*. With the aid of a paraboloid condenser the light is thrown nearly transversely across the preparation (Fig. 3), so that the field is dark except where particles lying in the path of the beam are able to reflect the light into the microscope (Fig. 3). This method will reveal the position of particles in living protoplasm, and give us some idea of their size, even though they are so small as to be invisible by any direct microscopic examination. Yet another useful technique is provided by a special method of illumination called *phase contrast* (Zernike), which develops contrast due to differences of refractive index, not normally detectable in the structure of living cells.* The reflecting microscope, in which lenses are replaced by curved mirrors, offers other advantages, *e.g.* absence of chromatic aberration, availability for any wave-length, including the ultra-violet, and long working distance, which facilitates manipulation under high powers.†

* BENSLEY *et al. Anat. Rec.* 1933, **57**, 205, 217, 369; **58**, 1; 1934, **60**, 251, 449.

Accelerated cinemicrophotography is a powerful aid to the observation of the changes taking place in living cells. Its use reveals the fact that many cells exhibit extensive changes in shape and position, inappreciable to unaided observation.

Much valuable information has been obtained with regard to the structure and behaviour of living cells by means of *micro-manipulation*, which has been extensively used as a means of dissecting the live cell or of injecting various fluids into it. The living cells are suspended, as a hanging-drop preparation, from a cover-glass, and are manipulated and dissected by means of two fine glass needles, the movements of which in all directions are controlled by micrometer adjustments (Fig. 4): injection is performed by fixating the cell with a needle and then perforating it at the desired place with a fine glass capillary through which the fluid is then forced from a micrometer syringe.

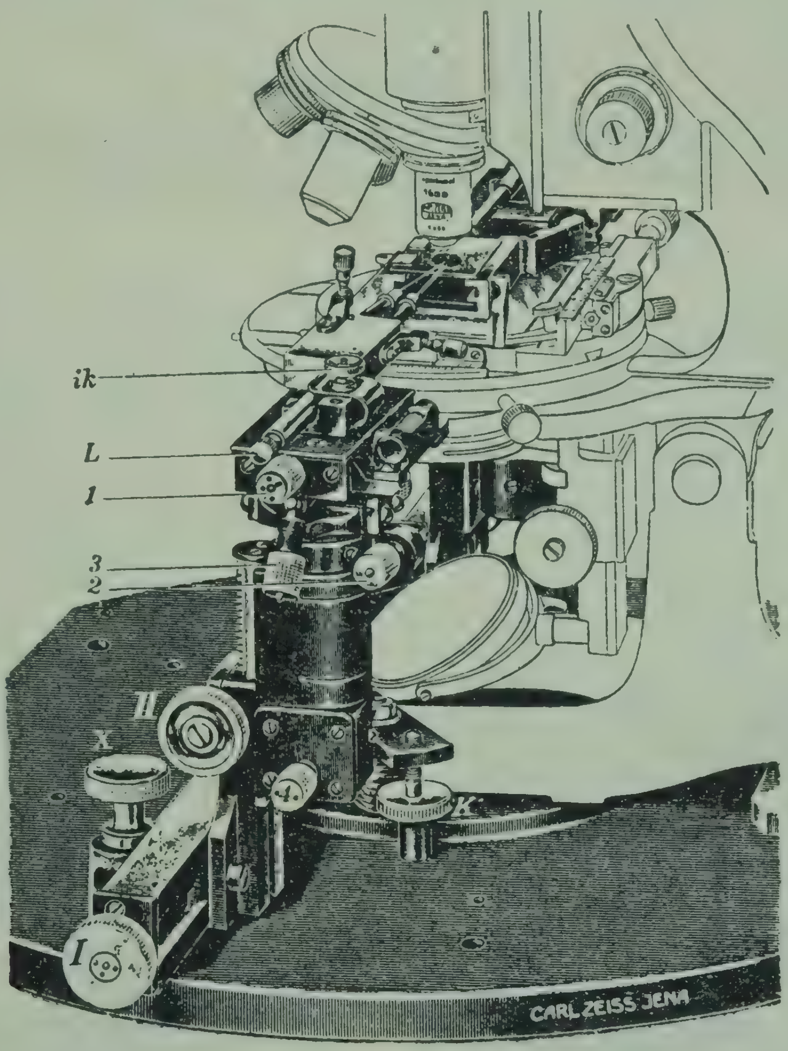

Fig. 4. Micro-manipulator in position. The manipulations are effected by six screws, two of which transmit coarse motions to the operating stands as a whole, while the other four actuate the micro-instruments. In the figure a double needle is shown on one stand and a single one on the other. (Courtesy of Messrs. Carl Zeiss.)

Another method which has found many applications of late is that of *tissue culture*, in which small portions of embryonic tissue are taken and kept at suitable temperatures in a nutrient fluid, such as a mixture of embryo extract, blood plasma and saline solution. The whole preparation must be aseptic, and is usually made as a hanging drop. The tissue continues to live, and under certain conditions the cells grow and multiply in an apparently normal manner until the cell mass reaches a certain size, when growth ceases and degeneration sets in unless a small piece of the tissue is taken and used to start another similar culture. In some cases the process of sub-culture can apparently be repeated indefinitely. Much has been learned of the structure, growth, and differentiation of embryonic cells by this method.

The histological staining methods are very usefully supplemented by a variety of so-called *intra-vitam staining* methods in which the dye is presented to the living organism, and *supra-vital staining*, in which the dye is added to a solution in which surviving tissues or isolated cells are suspended. Certain portions of cells have an affinity for particular dyes. Thus the mitochondria are stained in the live cell by Janus green, nerve material by methylene blue, many cell granules by neutral red, certain connective tissue cells by Pyrrol or Trypan blue, etc. This gives a valuable method for classifying cells, as well as for obtaining information with regard to their structure.

* Barer. *Q.J. Micr. Sci.*, 1947, **88**, 491.

† Barer. *Brit. Science News*, 1948, I, 12.

A good deal can be learned about the distribution of chemical substances within cells by means of various *microchemical reactions*. Thus the presence and location of fat, protein, glycogen, potassium, iron, etc., can be discovered by appropriate colour reactions applied to sections of tissues or to isolated cells. The distribution of the inorganic constituents can be studied by means of *micro-incineration* ; * sections of the tissue are incinerated on the slide, and on dark-ground illumination the deposit of ash is seen to vary in density in different kinds of cell or different parts of each cell.

Ultrastructure of Protoplasm. In its last resort the study of structure must become that of molecular orientation, and hence lies beyond the reach of ordinary microscopes. The electron microscope,† giving a resolution down to 4 mμ (·004μ) or less, has already found some applications, and the optical properties to polarised light have also been used. The latter shows whether molecules or micellæ are orientated in regular patterns. By the use of X-ray diffraction methods also, information regarding the molecular components of tissues can be obtained.‡ This gives resolution from 50 mμ down to 0·01 mμ. It therefore enables molecules to be studied. Some disease viruses have molecules 150 mμ long ; some proteins 5 mμ ; a water molecule 0·3 mμ. The methods are complicated and the interpretation of results, though promising, is still largely tentative.

STRUCTURE OF THE CELL. Cells are often enclosed by one or more outer coats not essential to life ; but there is always one indispensable layer, called the *plasma membrane*, which lies immediately outside the cytoplasm and represents its real boundary ; within this again is a thin shell, the *ectoplasm*, generally in gel form, and homogeneous. Inside this is the cytoplasm proper, within which is the nucleus.

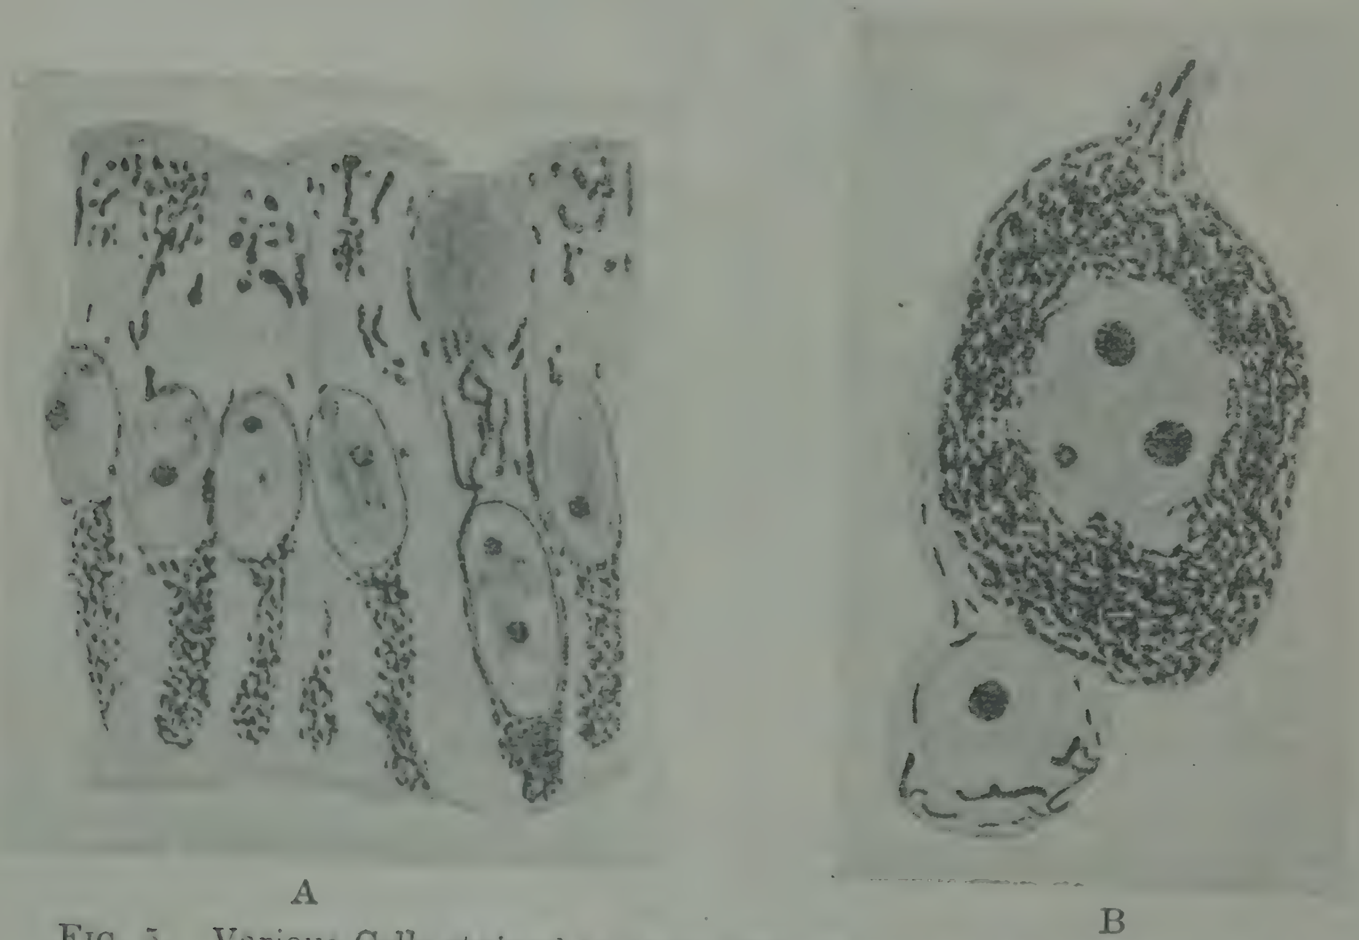

FIG. 5. Various Cells stained to show Mitochondria. (E. V. COWDRY.)
A. Lining Cells of the Small Intestine.
B. Two Nerve Cells, with different forms of Mitochondria.

The nucleus is generally bounded by a definite *nuclear membrane*. The contents of the nucleus are probably fluid in life, but on damage, death and coagulation rapidly occur. Within the nucleus are one or more smaller bodies called *nucleoli* ; in the living non-dividing nucleus no other structures are usually visible. After fixation various artefacts appear in the nucleus, *e.g.* masses or filaments of a material known as *chromatin*, which are strung, so to speak, on a fine network of material known as *linin*. The material filling up the meshes of the network is the nuclear sap or *nucleoplasm*. When the cell is about to divide, the chromatin becomes aggregated into filaments called *chromosomes*, and these are visible in the living cell.

The cytoplasm, which varies greatly in extent in different cells, varies also in its appearance, especially after fixation, being sometimes homogeneous, sometimes alveolar, sometimes granular in structure. In it can often be distinguished differentiated parts which may be regarded as organs of the cell.

The most universal of these cell inclusions, or possibly cell organs, are the *mitochondria*. These occur in the form of granules, rods or filaments in almost every type of cell, animal and vegetable (*cp.* Fig. 5). Their function is unknown, though they seem to be more numerous and longer in cells which are very active. Their presence must largely increase the surface of phase-boundaries within the cell, and it has been suggested that important chemical reactions occur at these surfaces of contact between mitochondria and cytoplasm. The important cytochrome oxidising systems are also located in the mitochondria. They are often grouped at one pole of the cell; thus in gland cells they are frequently found at the pole nearest to the blood capillaries and farthest from the lumen. They are more abundant in young than in old cells, and in the living cell are seen to move about readily in the cytoplasm. When the cell divides the mitochondria are shared between the two daughter cells. In some conditions the mitochondria can be dragged out of the cell by microdissection methods, hence they are relatively solid. They contain some 40 per cent. of fatty substance, and two different proteins, but are said to contain no lecithin or cephalin.* In the living cell they can be stained with Janus green. Usually they are dissolved by alcohol and by weak acids, and so are not displayed in cells hardened to display nuclear structure. They are best preserved by hardening in formalin and bichromate and staining with iron hæmatoxylin.

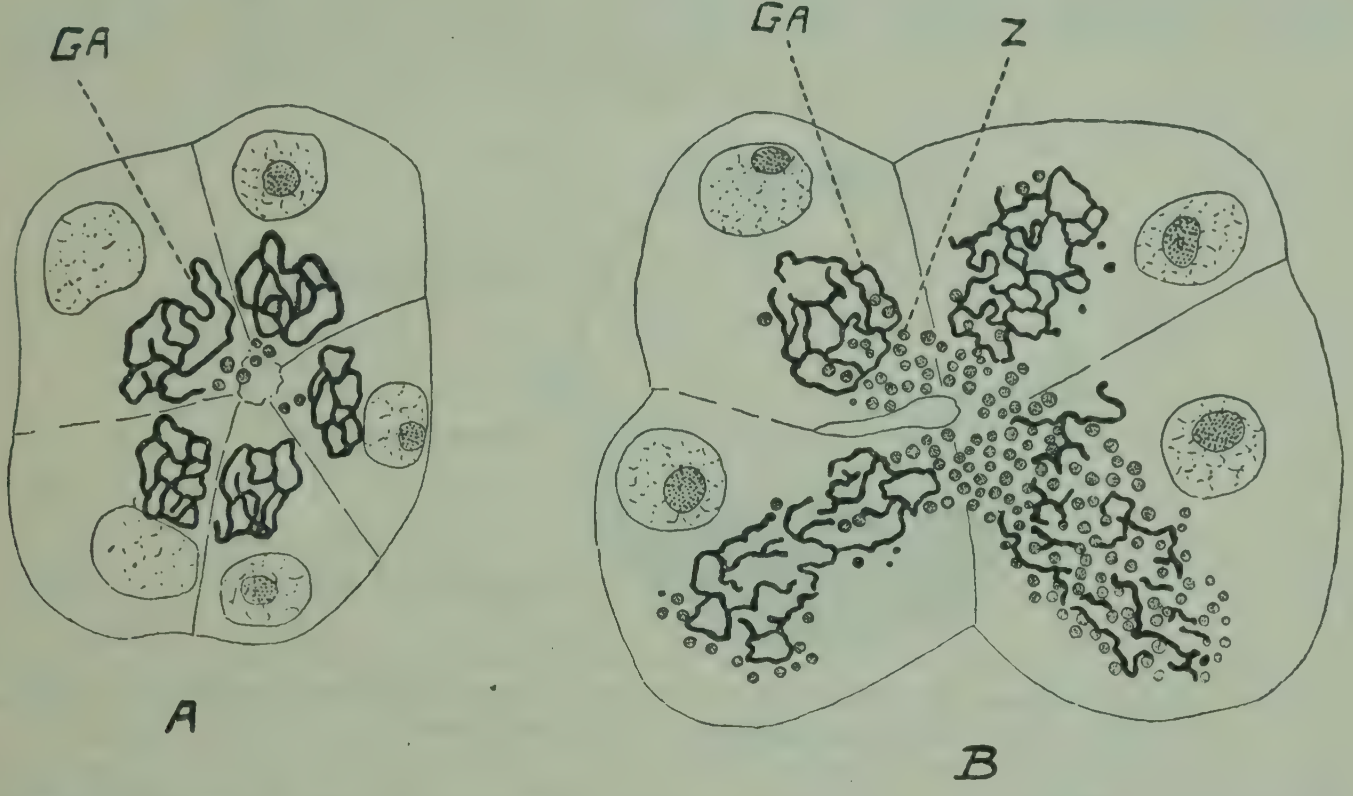

Fig. 6. Diagram of Golgi apparatus (GA) in secreting cells of the pancreas. A. In the contracted condition, after discharge and prior to re-formation of zymogen. B. Zymogen granules (Z) in relation to enlarged form of Golgi apparatus during active formation of zymogen. (Ludford.)

An organ of considerable importance is the *centrosome*, a specialised area of cytoplasm often containing a more deeply staining particle, the *centriole*. In the resting, *i.e.* the non-dividing cell, it commonly lies near the nucleus, and is sometimes double; cells which are incapable of division, *e.g.* nerve cells, have no centrosome, but there may also be no centrosome in certain resting cells which are nevertheless capable on occasion of further division; in those cases, when the time for division approaches, a new centrosome is formed in the cytoplasm. The process of cell-division is apparently heralded and initiated by a preliminary division of the centriole and centrosome. Next there appear birefringent striæ radiating out from each centriole, the structure so formed being called an *aster*. The asters on microdissection behave as relatively rigid elastic bodies, very distinct from the surrounding more liquid cytoplasm, and the two asters grow rapidly in size and appear to repel one another, so that they tend to travel to opposite poles of the cell.

Another cell structure is the so-called *Golgi apparatus*, a reticular structure often located at one pole of the cell, soluble in alcohol, blackened by osmic acid and, after suitable fixation, stainable with silver salts (Fig. 6). In secretory cells it is usually found between the nucleus and the lumen. The functions of the Golgi apparatus are uncertain. Its filaments are of lipoid nature, and it has been suggested that certain products of cell activity, *e.g.* zymogen granules, can be assembled at the surface of the filaments.

---

* Bensley and Hoerr. *Anat. Rec.*, 1934, **60**, 449.

Special inclusions are also met with in certain cells, the best example being the Nissl bodies of nerve cells. Sometimes these structures are artefacts produced in the course of fixation. In addition to these cell organs the cytoplasm may contain visible *granules* of material of various types, which are usually formed by the activity of the cytoplasm or stored there until required. Thus we have granules of *zymogen* found in secreting cells and representing a precursor of the enzymes which the cell liberates during activity, or granules of food material provisionally stored in the cytoplasm until required, *e.g.* fat or glycogen.

THE PHYSICAL STRUCTURE OF PROTOPLASM. It is usually impossible, even under the highest powers of the microscope, to make out any structure whatsoever in living cytoplasm. It is an apparently homogeneous colloidal solution, except for the ectoplasm, which is usually a gel. This gel may be reversibly liquefied, *e.g.* by potassium ions, or by exposure to high hydrostatic pressures (500 atm.): Ca ions make the gel more rigid. This ectoplasmic gelation and liquefaction is probably of importance in bringing about movement of a cell, or within it. Thus, within the pseudopodia in *amœba*, there is an increase of rigidity, which maintains the shape, and this gel is subsequently liquefied. In ciliary motion, cell division, etc., also, the ectoplasm probably plays an important part in causing movement.

In the remaining cytoplasm, or endoplasm, there is also some potentiality for gelation, though more feeble. Various inclusions and granules may be visible within it, but these are not essential components, and are not necessarily living. Differentiation between a more or less regular meshwork and a more fluid portion filling up its interstices, is the rule when cells have been fixed by hardening fluids. All the results obtained in this manner must be regarded with some suspicion, since, as has been shown by Fischer and by Hardy,* it is possible to imitate artificially the various structures, which have been assigned as characteristic of protoplasm, by hardening a homogeneous colloidal solution such as egg-white by orthodox methods. The results of differential staining, especially after fixation, also need further caution in their interpretation, since we know so little of the factors which combine to give any particular result. Thus various theories of protoplasmic structure, which have been put forward as the result of observations on hardened tissues, possess little more than historic interest.

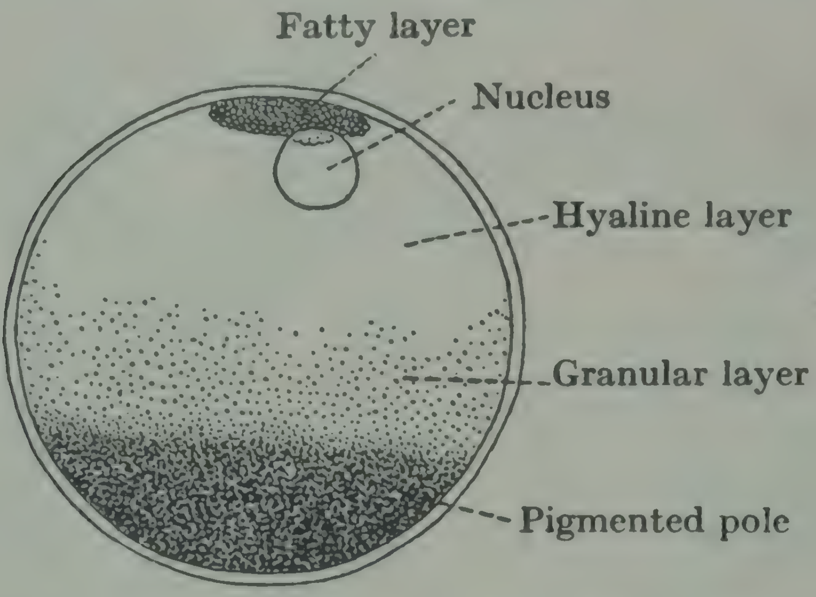

FIG. 7. Stratification in contents of *Arbacia* egg after two minutes' rapid centrifugalisation. (After LYON.)

The perfect potential mobility of the protoplasm of many cells, as instanced by the flow of the substance of an amœba into its pseudopodia, or the ready movements of granules or mitochondria within living cells, indicates a fluid character for the protoplasm. This view is supported by the observation that when small amounts of water are injected into the substance of a cell the water at once mixes freely with the cytoplasm.

Against such a character has been urged the fact that cells have shape, organisation, and power of resistance to deformation—qualities which are generally associated with the possession of solidity. It must be remembered, however, that the ectoplasm is not only often in the form of a gel, but that the whole cell surface must be in a condition of tension, and exercise pressure on the internal portions of the cell, which will tend to bring it into the spherical form. The smaller the mass of protoplasm the greater will be the pressure exerted by its surface layer on its contents and the greater resistance will it present to deformation of the spherical form. A fluid drop, if suspended in a fluid with which it is immiscible, will present greater rigidity the smaller its dimensions. Actual measurement of the tension at the surface of cells, however, shows it to be surprisingly low, viz. 0·1 to 2·0 dynes/cm. This is believed to be due to adsorption of protein on the surface. The endoplasm may therefore be regarded as usually fluid, the form and rigidity which are acquired by most cells being due to physical differentiation in its substance. In some cells, as for instance, muscle fibres, the cytoplasm on microdissection behaves as a gel. The cytoplasm in many cells is certainly of very low viscosity; when certain sea-urchin eggs are centrifuged, the granules settle in layers within the cell (Fig. 7), and in some species at a rate indicating a viscosity only four times that of water. The physical condition of protoplasm is without doubt subject to considerable and often very sudden changes. When, for instance, a living cell is damaged by a microdissection needle, the fluid homogeneous cytoplasm almost at once sets to a jelly-like semi-solid, in which definite granules soon appear. Bayliss showed that when an amœba was stimulated electrically, while observed by darkground illumination, the fine movement of the granules was momentarily checked, also presumably owing to a temporary gelation of the cytoplasm.

---

* HARDY, *J. Physiol.*, 1899, **24**, 158,

When subjected to stress, cytoplasm may show fine fibrillations, which vanish again when the stress is removed. The radiations of the aster are possibly the result of such a state of strain originating in the neighbourhood of the centrosome. They disappear at once if the cell is etherised.

Since the study of the behaviour of the cell shows that it must possess a much more complex structure than that which is revealed by the microscope, and one which permits of the spatial differentiation of the different chemical processes that may occur at one and the same time in the protoplasm, many theories of an ultramicroscopic cell structure have been put forward. Ultramicroscopic examination of living cells certainly shows that the cytoplasm is crowded with granules of various sizes, even though it may appear homogeneous to ordinary microscopic observation. These granules are able to move about within the cell, and indeed, in certain cases, display a lively Brownian movement, *e.g.* in muscle cells, leucocytes, etc. In many animal cells, however, the cytoplasm appears to be too viscous to allow of very active movement.

THE PLASMA MEMBRANE OF CELLS.* Colloid solutions have at their surfaces a layer in which the colloid substance is much more concentrated than it is in the body of the solution. If for instance we take a beaker containing egg-white diluted 100 times, and drop a steel magnetised needle on to the surface, it will float in consequence of the resistance of the surface. If the needle be greasy the same thing will occur on water, and in this case the needle will lie N. and S. On the albumin solution, however, the needle will lie in the position in which it has been dropped. The aggregation of the albumin molecules on the surface of the fluid results in the formation of a solid film which resists any turning of the needle. What applies to the interfacial surface between fluid and air applies also to that between two different fluids. Thus in milk, which is an emulsion of fat droplets in a protein solution, each droplet of fat is surrounded by a layer of concentrated, possibly solid, protein. A similar condensation leading to the formation of a very thin membrane is believed to take place at the surfaces of cells, so that, although the cytoplasm may be liquid, and miscible with water, the contents of the cell are separated from their surroundings by a semi-solid membrane.

Since it is by means of its surface layer that the organism enters into relation with its environment, this layer acquires a prime importance for the life of the cell, and we may therefore consider here at greater length some of the properties of this layer, the *plasma membrane*, as it has been called. This layer is not to be confounded with the cell wall of plant cells, which is generally freely permeable to all kinds of substances. Nor can it be related to any definite histologically demonstrable membrane. The retention of an individuality by the cell must be determined by chemical and physical differences between this layer and the aqueous phases inside and outside it, and one must assume the existence of a definite boundary layer of the protoplasm, even where it is impossible to see any differentiation between this layer and the deeper parts. Investigations into the nature of this frontier between cell contents and environment lead to the conclusion that the plasma membrane is a layer, less than 10 mμ thick, of peculiar molecular structure and remarkable physico-chemical properties. Its electrical resistance is high, and it exhibits unusual permeabilities.

A living cell must take up its food material in the form of solution; and it is the permeability of the superficial layers which will determine the passage of food substances from the surrounding medium into the body of the cell. The immiscibility of the protoplasm with the surrounding fluid shows that the permeability of the membrane must be a limited one. The qualitative aspect of permeability was first studied in vegetable cells. These present within a rigid, but freely permeable, cellulose wall a thin layer of protoplasm (the "primordial utricle"), enclosing a cell sap. The outermost (but invisible) layer of the primordial utricle is the plasma membrane. If the root hairs of tradescantia be immersed in a 10 per cent. solution of glucose or in a 2 to 3 per cent. solution of salt, a process of *plasmolysis* takes place. The cell sap diminishes in amount by the diffusion of water outwards so that the primordial utricle shrinks (Fig. 8 (4)). On placing the cells in distilled water, water passes into the cell sap until the further expansion of the protoplasmic layer is prevented by the tension of the surrounding cell walls (Fig. 8 (1)). This behaviour can be explained only on the assumption that the protoplasm (or its outer layer) is impermeable or but slightly permeable, both to sugar and to salt, but is freely permeable to molecules of water, *i.e.* it behaves as a semi-permeable membrane.

---

* Newton Harvey and Danielli. *Biol. Rev.*, 1938, **13**, 319.

Similar experiments can be made on red blood corpuscles. These also shrink when immersed in salt solutions with a greater molecular concentration than would correspond to the plasma, whereas if placed in weak salt solutions or in distilled water they swell up and burst, discharging their hæmoglobin in solution into the surrounding fluid (*hæmolysis*). By comparison of various solutions it is found that the strength of each solution which is just necessary to cause plasmolysis or hæmolysis, as the case may be, is determined entirely by its osmotic pressure, *i.e.*, solutions having the same osmotic pressures produce the same results. These experiments show the plasma membrane to be permeable to water, but less so to solutes.

The specialised nature of the cell surface is well illustrated by comparing the ionic composition of the cell contents with that of its normal environment. Thus in red blood cells there is a different ratio of K : Na to that in the plasma. This is in part due to the fact that the membrane is impermeable to Na and only slightly permeable to K. Even to the most easily permeable ions, however, the cell membrane is only penetrable with some difficulty, and it has been stated that under the most favourable circumstances the ion permeability of the membrane is only 10^{-8} of that of a layer of water of equal thickness.

The impermeability of the plasma membrane does not apply to all dissolved substances. Overton found that, whereas this layer is practically impermeable to salts, sugars and amino-acids, it permits the easy passage of monatomic alcohols, aldehydes, alkaloids, etc. All these substances are more soluble in ether, oil and similar media than they are in water. The passage of dissolved substances through a membrane may be supposed to depend on the solubility of these substances in the membrane. A layer of lipoid material one molecule in thickness has been shown to hinder the rate of evaporation of water, but not that of ether.* Overton concluded that the superficial layer of cells must itself partake of a "lipoid" character, and that cholesterol and lecithin probably enter largely into its composition. He stated that only such dyes, or other substances, as are soluble in a mixture of melted lecithin and cholesterol have the property of penetrating the living cell, and only those dyes, such as methylene blue, and neutral red, can be used for *intra vitam* staining. This does not apply, however, universally. For example, methylene green, thionin and malachite green are not "lipoid-soluble," but penetrate cells readily, whereas cyanosin and Bengal rose are "lipoid-soluble," but will not enter. The kidney cells can take up many dyes which are not "lipoid-soluble," such as phenol sulphone-phthalein and indigo-carmine, and the same applies to other gland cells.

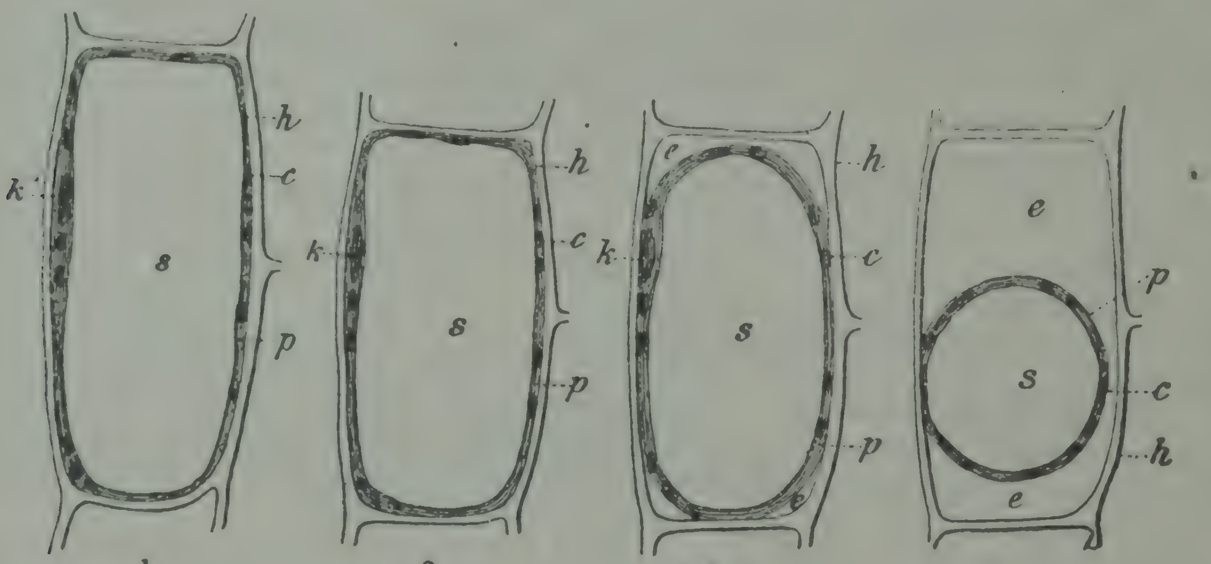

FIG. 8. Vegetable Cells, showing varying degrees of Plasmolysis. (DE VRIES.)

Substances which have the power of dissolving lecithin and cholesterol, such as ether or bile salts, also act as hæmolytic agents, *i.e.* they cause a destruction of the red blood cells by rendering porous the superficial layer which is necessary for their preservation from the solvent effects of the surrounding fluid. Further evidence in favour of the lipoid character of the cell surface is that oil readily wets and adheres to some cells, *e.g.* erythrocytes, *Amœba*; in naked *Arbacia* eggs, an oil globule not only adheres to the surface, but may later pass right through the membrane and collect on its inner surface. For penetration to occur in this mass fashion it has been supposed that the ectoplasmic layer must first be liquefied. An interesting feature of permeability is that weak acids or bases, *e.g.* CO_2, H_2S, HCN, NH_3, penetrate cells readily, whereas strong ones, *e.g.* HCl, NaOH, fail to do so. The semi-permeability of the plasma skin can be altered by changes in the surrounding medium; it seems certain that in some way its integrity is dependent on the presence of certain salts or ions in the outer fluid which may be adsorbed on the external surface of the membrane and so contribute to its qualities. Thus many cells, such as egg cells, muscle cells, entirely alter their permeability if immersed for a time in a fluid free from Ca salts, and under these circumstances may become permeable to substances such as KCl, which they do not ordinarily allow to pass.

---

* RIDEAL. *J. Physical Chem.*, 1925, **29**, 1585. LANGMUIR. *Ibid.*, 1927, **31**, 1719.

It is possible that in order to serve the nutrient needs of the cells, changes may take place in the permeability of the surface layer under certain conditions. Further, in the case of the red blood cells, if we assume complete and permanent impermeability to cations, it is difficult to explain how the relative concentrations of potassium and sodium in cell and plasma could arise in the first place. When cells are damaged, or dead, and often also when they are stimulated, a change in permeability occurs, so that cell contents then diffuse freely through into the surrounding medium.

No doubt protein also enters into the composition of the surface membrane and considerably modifies the properties attributable to lipoids. According to this view * (Fig. 9) the cell surface consists of a solid layer of lipoid perhaps only two or three molecules in thickness, but with a film of protein adsorbed upon its surfaces. The lipoid molecules, at both surfaces, would be arranged perpendicular to the surface like a palisade, with the hydrated polar groups in the oil-water interphase (negative pole nearest the water). The protein is probably either adsorbed to the surface in a partly denatured form, in which case the surface would be wettable with oil, or else each protein molecule would be surrounded by a hydrated envelope ; in that case the surface would be oil-repellant, as is the case with leucocytes.

Some of the permeability properties of the plasma membrane suggest that the surface may be like a mosaic, some patches being lipoid and others not. This really means that there are some properties that are not compatible with the view that the membrane is entirely lipoid. Lipoid-soluble substances would easily penetrate the membrane and would also tend to dissolve and weaken it.

Experiments carried out by micro-dissection methods with living cells demonstrate the elastic and semi-solid nature of the peripheral layers of cells, and show that when the surface of a cell is torn or punctured, or even when part of the cell is cut away, the surface film is often at once reformed. It thus appears to be in many cases a condensation layer formed at the surface of separation in accordance with the laws of surface tension. The presence of calcium appears to be essential for the formation of this membrane.

In such animal cells as are connected together by protoplasmic bridges, *e.g.* the cells of the deeper layers of the epidermis, Chambers found that when one of the cells in the mass was damaged, the coagulative process spreads to neighbouring cells.

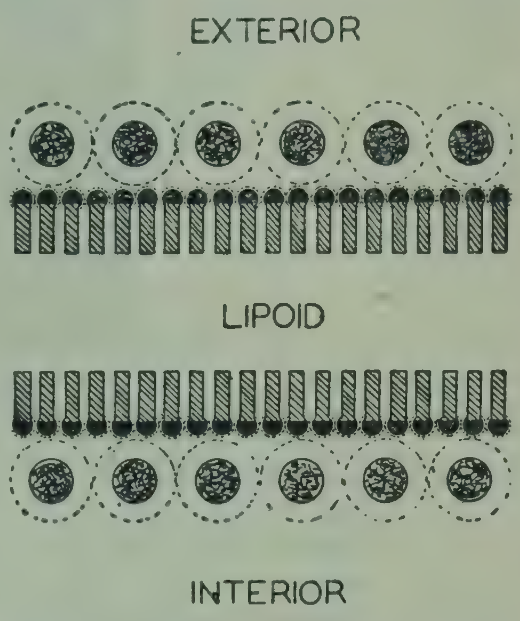

FIG. 9. Schema of molecular conditions at the cell surface. The thin lipoid membrane has its molecules oriented. Outside them is an adsorbed layer of hydrated protein molecules. (DANIELLI and DAVSON.)

THE NUCLEUS. The different staining reactions of nucleus and cytoplasm, and the fact that the nucleus is more opaque to ultra-violet light, suggest a difference in their chemical composition, a suggestion which is confirmed by analysis. Whereas in the cytoplasm the basis consists of ordinary proteins, in the nucleus the chief constituents are nucleo-proteins. Material of somewhat similar nature is occasionally found in the cytoplasm, where it forms *chromidial substance, e.g.* the Nissl bodies of nerve cells or the basal filaments of gland cells such as the pancreas.

The readily stainable material of the nucleus, called *chromatin*, consists mainly of nucleo-protein and "chromosomin."† It can be distinguished from other stainable cell contents by Feulgen's "nucleal" reaction, *i.e.* by treating sections with warm dilute hydrochloric acid for a few minutes, transferring to fuchsin-sulphurous acid (Schiff's reagent) and washing in dilute sulphurous acid. Chromatin is stained violet owing to the presence of pentose in the nucleic acid.

Microscopically, even with dark-ground illumination, the resting nuclear contents are quite homogeneous, except for the presence of nucleoli (Fig. 10). The consistency of the nucleus is found on micro-dissection to be liquid, though perhaps less so than the cytoplasm ; the nucleoli can be freely rolled about within it. When punctured it often rapidly coagulates, and then there may appear, especially in cells about to divide, the characteristic chromatin filaments. These filaments can be drawn out like elastic by the needle, and retract again when released (Fig. 11). Alternatively puncture of the nucleus may lead to disintegration of both nucleus and cytoplasm (Figs. 10, 12).

The nucleus is essential for the continued existence of most cells. By micro-dissection it is possible to divide the larger protozoa into two pieces, one with and one without a nucleus. Hofer, experimenting on the amœba, found that the fragment containing the nucleus quickly regenerated the missing part and pursued a normal existence. On the other hand, the non-nucleated fragments showed no signs of regeneration (Fig. 13). Their movements continued for a short time and then ceased, though the pulsations of the contractile vesicle were but little affected. The power of digestion of food was completely

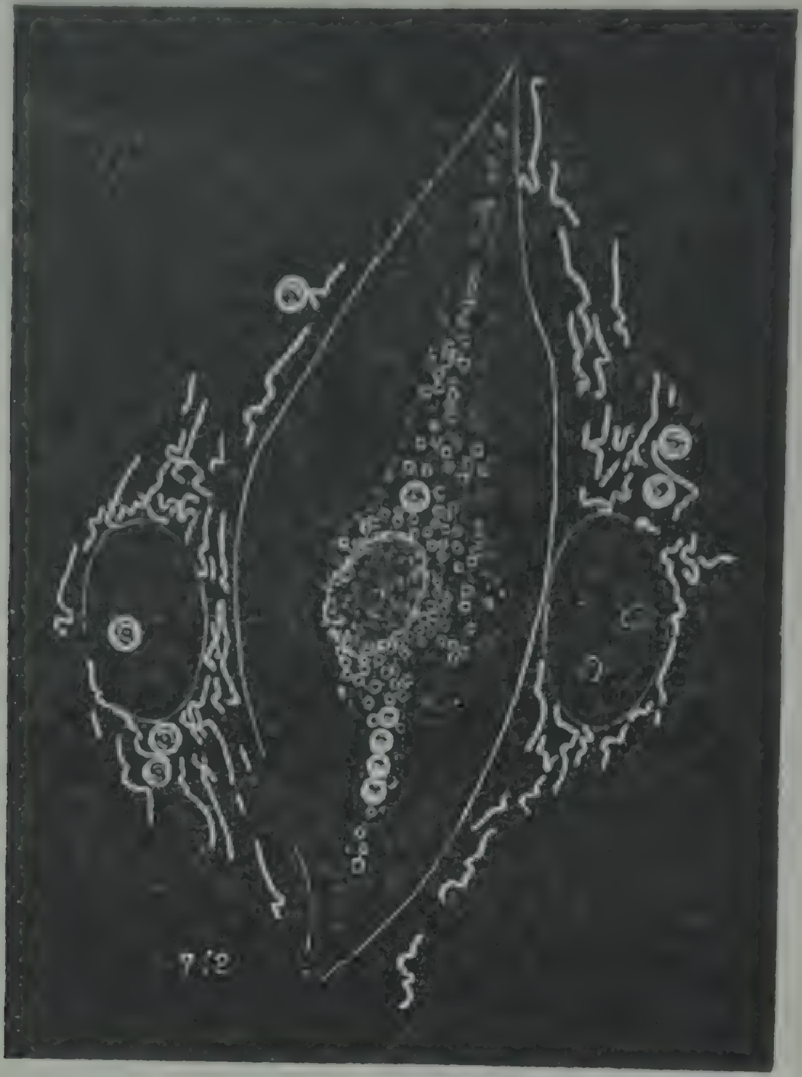

FIG. 10. Three living intestinal epithelial cells in tissue culture, viewed by dark-ground illumination. The nucleus of the middle cell has been punctured by a micro-dissection needle eight minutes previously. The outer boundaries of the two outer cells are invisible, and these cells with their nuclei and mitochondria appear normal. The cytoplasm of the middle cell has shrunk away from its neighbours and is granular: the mitochondria are also altered. (CHAMBERS and FELL. *Proc. Roy. Soc.*, 1931, **109B**, 380.)

lost. In ciliated mammalian cells, the ciliary movement ceases when the nucleus is destroyed or removed. Fibroblasts in tissue culture often have two nuclei. If the nucleus of a uninucleated cell is punctured, the cell dies, but if one nucleus of a binucleated cell is punctured it continues to live.*

The nucleus plays an important part in cell-division. But it is apparently not indispensable for this. When *Arbacia* eggs are centrifuged they elongate, and when the length of such a cell reaches π times its diameter, it breaks into two, one half containing the nucleus. If the non-nucleated half is now subjected to the action of parthenogenetic reagents, it proceeds to divide as a normal cell would, and the subdivision continues until a blastula of about 500 cells is reached, before it finally dies.*

---

* CHAMBERS and FELL. *Proc. Roy. Soc.*, 1931, **109B**, 381.

The nuclear chromatin contains, or consists of, those large nucleoprotein molecules, or micellæ, the *genes*, on which the phenomena of inheritance depend. The transmission of the paternal qualities from one generation to the next is effected by the entrance simply of the nuclear material of the male cell, the spermatozoon, into the ovum.

Conclusions regarding the importance of the nucleus may be drawn from a study of the changes in the nucleus which accompany different phases in the activity of the whole cell. The active state of cytoplasm, which accompanies the activity of secreting cells, is always associated with changes in the position and in the size of the nucleus.

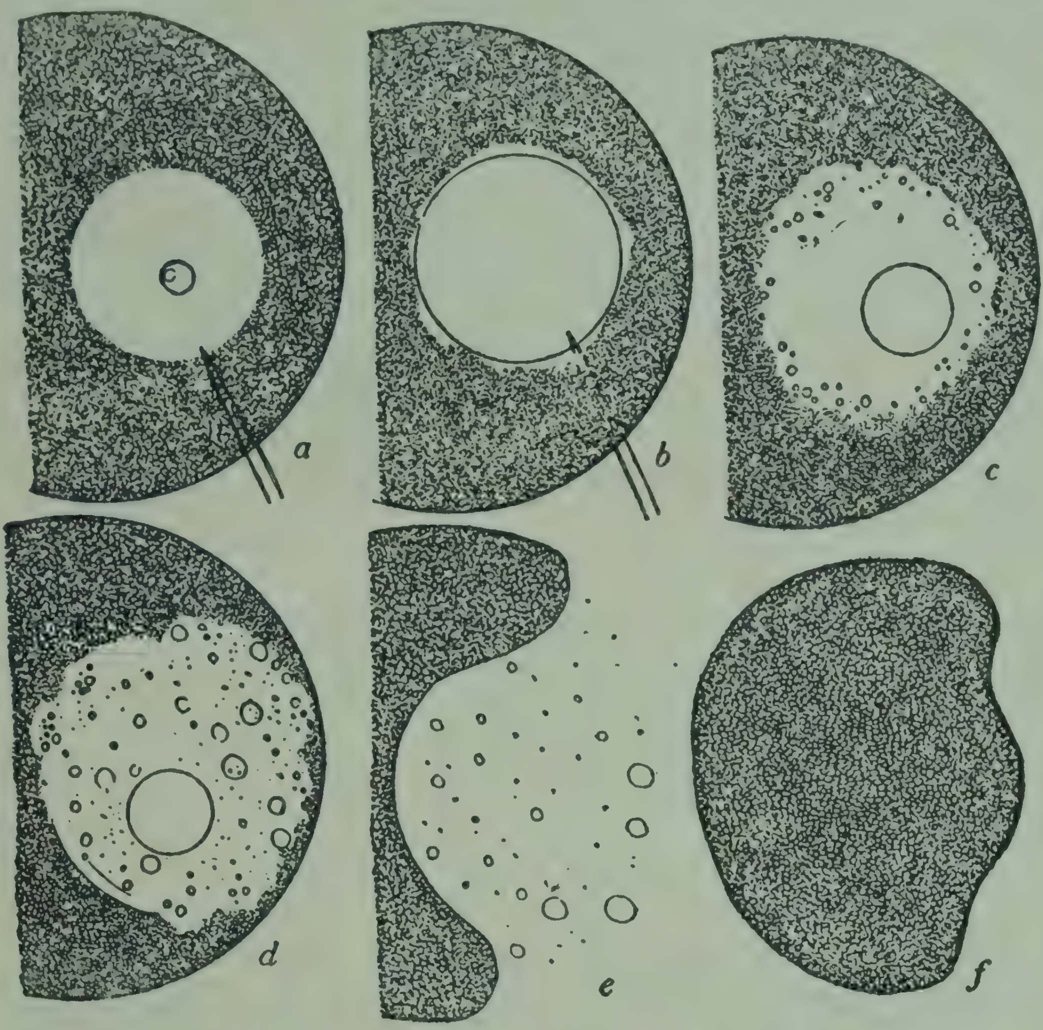

FIG. 12. Disintegration of cytoplasm of starfish egg following puncture of nucleus by micro-dissecting needle. (CHAMBERS.)

HISTOLOGICAL DIFFERENTIATION OF CELLS. Even within the limits of a single cell, differentiation of structure can take place by the setting apart of distinct portions of the cell for isolated functions.

The organs which are thus formed in unicellular animals or plants can be divided into two classes, namely (1) temporary organs, which are formed out of a common structural basis and can therefore be replaced at any time by the cytoplasm if destroyed. Examples of such organs are the cilia of unicellular organisms, and the mouth of animals such as vorticella. In contradistinction to these organs are (2) a number of others which must be regarded as permanent. These cannot be formed by differentiation from the cytoplasm of the cell, but are derived by the division of pre-existing organs of the same character, and are therefore transmitted from one generation to another. As examples of such cell organs may perhaps be mentioned the nucleus with its chromosomes, and the mitochondria and plastids.

The possibility of histological differentiation and of the adaptation of structure to definite functions becomes much more pronounced as we pass to the multicellular organisms. The lowest of the Metazoa, such as the sponges, consists of little more than an aggregation or colony of cells. In the Cœlenterata the differentiation is already much more marked. In all these classes of animals the external medium of every cell forming the organism is the sea-water or other medium in which it lives, and every cell is therefore exposed to all the possible variations which may occur in the composition of the surrounding medium.

A great step in evolution was accomplished with the formation of the Cœlomata, the class to which all the higher animals belong. In these, by the formation of a body cavity containing fluid, an internal medium is provided for all the working cells of the body. The composition of this internal medium is maintained constant by the activity of the cells in contact with it, and the stress of sudden changes in the chemical composition of the surrounding medium is borne entirely by the outer protective layer of epiblast cells. These are rendered more or less impermeable by the secretion on their surfaces of a cuticular layer, and only such of the constituents of the surrounding medium are allowed to enter the organis as can be utilised by it. Out of the cœlom is later on formed a circulatory system whic by the circulation of the cœlomic fluid or of blood through the whole body, can procure still more perfect uniformity in the chemical conditions to which every cell is exposed. On of the main results of the differentiation of function and structure is therefore a gradu setting free of the majority of the cells of the body from the influence of variations in th environment.

---

* E. B. HARVEY. *Biol. Bull.*, 1936, **71**, 101.

The differentiation of the cells which compose the organs of the body, is determined i the first place by the different conditions to which they are exposed in virtue of thei positions in the course of embryonic development. All the higher animals may be considered as built in the form of a tube, the external surface of which is modified for th purpose of defence and for adaptation to changes in the environment. From this laye there are developed not only the protective cuticle, but also the organs of motor response, namely, the special senses and the nervous system. The internal surface of the tube is modified for purposes of alimentation. From it are developed all those structures which serve for the digestion of the foodstuffs, for their absorption into the common circulating fluid, for their elaboration after absorption, and their preparation for utilisation by other cells of the body. Between these two surfaces are situated the supporting tissues of the body as well as the muscles. Here also is the cœlom, represented in the higher animals by the pleural, pericardial and peritoneal cavities. The alimentary canal projects for a considerable part of its course into this cœlom, being attached to the body wall only by one side. From the cœlom is also developed the blood vascular system, which maintains a constant circulation of the blood throughout the body. By this differentiation the body becomes divided into a number of organs, each of which is composed of like cells, modified for a common function and bound together by connective tissue, the latter serving also to carry the blood vessels which convey the common medium for the working cells.

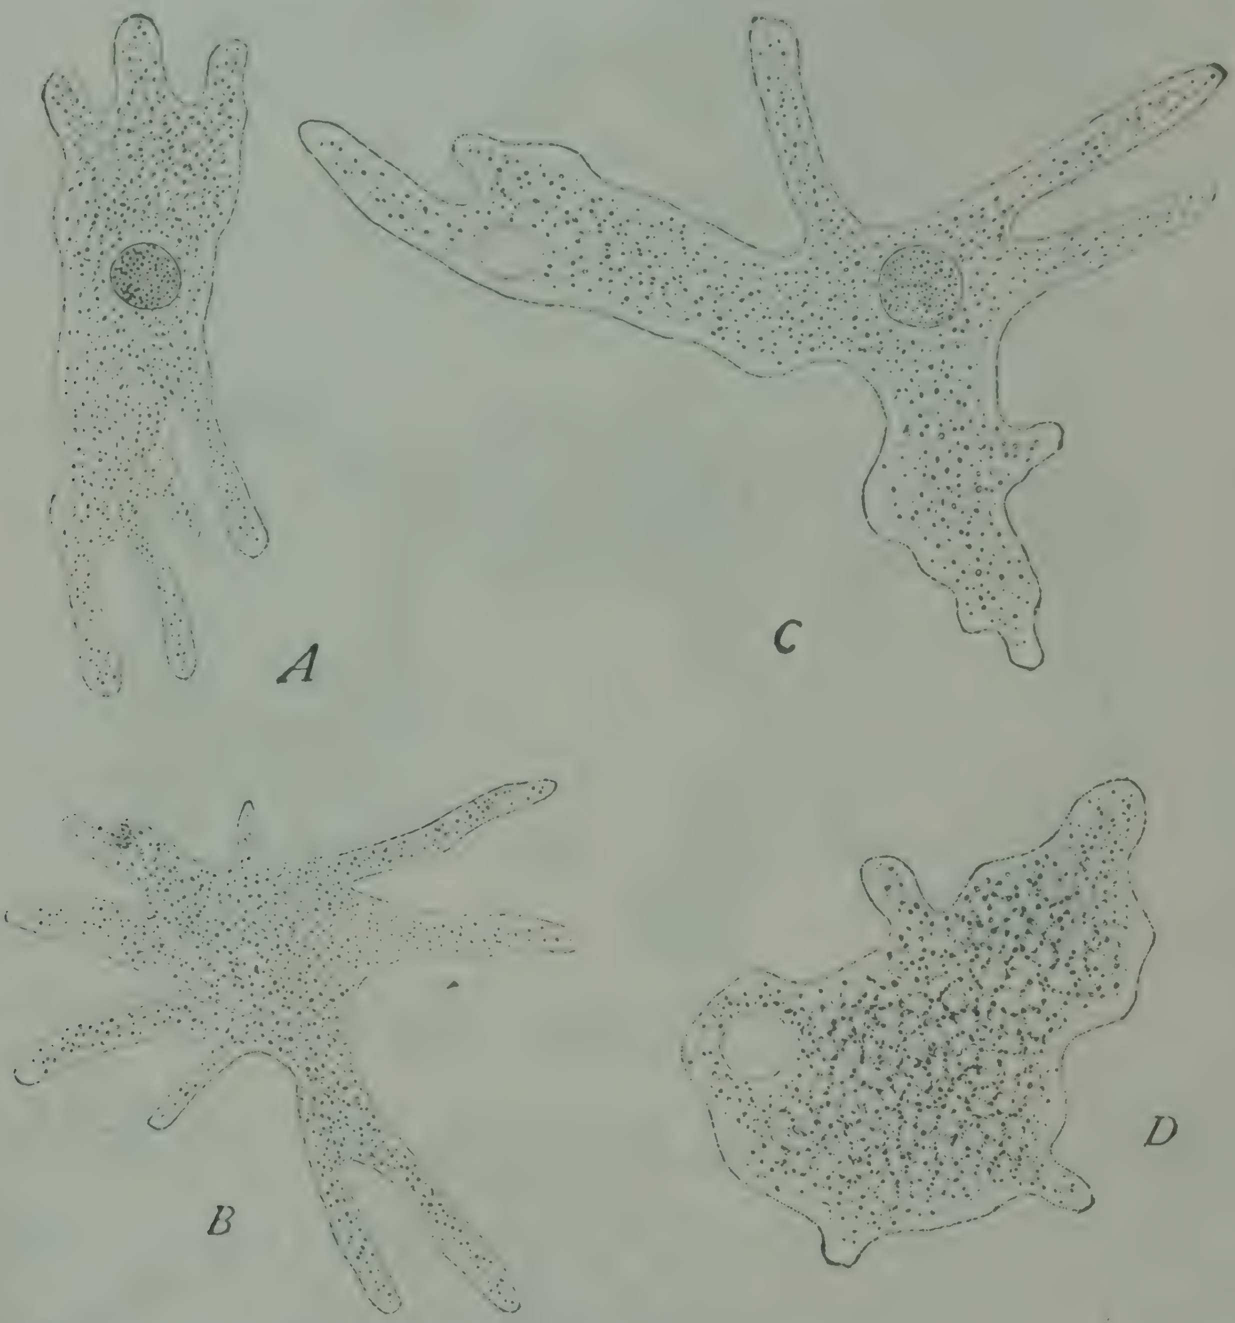

FIG. 13. Nucleated and Non-nucleated Fragments of *Amœba*. (WILSON after HOFER.)
A, *B*. An *Amœba* divided into nucleated and non-nucleated halves, five minutes after the operation.
C. *D*. The two halves after eight days, each containing a contractile vacuole.

The study of the factors which are responsible for the differentiation of the numerous types of tissue cell from the division of the one common cell, the fertilised egg-cell, is a branch of the subject of experimental embryology. It has up to the present not been possible to obtain much beyond a few scattered hints as to what the nature of these factors may be. In the early divisions of some fertilised ova, all the cells appear to be exactly alike. We may believe that to some extent the subsequent course of development of these cells is mechanically determined by their positions and by their relations to one another, but it is certain that this is not the chief factor.

Interesting experiments by Spemann * on embryo newts have shown that at the earliest stages, portions of medullary plate (rudiment of nervous system) and of epidermis can be exchanged, and it is then found that the transplanted portions grow into tissues which are normal for the positions into which they have been transplanted. The position occupied by the tissue is here the decisive factor in its differentiation. But in other experiments it was found that there is a region of the embryo, probably that which later forms the mesoderm, which is not so subjected to its surroundings but which instead determines the formation of definite structures, foreign to their new surroundings. The region is called an "organiser." It seems likely that the directing influence of this region may be due to the presence in its cells of a definite chemical substance, † probably a steroid.

During the course of the development of various organs also it would seem that after a certain stage of embryonic development has been reached, local organising influences are set up. For example, the femur of a five-and-a-half-day chick embryo can be grown *in vitro*, reach more than three times its initial length, and show almost normal form and bone structure ‡ in spite of isolation from its normal surroundings. Similarly, an eye from a three-day chick embryo can be grown *in vitro*, and shows a remarkable development and differentiation into normal eye tissues.§

Experiments in tissue-culture with embryonic tissues also indicate that chemical factors play a part in causing differentiation.

In the foregoing lines we have spoken of an isolated cell of the body as if it were an independent elementary organism. A better term for such an aggregation of cells as presented by the higher animals is not, however, "cell colony," but "cell state," since, just as in the state politic, no cell is independent of the activities of the others, but the autonomy of each is merged into the life of the whole. With increasing differentiation there is increasing division of function among the various members of the state, and each becomes less and less fitted for an independent existence or for the discharge of all its vital functions. Thus the life of the organism is essentially composed of and determined by the reciprocal actions of the single elementary parts. It is evident that, if the process of specialisation has gone far enough, a discussion whether each unit has or has not an independent life is beside the mark, since it cannot possibly exist apart from the activities of the other cells. From this aspect the morphological unit is not the cell but the whole organism, and the division of the common cytoplasm into cells is merely a question of size and convenience. There can be no doubt that an important factor in the division of cells is their growth: the cell divides because it grows. With increased mass of living substance it is necessary to provide for increase of surface both of cytoplasm and of nucleus. Whether all the tissues of the higher animals remain in structural continuity by protoplasmic bridges, etc., must be a matter of indifference, since all that is necessary for the interdependent working of the different cells of the body is a functional continuity, and this in the higher animals is effected by the presence of a common circulating fluid and a reactive nervous system connected with all the cells of the body.

B. BIOCHEMICAL PRINCIPLES *

CHAPTER III

THE ELEMENTARY CONSTITUENTS OF PROTOPLASM

LIVING things contain no chemical elements peculiar to themselves. Every living organism without exception contains the following elements: carbon, hydrogen, oxygen, nitrogen, sulphur, phosphorus, chlorine, potassium, sodium, calcium, magnesium, copper and iron. In addition to these thirteen elements others are found in certain organisms, sometimes to a large extent. Of these elements we may mention especially silicon, iodine, fluorine, bromine, aluminium, nickel, cobalt, zinc, lead, silver, cadmium, lithium, strontium and manganese.† Dealing with the first class, which includes those essential to all forms of life, we find that their relative proportions in living organisms have little or no relation to their proportions in the environment of the organisms. Their presence, however, in the latter is a necessary condition of life. In the case of plants, growth is limited by the amount of the necessary element (*e.g.* potassium, nitrogen, phosphorus) which is present in smallest quantities in the surrounding medium.

Carbon forms the greater part by weight of the solid constituents of living protoplasm and the proximate constituents of living organisms are practically all carbon compounds and hence are combustible. In the inorganic world practically all the carbon occurs as carbon dioxide, which is present to the extent of about 0·04 per cent. in the atmosphere, while vast quantities are immobilised in the form of chalk and limestone. In this condition the carbon is practically removed from the life cycle, the whole of the carbon contained in the tissue of living beings being derived from carbon dioxide present in the atmosphere.

The energy for the conversion of carbon dioxide into the oxidisable forms which make up the tissues of plants and animals, is furnished by the sun's rays. The conversion of the radiant energy into the potential chemical energy of the carbon compounds is performed by the chlorophyll corpuscles in the green parts of plants. In these corpuscles, under the influence of the sun's rays, the carbon dioxide of the atmosphere, together with water, is converted into starch, and the oxygen liberated in the process is set free.

$$\mathrm{n}\,[6CO_2 + 5H_2O] = (C_6H_{10}O_5)_n + 6nO_2.$$

In this process a large amount of energy is absorbed, which can be set free later by the oxidation of the starch to carbon dioxide. In the oxidation of 1 gramme of starch about 4·5 kilo-calories are evolved, and this represents therefore the measure of the solar energy which must be absorbed by the chlorophyll corpuscle in the process of formation of 1 gramme of starch from carbon dioxide. By this means the world of life is provided with a source of energy. At the expense of the energy of the starch further synthetic processes are carried out and fats and proteins manufactured.

All animals take in carbon, hydrogen, nitrogen, oxygen and sulphur in the form of the carbohydrates, fats and proteins which have been built up in the living plants. In the animal organism these foodstuffs serve as sources of energy.

Oxygen is taken up in the free as well as in the combined state. It takes a position apart from the other foodstuffs in that its presence is the essential condition for the utilisation of their potential energy. In the living cells it combines with the oxidisable compounds formed by the agency of the living protoplasm, with the production of carbon dioxide and water and the evolution of energy.

Nitrogen is also derived indirectly from the air. It can be taken up by most plants only in the form of ammonia, nitrites or nitrates. Animals cannot utilise these compounds, and their only source of nitrogen is the protein which has been built up from them by the agency of the plant cell.

Since nitrogen in the free state is useless, the existence of life must depend on the amount of combined nitrogen which is available. Every thunderstorm results in the production of small quantities of ammonium nitrite, which will be washed down with the rain and serve as a source of combined nitrogen to the soil. Many of the higher plants require their nitrogen in the condition of nitrates, and this conversion is effected by micro-organisms. There are a number of bacteria (*bacterium nitrosomonas*) which have the power of converting ammonia into nitrites. Others (*b. nitromonas*) convert nitrites into nitrates. This has been made the basis of a method now largely employed for the treatment of ammoniacal sewage. These different bacteria play an important part in all soils.

---

* Physiology and biochemistry overlap considerably, and it is desirable for the advanced student of physiology to enter more deeply into the biochemical side of the subject than is possible in this volume. For this purpose he may profitably consult:—

BALDWIN (1947). Dynamic Aspects of Biochemistry (Cambridge Univ. Press).

HARROW (1946). Textbook of Biochemistry (Philadelphia and London. W. B. Saunders Co.)

in addition to the various references given in the present volume.

† **Fox and RAMAGE.** *Proc. Roy. Soc.*, 1931, **108B**, 157.

Organisms also exist which can bring into combination the free atmospheric nitrogen itself. Thus certain soils have been found to undergo a gradual enriching in nitrogen although no nitrogenous manure has been applied to them. This fixation of nitrogen by soils is effected by a distinct micro-organism, *clostridium pasteurianum.*

In addition to this spontaneous fixation of nitrogen by humus, it has long been known to farmers that the growth of almost any leguminous crop in a soil poor in nitrogen may result in an actual increase of nitrogen in the soil from which the crop is taken. It was found that this was dependent on the presence on the roots of certain small nodules swarming with bacteria. These bacteria, like those of humus, are able to assimilate the free nitrogen of the atmosphere but, unlike them, can effect this assimilation only in a condition of symbosis, *i.e.* living in the growing tissues of a leguminous plant.

Sulphur is found in all soils in the form of sulphates, generally of calcium. In the plant cell it is built up, together with nitrogen, carbon and hydrogen, to form a part of protein molecules. Practically the whole of the sulphur utilised by animals is in the form of proteins. It is oxidised in the body which it leaves in the form of sulphates.

Boron is essential for the life of some plants.

Iron, although forming but a minute proportion of the material basis of living organisms (the whole body of man contains only six grammes), is nevertheless indispensable for the maintenance of life. It is necessary for instance in two important functions, viz. the formation of chlorophyll in the green plant and the respiratory process in the higher animals. Iron forms an essential constituent of hæmoglobin, the red colouring matter of the blood, whose office it is to carry oxygen from the lungs to the tissues. The pigment chlorocruorin, present in the plasma of polychæte worms, is an iron compound resembling hæmoglobin. It is probable too that the minute traces of iron in protoplasm exercise an important function in the processes of oxidation which are continually going on. Iron obtained by plants from the soil is built up into highly complex organic compounds, and in this form is taken up by animals. It is probable that the main requirements of the animal for iron, which in the day's diet for man is present to the extent of about 15 mg. in all, may be satisfied entirely at the expense of these organic compounds, but there is little doubt that the animal can, if need be, also utilise the iron salts present in its food. The animal proceeds extremely economically with its supply of iron. Any excess of iron above that needed to supply the iron lost to the body is excreted almost entirely with the fæces in the form of sulphide.

Phosphorus is absorbed by the plant as phosphates. It is one of the most important elements and is concerned in many fundamental biochemical processes, usually in the form of organic phosphoric esters of various types. In the cell it is built up with fatty acids and other organic radicals to form complex compounds such as lecithin, and nuclein. The different phosphorus compounds are broken down by processes of dissociation and oxidation, with the production, as a final result, of phosphates which are excreted with the urine or fæces and return to the soil.

Chlorine, potassium, sodium, calcium and *magnesium* are taken up by the plants in the form of salts ; magnesium is one of the elements present in the chlorophyll of plants. They are taken up by animals in the form of salts, and as such are again excreted with the urine.

Little is known about the significance, if any, of the other elements which have been mentioned as frequent constituents of living beings. *Silicon,* which is of very wide distribution, is assimilated as silica, probably in colloidal solution, and is distributed in minute quantities through all plant and animal tissues. It forms a very large percentage of the mineral basis of grasses, but even here it does not seem to be indispensable.

Fluorine is found in the enamel of the teeth and in minute traces in other tissues of the body.*

Bromine, though present in quantity in some seaweeds, appears to play no part in the economy of higher animals.

Iodine is found in large quantities in many seaweeds and sponges. The substance thyroxine, the active principle of the thyroid gland, contains iodine, and is essential for normal life in the higher animals. Iodine therefore is an essential constituent of the higher animals.

Aluminium is found in large quantities in certain lycopods. Whether it is essential to their growth is not known.

Copper in traces is often a valuable constituent of the diet of animals. In the cephalopods and crustacea it appears to take the part of iron in the formation of a blood pigment, hæmocyanin, which plays the same part in the blood of these animals that is played by hæmoglobin in the blood of vertebrates. When oxidised it is of a blue colour, but gives off its oxygen and is reduced to a colourless compound on exposure to a vacuum.

---

* McClure. *Physiol. Rev.*, 1933, **13**, 277.

Manganese is widely distributed in traces, and in the lamellibranch *Pinna squamosa* appears to form an essential constituent of a blood pigment, like hæmocyanin in its functions, and called pinnaglobulin. An ordinary mixed diet for man probably contains about 2 mg. each of copper and manganese per day.

Cobalt is a constituent of the anti-anæmia factor in the liver.

CHAPTER IV

THE PROXIMATE CONSTITUENTS

In spite of the enormous variety of the proximate organic constituents of living organisms (and hence of all foodstuffs), most of them are members or derivatives of three classes of compounds. These classes are :—

The Lipides.
The Carbohydrates.
The Proteins.

It is assumed that the student has some acquaintance with the elements of organic chemistry and we shall therefore confine our description here to those aspects which have a direct bearing on the physiology of nutrition and metabolism.

1. THE LIPIDES

The ethereal extract of a tissue contains a variety of fat-soluble substances, many of which are characterised by the fact that they contain fatty acids as integral parts of their molecules. They may be classified into the following groups :—

(1) *Fats.* Neutral esters of glycerol and fatty acids.

(2) *Sterols and Waxes.* Of these the sterols are by far the most important. They are alcohols, the chief sterol of the animal body being cholesterol. Waxes are neutral esters of alcohols, such as cholesterol, cetyl alcohol, etc., with fatty acids.

(3) *Phospholipides* (Phosphatides) are nearly insoluble in acetone, a property which is utilised in their separation from other lipides. Lecithin and kephalin are compounds of an alcohol (glycerol) with two fatty acids, phosphoric acid and an organic base (choline or ethanolamine respectively). Sphingomyelin contains phosphoric acid linked to choline and a base, sphingosine, which in turn is linked to a fatty acid.

(4) *Glycolipides* (Galactosides or Cerebrosides). Compounds of a carbohydrate (galactose), with a fatty acid and an organic base (sphingosine).

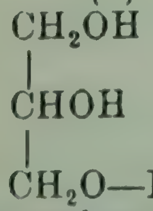
(5) *Hydrocarbons.* Very small amounts of substances belonging to the class of lipochrome pigments occur in the tissues. An important one of these is the hydrocarbon carotene, $C_{40}H_{56}$, which is converted into vitamin A in the liver. Another unsaturated hydrocarbon, squalene, $C_{30}H_{50}$, occurs in very large quantities in some shark liver oils.

1. THE FATS

Quantitatively the fats themselves are easily the most important of the lipide groups and they are widely distributed throughout the animal and vegetable kingdoms. In the higher animals they are the main constituents of the fatty or adipose tissue. They also occur as fine particles in the protoplasm of cells and probably also in combination with the other constituents of protoplasm. In contrast to the mammal, certain fish store up their fat reserve in the liver (*e.g.* cod liver oil), instead of in adipose tissue. Large amounts are also found in certain seeds (cotton seed), and nuts (brazil nut).

COMPOSITION. The fats, the chief representatives of simple lipides, are esters of glycerol and the fatty acids. Glycerol can form esters (glycerides) with one, two or three of its hydroxyl groups. Thus with phosphoric acid the following important compounds are formed :—

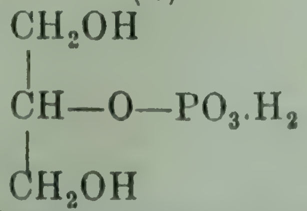
(1)



$$\begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2O{-}PO_3.H_2 \end{array}$$

α glycerophosphoric acid

(2)

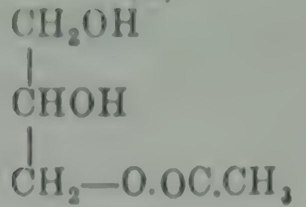


$$\begin{array}{l} CH_2OH \\ | \\ CH{-}O{-}PO_3.H_2 \\ | \\ CH_2OH \end{array}$$

β glycerophosphoric acid

With a fatty acid, such as acetic acid, it forms mono-, di- or triglycerides *e.g.* :—

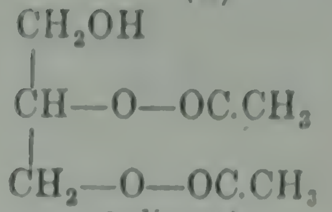
(3)



$$\begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2—O.OC.CH_3 \end{array}$$

α monacetin
(monoglyceride)

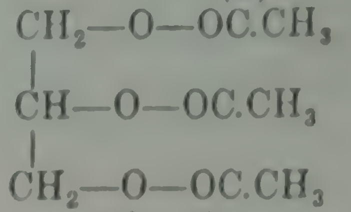
(4)



$$\begin{array}{l} CH_2OH \\ | \\ CH—O—OC.CH_3 \\ | \\ CH_2—O—OC.CH_3 \end{array}$$

α, β diacetin
(diglyceride)

(5)



$$\begin{array}{l} CH_2—O—OC.CH_3 \\ | \\ CH—O—OC.CH_3 \\ | \\ CH_2—O—OC.CH_3 \end{array}$$

triacetin
(triglyceride)

The fats are mainly triglycerides, and natural fat is usually found to consist of various mixed triglycerides ; these are not generally simple esters of the type shown in formula (5), but have different fatty acid radicals combined with the glycerol, and in the animal these fatty acids usually have sixteen or more carbon atoms. The fatty acids which enter into the composition of the triglycerides may be either saturated or unsaturated, belonging to homologous series having the following formulæ :—

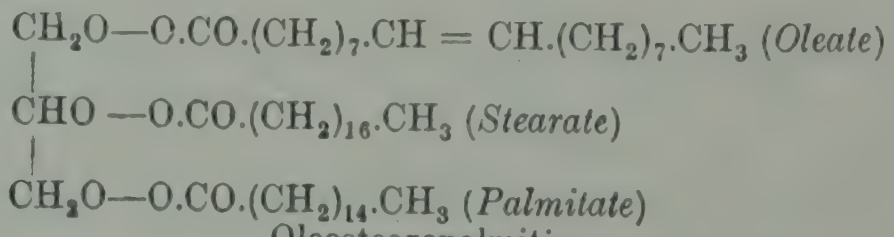
Saturated fatty acids : $C_nH_{2n+1}COOH$ *e.g.*

Butyric acid,	C_3H_7COOH
Palmitic acid,	$C_{15}H_{31}COOH$
Stearic acid,	$C_{17}H_{35}COOH$

Unsaturated fatty acids, e.g. :—

Series $C_nH_{2n-1}COOH$	Oleic acid,	$C_{17}H_{33}COOH$	(1 double bond)
,, $C_nH_{2n-3}COOH$	Linoleic acid,	$C_{17}H_{31}COOH$	(2 double bonds)
,, $C_nH_{2n-5}COOH$	Linolenic acid,	$C_{17}H_{29}COOH$	(3 double bonds)
,, $C_nH_{2n-7}COOH$	Arachidonic acid,	$C_{19}H_{31}COOH$	(4 double bonds)

Adipose tissue, so-called, consists almost exclusively of the fats derived from palmitic, stearic and oleic acids, *e.g.* dioleo stearin, oleo-palmito stearin, triolein, etc., *e.g.* :—



$$\begin{array}{l} CH_2O—O.CO.(CH_2)_7.CH = CH.(CH_2)_7.CH_3 \ (\textit{Oleate}) \\ | \\ CHO —O.CO.(CH_2)_{16}.CH_3 \ (\textit{Stearate}) \\ | \\ CH_2O—O.CO.(CH_2)_{14}.CH_3 \ (\textit{Palmitate}) \end{array}$$

Oleostearopalmitin

The great differences in the appearance of the fat of different animals are due to the varying proportions in which these different mixed glycerides occur. While triolein is liquid at 0° C., tristearin and tripalmitin are solid at the temperature of the body. According, therefore, to the relative amounts of these three fatty acids present in the mixed glycerides, we may have a fat which, like mutton suet, is solid at the body temperature, or a fat containing much olein which is still fluid when the body is opened after death, even when it has already cooled. Milk fat is the one animal fat which contains large proportions of lower fatty acids (butyric acid 5 per cent.).

PROPERTIES. The fats are colourless substances devoid of smell. They float, but are insoluble, in water. They are soluble in warm absolute alcohol, but separate out into crystalline form on cooling, and are easily soluble in ether, petroleum ether, acetone, benzene and chloroform. If they are heated with steam or, more readily, with dilute alkalies, or submitted to the action of certain enzymes, they undergo hydrolysis, and are finally split into three molecules of fatty acid and one molecule of glycerol, *e.g.* :—

$$\underset{\text{(neutral fat—tripalmitin)}}{C_3H_5(OOC.C_{15}H_{31})_3} + 3H_2O = \underset{\text{(palmitic acid)}}{3C_{15}H_{31}.COOH} + \underset{\text{(glycerol)}}{C_3H_5(OH)_3}$$

The action takes place in stages, at each of which one molecule of fatty acid is removed, with the formation, successively, of diglyceride, monoglyceride and glycerol. This process may occur spontaneously when fat is left exposed to the air. Fat is then said to be rancid and has an increased acid value. Most natural fats generally contain a small amount of fatty acid.

Saponification. On boiling a neutral fat for a long time with a solution of potassium or sodium hydroxide, the fat, like other esters, undergoes *saponification*, giving the alkaline salt of a fatty acid, and glycerol. The former compound is spoken of as a soap. In water soap forms a colloidal solution, which, if concentrated, sets to a gel on cooling. From a dilute watery solution the soap can be thrown down in the solid form by the addition of neutral salts.

Emulsification. An emulsion is a system of two immiscible liquid phases, one of which is "dispersed" as globules in the other, as, *e.g.* oil in an aqueous solution, which is spoken of as an oil-in-water emulsion. Milk is such an emulsion, and butter is one of "water" in oil. Oil-in-water emulsions are important, *e.g.* in digestion, since the provision of a large surface area by emulsification of the fat accelerates the action on it of fat-splitting enzymes.

Permanent concentrated emulsions cannot be formed merely by shaking the two components together. In order to form them, at least one other substance, called an *emulsifying agent*, must be present. The emulsifying agent is believed to exert its effect by being adsorbed as a film on the surface of the dispersed globules. The dispersing and stabilising effect of this film is due to (*a*) lowering of interfacial tension between the two phases, thus opposing coalescence of globules; (*b*) establishment of an electric charge at the surface, which also opposes coalescence: and (*c*) a purely mechanical action in coating the globules.

An enormous number of substances, mostly colloids, can act as emulsifying agents under appropriate conditions, the best one in each instance depending on the properties of the substances in the two phases. Thus, soap, fatty acid, bile salts, lecithin and protein can each, under appropriate conditions, act as emulsifying agents for fat/water systems: for example, if we shake together olive oil, soap solution and bile salts, a good emulsion results.

Analysis of Fats. Owing to the difficulty which attends the complete separation of each acid from a mixture of allied fatty acids, such as is obtained by the hydrolysis of a fat, the complete analysis of a sample of a fat is seldom attempted, and in routine work a series of empirical determinations is made which together suffice to give a good deal of information as to the chemical nature of the fatty acids concerned. The following determinations are usual:—

The *melting point.*

The *acid value* of a fat is the amount of potassium hydroxide in milligrammes required to neutralise the free fatty acids in 1 gramme of fat.

The *saponification value* is the amount of potassium hydroxide in milligrammes required to saponify 1 gramme of fat.

The *iodine value* is the amount of iodine in grammes with which 100 grammes of fat will combine.

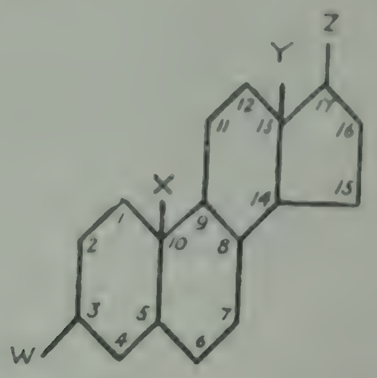
The *Reichert-Wollny value* or *volatile fatty acid value* is the amount of N/10 potassium hydroxide in c.c. required to neutralise the volatile fatty acids in 5 grammes of hydrolysed fat.

The acid value gives an indication of the acidity, or rancidity, of the fat. The saponification value gives some idea of the mean molecular weight of the total fatty acids. The Reichert-Wollny value indicates the proportion of these which are volatile in steam (*i.e.* are of low molecular weight); and the iodine value represents the mean degree of unsaturation of the acids of the fat.

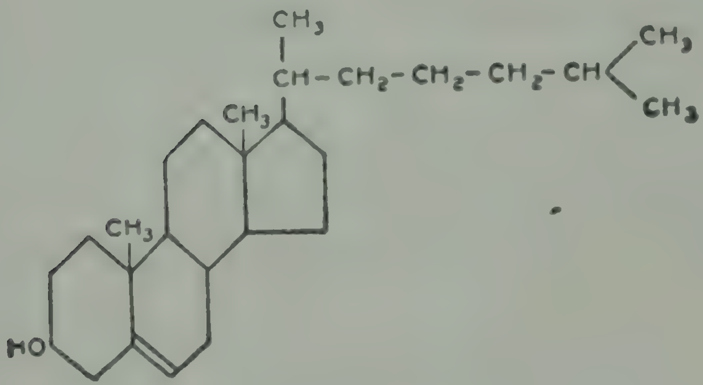
2. THE STEROLS

A certain number of substances occur in the body derived from a formation of esters of the fatty acids with sterols such as cholesterol. The fatty secretion of the sebaceous glands in man and the higher animals, which furnishes the natural oil of hair, wool (lanolin) and feathers, consists of cholesteryl esters with small traces of glycerides. The sterols also occur in the cells in the free state.

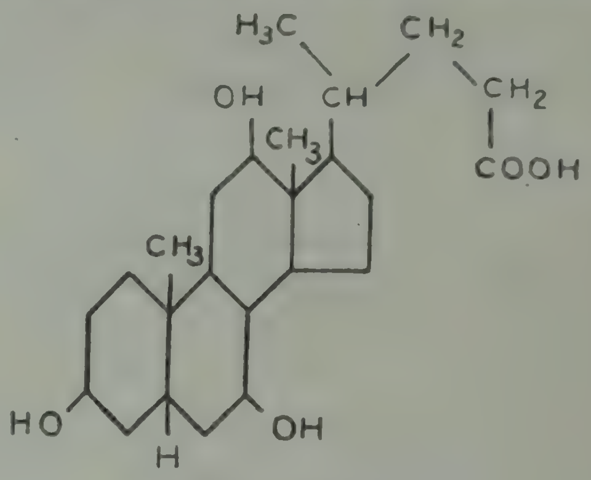
The sterols are mostly complex monatomic alcohols which are widely distributed throughout all the cells and fluids of the body. They contain the characteristic "*cholane*" ring :—



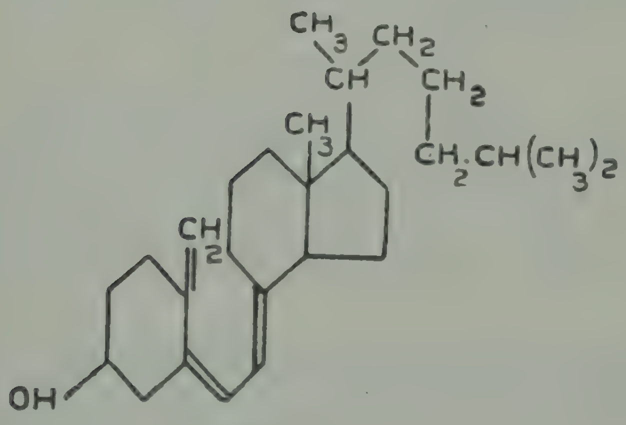
The most widespread member is *cholesterol*, an unsaturated secondary alcohol, $C_{27}H_{45}OH$, which is possibly the precursor in the body of the numerous derivatives. Its corresponding saturated compound, *coprosterol*, is found in fæces,



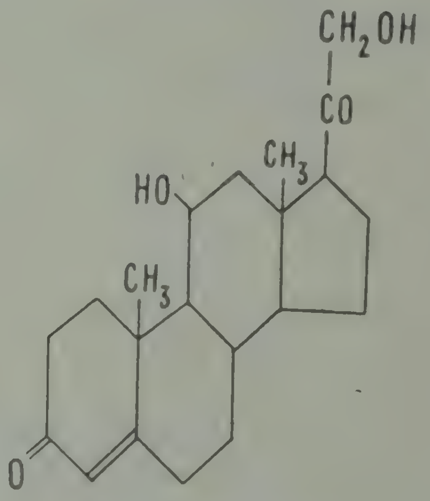
Cholesterol.



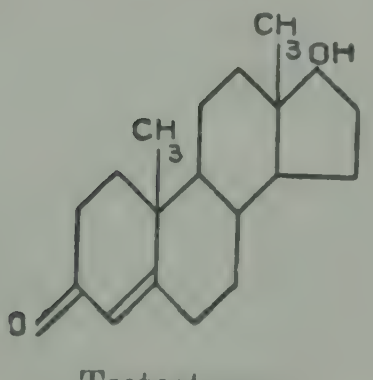
Cholic acid.



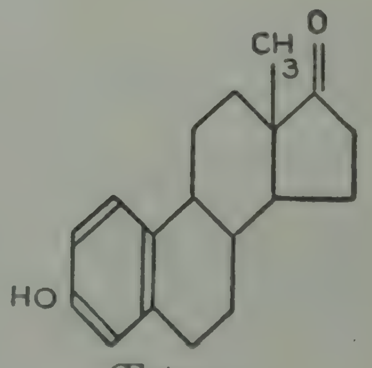
Vitamin D_3.



Corticosterone.



Testosterone.



Œstrone.

while the closely related *ergosterol*, $C_{28}H_{43}OH$, yields one of the vitamins D on irradiation. All the sterols are very stable, are optically active, and resist the action of enzymes and most bacteria.

The sterols are now recognised as a very important class of biological compounds. How closely related chemically are some substances of widely different physiological properties may be seen by the formulæ given above for cholesterol, a bile acid, a vitamin, a suprarenal hormone (corticosterone), a male sex hormone and a female sex hormone (œstrone).

Cholesterol is an important constituent of all cells and it, or its esters, forms part of the framework of the living cells, in the interstices or at the surfaces of which the numerous biochemical reactions associated with their life processes proceed.

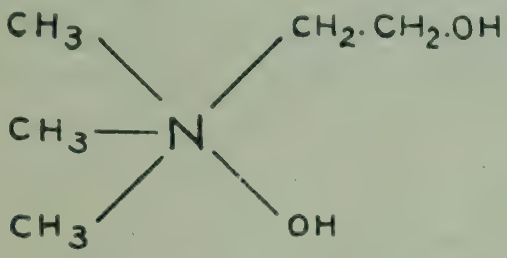
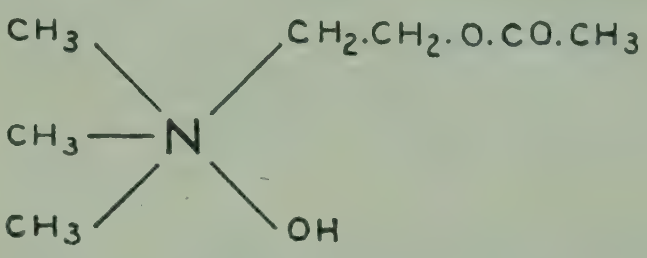
3. PHOSPHOLIPIDES

The chief phospholipide is *lecithin*, which contains glycerol, two molecules of fatty acid, phosphoric acid, and the base choline, a substance which has recently acquired considerable importance.



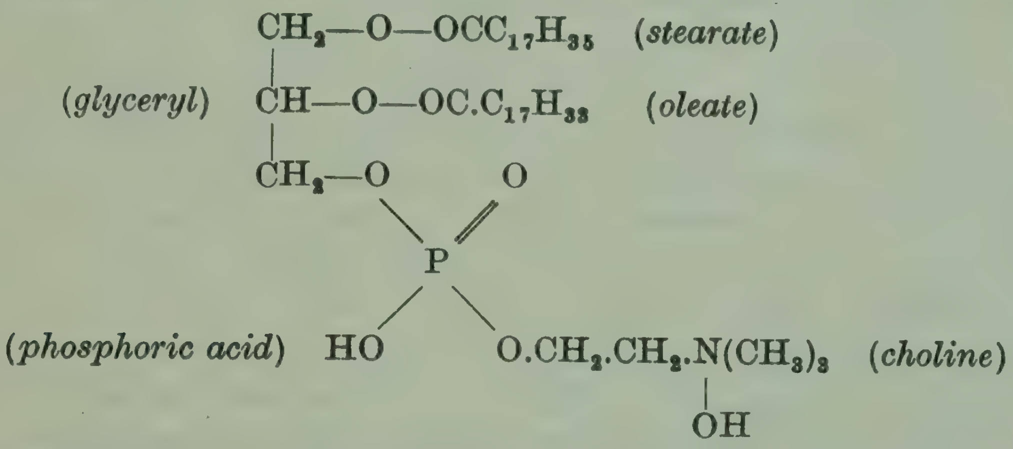
Choline.



Acetyl choline.

Choline has an important biochemical function as a transmethylating agent, which furnishes methyl groups for transfer to other molecules. One of its derivatives, *acetyl choline*, produces potent physiological effects.

Various lecithins, differing only in the nature of the fatty acids contained in them, have been prepared from different tissues. In general, their fatty acids are much more highly unsaturated than those of the food or the reserve fats of the animal—a fact which might suggest that the desaturation of fatty acids is an important preliminary to their metabolism. One of the various lecithins is represented by the following formula in which the two fatty acids are stearic acid and oleic acid :—



Other more unsaturated acids, linoleic, linolenic or arachidonic acids, are however usually present.

Lecithin is a substance very unstable to oxygen, owing to the highly unsaturated acids present in it, and for this reason extreme precautions must be taken in its preparation from tissues. Much of the work on the physiological effect of the phospholipides is probably vitiated by the presence of oxidation products. The universal distribution of lecithin signifies an important function in cellular activity. It undoubtedly plays an important part in the transport and metabolism of fats, related on the one hand to the fact that it is capable of colloidal solution in water, facilitating its free transport and, on the other, to the possibility that desaturation is involved in its production from neutral fats. Some work, however, suggests that the highly unsaturated acids of lecithin may be derived direct from those present in the ingested food. The importance of the constituent base choline in the control of the amount of fat in the liver is discussed later.

It is not improbable that the phosphoric acid of the phospholipides is concerned in the synthesis of the phosphorus-containing nucleo-proteins of the cell, and perhaps also in the normal processes of carbohydrate metabolism. Apart altogether from the chemical significance of its constituents, it is certain that lecithin and the allied substances, by virtue of their special physico-chemical condition in solution, play an important part in determining the peculiar permeabilities, osmotic relations and surface conditions of the cell.

Kephalin has a structure identical with that of lecithin, save that the choline of the latter is replaced by amino ethyl alcohol (ethanolamine), $CH_2NH_2CH_2OH$, linked to the phosphoric acid through its alcoholic hydroxyl group.

4. THE GLYCOLIPIDES

The glycolipides are found chiefly in nervous tissue, and are generally prepared from the acetone extract of brain. They do not contain phosphoric acid. The organic base present is a complex substance called sphingosine, present with a higher fatty acid and galactose. They are relatively more stable to oxygen than is lecithin.

The characterisation of individual conjugated lipides is a matter of much difficulty owing to their instability, to the similarity of their general properties and to their eccentric solubilities.

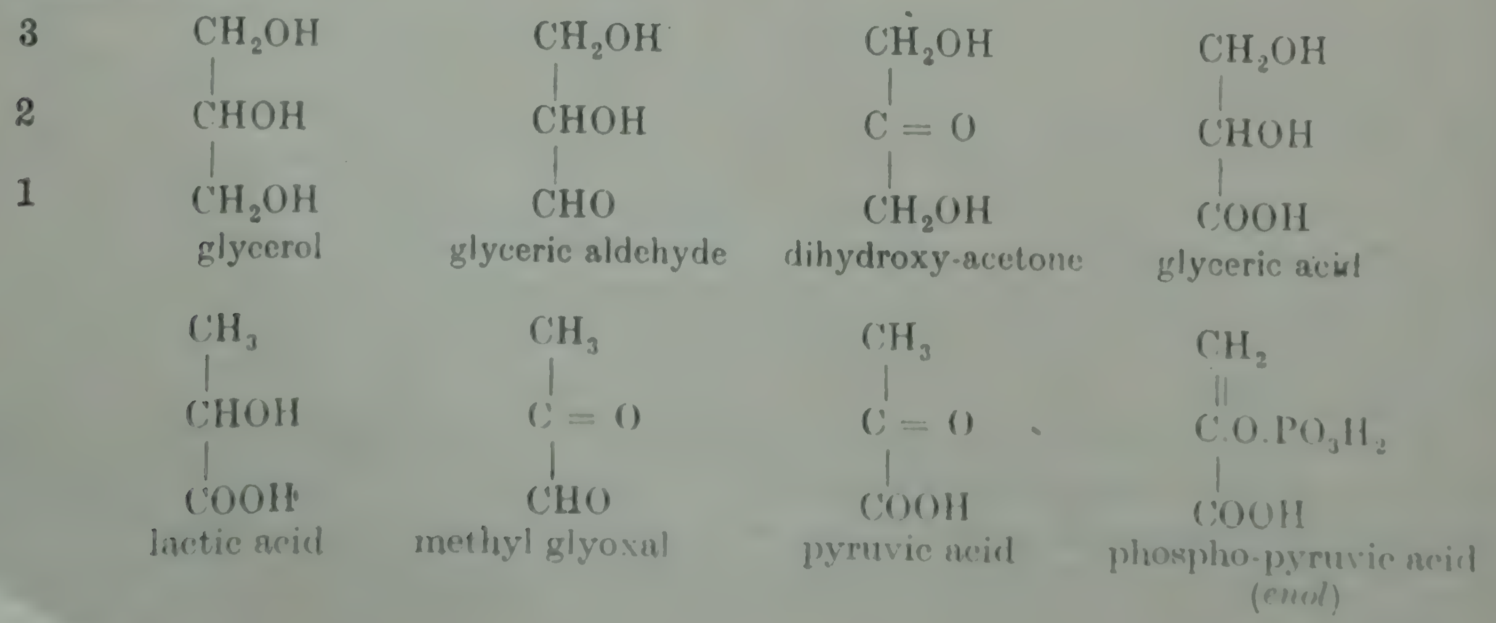
2. THE CARBOHYDRATES

The Carbohydrates are a group of bodies of wide distribution and great importance in both the vegetable and animal kingdoms. In plants the first product of assimilation of carbon is a carbohydrate, and in animals these substances form one of the most important sources of energy. They consist of the elements carbon, hydrogen and oxygen, the two last-named being almost invariably in the proportions necessary to form water. Their general formula might be expressed $C_nH_{2n}O_n$. Many of the carbohydrates which are of importance in the animal economy contain six carbon atoms or a multiple of this number. Analogous substances, however, can be prepared containing less or more than this number of carbon atoms. A series of compounds exist which contain in their molecule 2, 3, 4, 5, 6, 7, 8, 9 carbon atoms, and are termed dioses, trioses, tetroses, pentoses, hexoses, heptoses, and so on; the termination "ose" with the Greek numeral prefixed, indicating the number of carbon atoms, gives them a distinct designation. They are all either ketones or aldehydes of polyatomic alcohols, and known as *ketoses* and *aldoses* respectively.

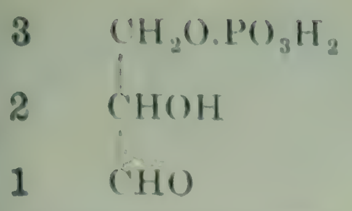
THE TRIOSES ($C_3H_6O_3$)

Two important trioses are glyceric aldehyde (an aldose) and dihydroxy-acetone (a ketose). Both can be obtained by oxidation of glycerol. Their relation to glycerol and to other physiologically important 3-carbon substances are shown below:—



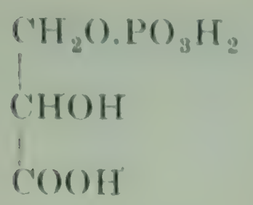
$$\begin{array}{ccccc} 3 & CH_2OH & CH_2OH & CH_2OH & CH_2OH \\ & | & | & | & | \\ 2 & CHOH & CHOH & C=O & CHOH \\ & | & | & | & | \\ 1 & CH_2OH & CHO & CH_2OH & COOH \\ & \text{glycerol} & \text{glyceric aldehyde} & \text{dihydroxy-acetone} & \text{glyceric acid} \end{array}$$

$$\begin{array}{cccc} CH_3 & CH_3 & CH_3 & CH_2 \\ | & | & | & \| \\ CHOH & C=O & C=O & C.O.PO_3H_2 \\ | & | & | & | \\ COOH & CHO & COOH & COOH \\ \text{lactic acid} & \text{methyl glyoxal} & \text{pyruvic acid} & \text{phospho-pyruvic acid} \\ & & & (\textit{enol}) \end{array}$$



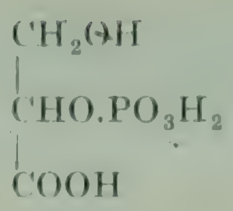
$CH_2O.PO_3H_2-CHOH-CHO$

3-phosphoglyceraldehyde



$CH_2O.PO_3H_2-CHOH-COOH$

3-phosphoglyceric acid

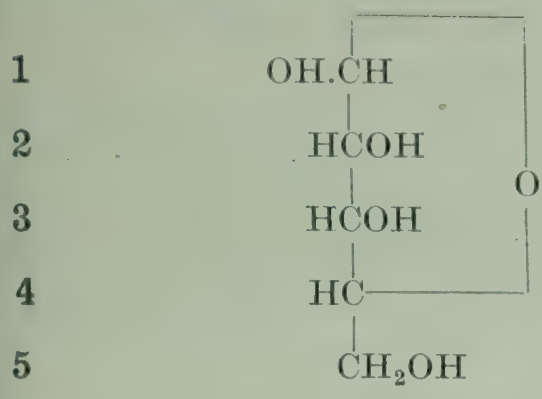


$CH_2OH-CHO.PO_3H_2-COOH$

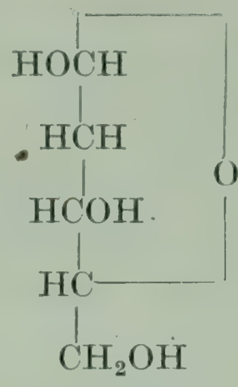
2-phosphoglyceric acid

THE PENTOSES

These bodies occur largely in plants in the form of complex polysaccharides, the Pentosans, which give pentoses on hydrolysis with acids. Three forms of pentose have been found in the animal body, namely, i-arabinose, which has been isolated from the urine in cases of pentosuria, and d-ribofuranose and desoxyribofuranose,



β-d-ribofuranose

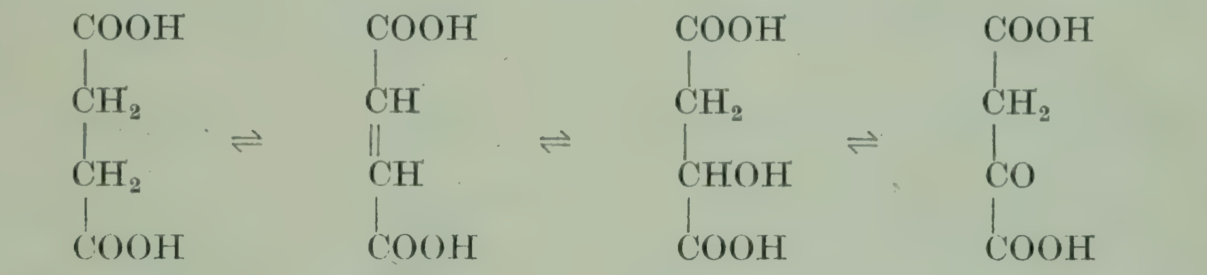


β-d-2 desoxyribofuranose

which occur built up into the nucleic acids, and in various important nucleotides.

SOME IMPORTANT 4- AND 5-CARBON DI- AND TRI-CARBOXYLIC ACIDS

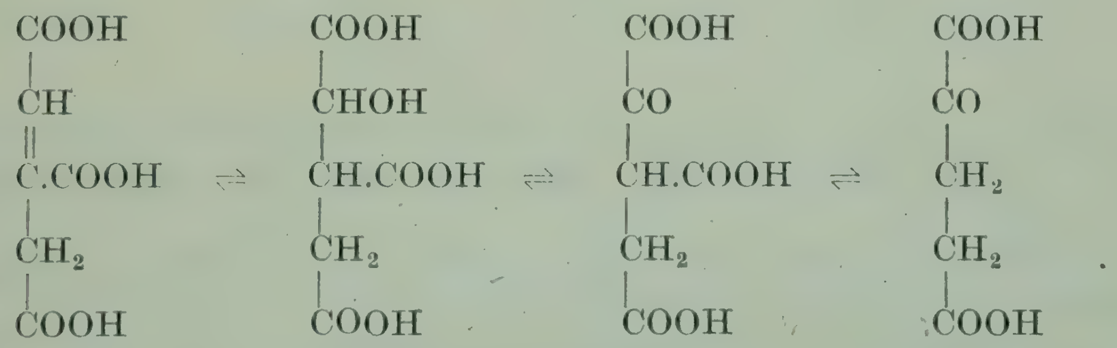
Some compounds which fall under these headings are included here because they probably play an important part in the metabolism of carbohydrates. Four of these 4-carbon dicarboxylic acids are shown below ; they are convertible as shown :—



$COOH-CH_2-CH_2-COOH \rightleftharpoons COOH-CH{=}CH-COOH \rightleftharpoons COOH-CH_2-CHOH-COOH \rightleftharpoons COOH-CH_2-CO-COOH$

Succinic acid. *Fumaric acid.* *Malic acid.* *Oxaloacetic acid.*

and four 5-carbon tricarboxylic and dicarboxylic acids, with convertibilities, are :—



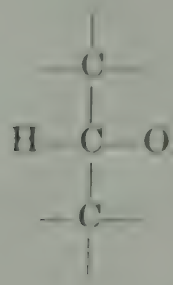
$COOH-CH{=}C.COOH-CH_2-COOH \rightleftharpoons COOH-CHOH-CH.COOH-CH_2-COOH \rightleftharpoons COOH-CO-CH.COOH-CH_2-COOH \rightleftharpoons COOH-CO-CH_2-CH_2-COOH$

Aconitic acid. *Iso-citric acid.* *Oxalosuccinic acid.* *a-ketoglutaric acid.*

THE HEXOSES OR MONOSACCHARIDES ($C_6H_{12}O_6$)

It is convenient to call those compounds containing six carbon atoms the simple sugars, or hexoses.

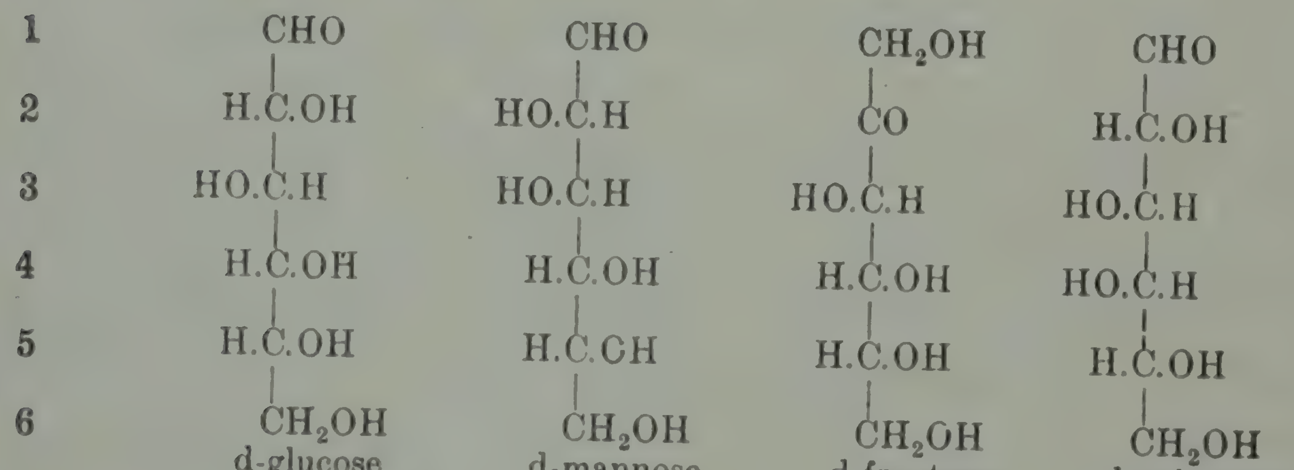
STEREOISOMERISM IN THE SUGARS. It will be noticed that of the six carbon atoms contained in the hexose molecule, *e.g.* the aldose $CHO.(CHOH)_4.CH_2OH$, four are *asymmetric*, *i.e.* their four combining affinities are combined with groups of different kinds, viz. two carbon chains, one H atom, and one OH group



$$\begin{array}{ccc} & | & \\ - & C & - \\ & | & \\ H & -C- & OH \\ & | & \\ - & C & - \\ & | & \end{array}$$

They must therefore present many stereoisomeric optically active forms. Thus an aldohexose with four asymmetric carbon atoms $(CHOH)_4$ must present 2^4 isomers, *i.e.* sixteen isomeric compounds, so that there must be sixteen optically active sugars all possessing the formula $CH_2OH(CHOH)_4CHO$. Only a small number are of any physiological importance. These include the aldoses glucose, mannose and galactose, and the ketose fructose.

Since these sugars can be divided into the dextro-rotatory and lævo-rotatory optically active varieties, an obvious mode of designation would be to represent them as d- or l- varieties respectively. But this mode of nomenclature has been altered in favour of representing by the letter prefixed, not the optical qualities of the substance in question, but its structural relation to dextro-rotatory glucose. Thus d-fructose means that fructose is the ketose corresponding structurally to the dextro-rotatory glucose, d-fructose itself being lævo-rotatory, though its active asymmetric C atoms are identically arranged with those in glucose. With this definition one may say that it is only the d-hexoses of a particular form which are assimilable, and therefore of physiological importance. If the optical activity is indicated, this is done by enclosure in brackets. Thus d (−) fructose means the fructose related to d-glucose, and of lævo-rotatory optical activity. The small differences in the configuration of the four d-sugars can be readily seen if their graphic formulæ, which for simplicity are shown as straight chains, be compared :



$$\begin{array}{ccccc} 1 & CHO & CHO & CH_2OH & CHO \\ 2 & H.C.OH & HO.C.H & CO & H.C.OH \\ 3 & HO.C.H & HO.C.H & HO.C.H & HO.C.H \\ 4 & H.C.OH & H.C.OH & H.C.OH & HO.C.H \\ 5 & H.C.OH & H.C.CH & H.C.OH & H.C.OH \\ 6 & CH_2OH & CH_2OH & CH_2OH & CH_2OH \end{array}$$

d-glucose d-mannose d-fructose d-galactose

Only four hexoses out of the large number which have been synthesised are assimilable by the animal body. These are mannose, glucose, galactose and fructose. They may be synthesised in several ways. The most interesting, because it probably represents the mechanism of synthesis of hexoses in plants, is the formation from formaldehyde.

d-(+)-GLUCOSE is the chief constituent of the sugar of fruits. It occurs in the body as the end product of the digestion of starch. It forms white crystals which melt at 86° C. and lose the one molecule of water of crystallisation at 110° C. It is easily soluble in water, and the solution shows mutarotation. Its final specific rotatory power at 20° C. is $[\alpha]_D = +52{\cdot}74°$. It ferments with yeast.

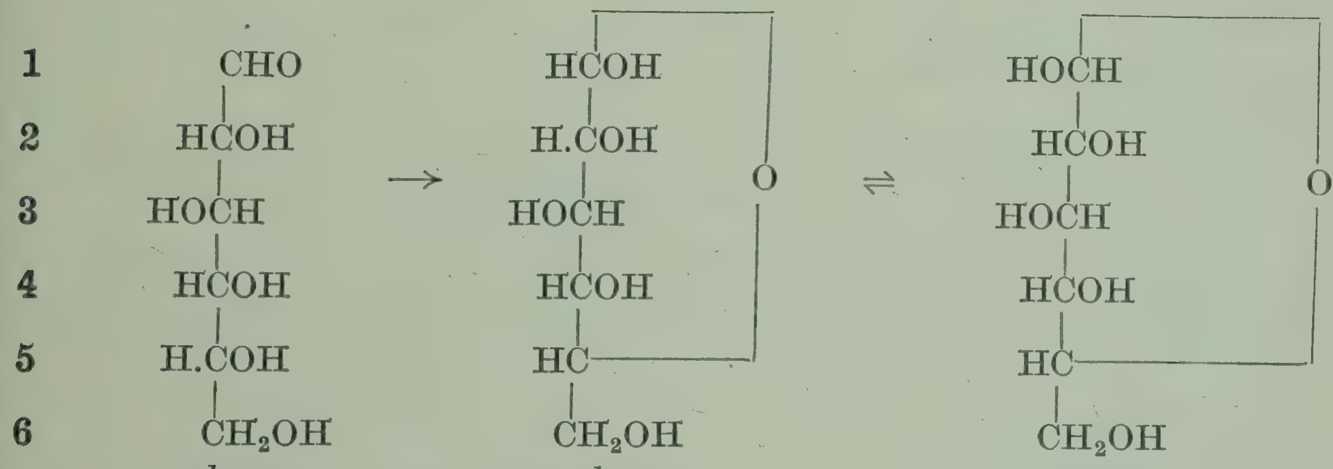
d-(−)-FRUCTOSE or LÆVULOSE occurs mixed with glucose in honey and in fruit sugar. It is also, with glucose, formed by the digestion or inversion of cane sugar. It is crystallisable with difficulty. Its watery solution is lævo-rotatory, and reduces Fehling's solution somewhat less strongly than glucose, its reducing power being 92, if we take that of glucose as 100. It ferments readily with yeast; with phenyl hydrazine it gives the same osazone as is formed from glucose.

d-(+)-GALACTOSE is formed by the hydrolysis of milk sugar or the galactosides of the brain with dilute mineral acids, and by the hydrolysis of certain vegetable gums. It is much less soluble in water than glucose. It is dextrorotatory and shows marked mutarotation. With ordinary yeast it ferments, but extremely slowly. Its reducing power is somewhat less than that of glucose.

MANNOSE. Mannose, though an assimilable sugar, is of such rare occurrence in our foodstuffs that it plays practically no part in animal physiology. It is dextro-rotatory, reduces Fehling's solution, ferments easily with ordinary yeast, and gives an osazone which is identical with that derived from glucose.

The straight-chain formulæ already given for the hexoses suffice to explain the majority of the reactions of the sugars; but a study of the behaviour of the reducing sugars in solution indicates that they possess a structure more labile than is suggested by the conventional static formula. A sample of glucose recrystallised from water exhibits when dissolved in water, a progressive decrease in rotatory power, during which the specific rotation falls from about 100° to a constant value of 52·7°. On the other hand, glucose recrystallised from pyridine gives, upon solution in water, an initial specific rotation of about 20°, rising slowly to 52·7°. This phenomenon receives the name of mutarotation, and is due to the fact that in solution glucose exists as an equilibrium mixture of two optical isomers which are designated α and β glucose respectively. α Glucose is the isomer usually handled as solid glucose. On the other hand, β glucose is obtained when the sugar is crystallised from pyridine.

Structural investigation of the two forms has shown that a lactone ring bridges the first and fifth carbon atoms, thus creating a new asymmetric carbon atom at position 1, and making it thus possible to have two isomers, the α and β forms, by altering the positions of the H and OH at position 1.



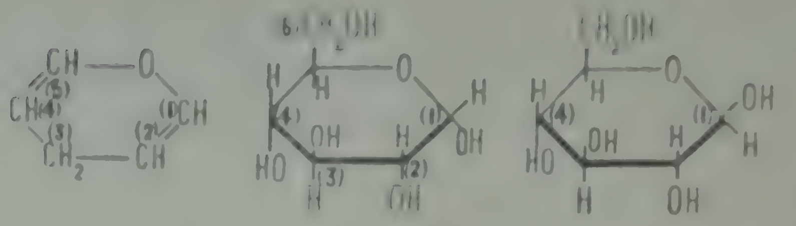
glucose (straight-chain formula)

α-glucose

β-glucose

Owing to the angle at which the bonds operate, the sugars are more correctly considered as derived from a six-atom heterocyclic ring called Pyran. According to the nomenclature proposed by Haworth these sugars are called pyranoses, *e.g.* glucose could exist as α or β gluco-pyranose; a 1 : 4 or γ lactone (butylene oxide) linkage can also exist, being a very reactive form called γ glucose (or gluco-furanose, owing to its relation to the 5-atom ring called Furan) of which again there are α and β forms. It is similar with other sugars.

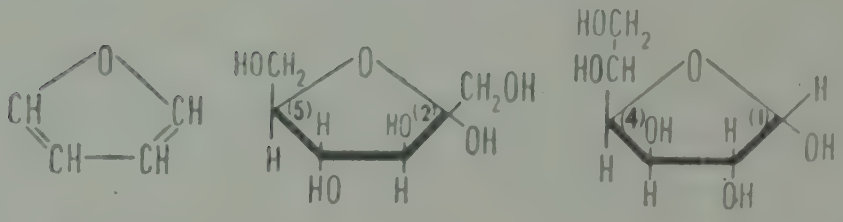
The formulæ, which are now conventional, given below, exhibit this ring structure for glucose and fructose: a carbon atom is to be assumed at each corner, except where the O appears. The diagrams suggest the spatial arrangement in relation to the carbons.



Pyrane

α-glucose (α-gluco-pyranose)

β-glucose (β-gluco-pyranose)



Furane

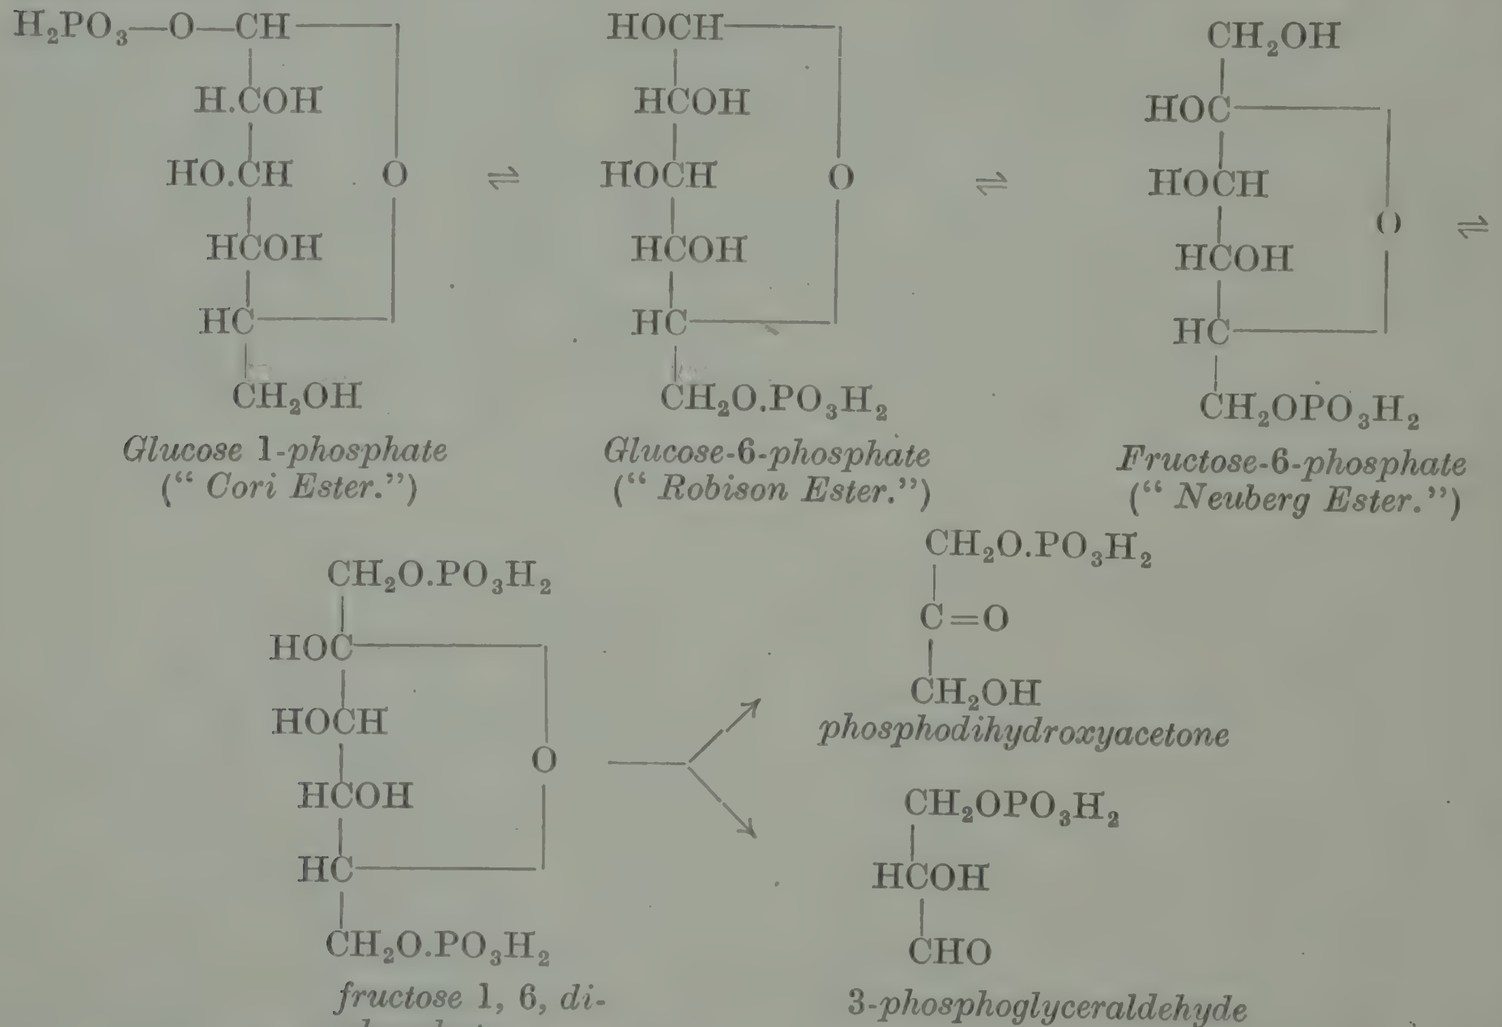
fructose (α-fructofuranose)

α-gluco-furanose

The figures shown in brackets are the conventional position-numbers.

DERIVATIVES OF THE HEXOSES

The phosphoric esters of the hexoses play an important part in the intermediary metabolism of carbohydrates, since they break down into triose phosphates (*v.* p. 31) :—



Glucose 1-phosphate ("*Cori Ester.*")

Glucose-6-phosphate ("*Robison Ester.*")

Fructose-6-phosphate ("*Neuberg Ester.*")

phosphodihydroxyacetone

fructose 1, 6, di-phosphate ("*Harden-Young Ester.*")

3-phosphoglyceraldehyde

The so-called "Embden ester" is a mixture of glucose-6- and fructose-6-phosphates.

Asymmetric syntheses of sugars from phosphorylated derivatives have been brought about by the use of enzymes from muscle and yeast ; these bring about an aldol condensation between dihydroxyacetone phosphate and an aldehyde.* Thus with *d*-glyceraldehyde, fructose 1-phosphate results. It is probably by some such means that sugars are interconverted in the body.

Two other derivatives of glucose are of physiological importance, namely, glucosamine and glucuronic acid.

Glucosamine has the structural formula :—

$$CH_2OH.(CHOH)_3.CHNH_2.CHO$$

---

* Lohmann. *Angew. Chem.*, 1936, **49**, 327.

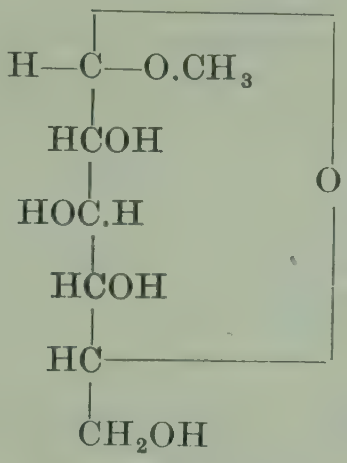
It is obtained from chitin, which forms the exoskeleton of large numbers of the invertebrata, by boiling this with concentrated hydrochloric acid. It is obtained as a decomposition product of the glucoproteins, such as the mucins. In solution it is dextro-rotatory, reduces Fehling's solution, and gives an osazone resembling that derived from glucose.

Glucuronic Acid may be regarded as one of the first results of oxidation of the glucose molecule. The group which has undergone oxidation is not the readily oxidisable CHO group, but the CH_2OH group at the other end of the molecule. The formula of this acid is therefore :

$$COOH.(CHOH)_4.CHO$$

It may be produced by the oxidation of glucose by means of hydrogen peroxide. In the free state it does not occur in the animal body. It is constantly found in the urine after administration of certain drugs such as phenol, camphor or chloral, and then occurs as a conjugated acid with these substances. These glucuronates are lævo-rotatory, though the free acid is dextro-rotatory. In the free state it reduces Fehling's solution and gives an osazone which is not sufficiently characteristic to distinguish from glucosazone. It does not undergo fermentation with yeast.

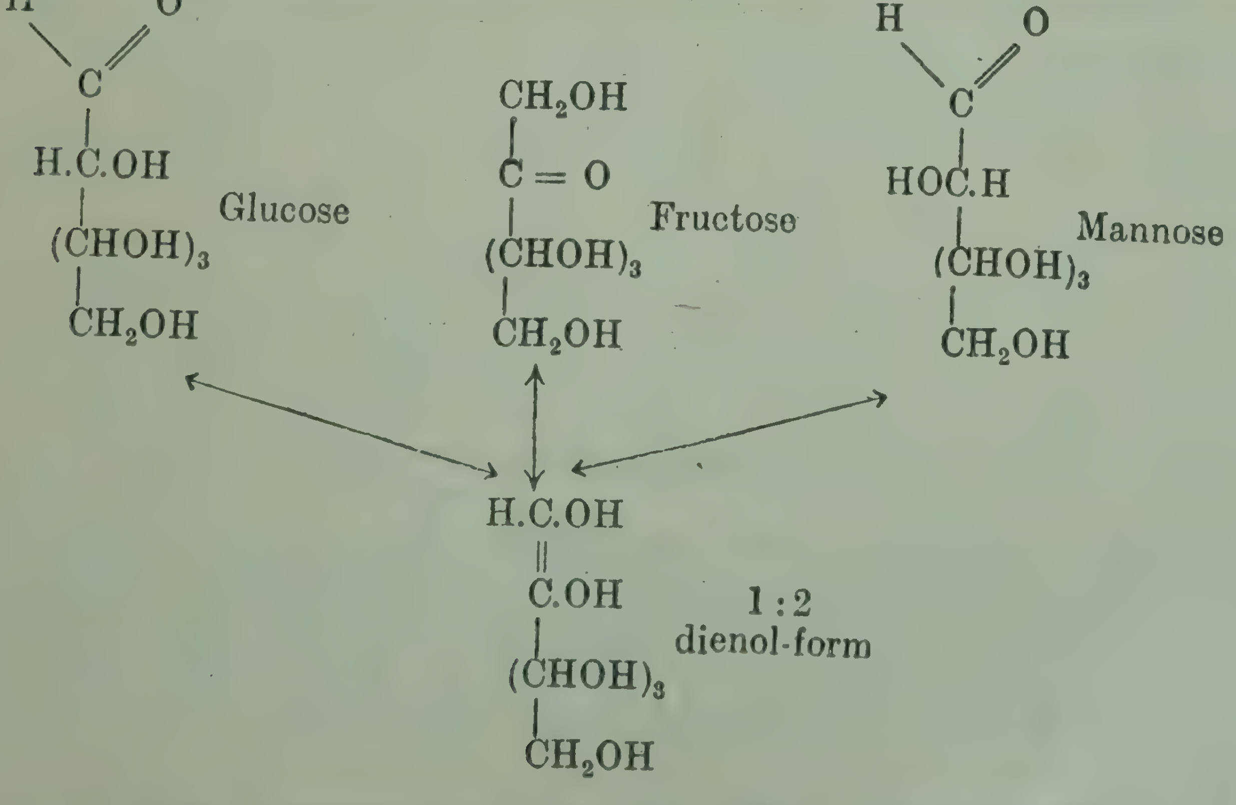
Glycosides. The glycosides are ethers formed by the reducing group of sugars. Thus by methylating α-glucose we get α-methyl glucoside (the glucosides being the glycosides derived from glucose, galactosides from galactose, etc.).



α-methylglucoside

A large number of glucosides occur as plant products—amygdalin, salicin, phlorrhizin indican, saponin—and appear to be β glucosides, *i.e.* are ethers formed from β glucose and an alcohol. The disaccharides are also glucosides : thus maltose is glucose α glucoside, whilst lactose is probably glucose β galactoside.

The Action of Alkali on the Hexoses. A trace of alkali greatly accelerates the mutarotation of the hexoses, indicating an increased lability of the carbon atom at position 1. In more strongly alkaline solutions further changes occur. In the case of glucose a progressive fall in rotatory power reaching a lævo-rotation will be observed. Examination of the solution will then show the presence not only of glucose but also of fructose and mannose.* Since the differences between these three hexoses are confined to the carbon atoms 1 and 2, it will be seen that their ready interconversion in alkaline solution may be explained as occurring through the intermediate production of a 1 : 2 dienol-form.

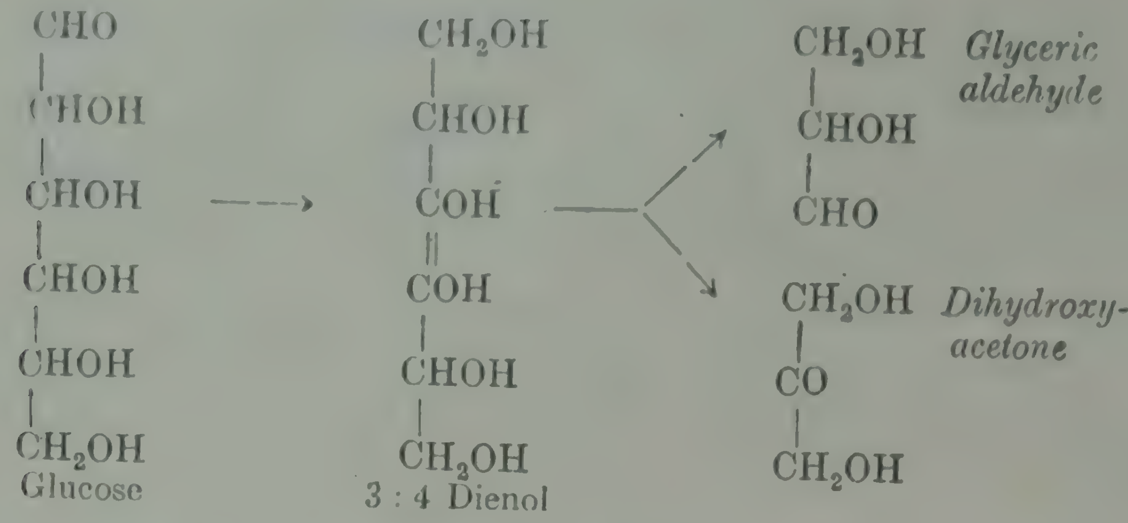


---

* Nef. *Annalen der Chemie*, 1910, **376**, 1 ; 1914, **403**, 204.

It is of interest that these three hexoses, which are most nearly related *in vitro*, are als the most readily assimilated by the animal. The difference is that, whereas alkali effect an indiscriminate interconversion of glucose, fructose and mannose, the living cell show directional activity in turning them all into glucose. The anomalous position of galactos as an assimilable sugar is not capable of so facile an explanation on structural lines.

In somewhat stronger alkaline solutions and in absence of oxygen, the 3 : 4 dienol-form results, and this readily breaks up into two important 3-carbon derivatives, glyceric aldehyd and dihydroxyacetone :—



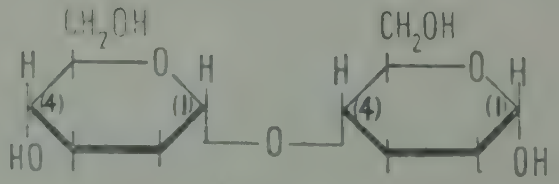
In strongly alkaline solutions in presence of oxygen still more extensive changes occur. A large number of different acids containing varying numbers of carbon atoms, such as oxalic, lactic, tartaric and saccharic acids, and complex resinous substances are formed. There is so much in common between the alkaline and the biochemical degradation of carbohydrate that one could expect that the same broad lines are followed in each, though in the living cell the notable distinction is the production of a selected few of the substances appearing in alkaline solution *in vitro.*

THE DISACCHARIDES ($C_{12}H_{22}O_{11}$)

The disaccharides are formed by the union of two molecules of monosaccharides with the elimination of one molecule of water, and can be regarded as glucosides, galactosides, etc. On hydrolysis, *e.g.* on heating with acids, they take up one molecule of water and are split up into the corresponding monosaccharides. Thus cane sugar gives glucose and fructose, maltose gives two molecules of glucose, while lactose gives glucose and galactose.

Cane Sugar, or sucrose, is widely distributed throughout the vegetable kingdom, and forms an important article of diet. It has no reducing power, is strongly dextro-rotatory and has a specific rotatory power of + 66·5°. On hydrolysis it is converted into glucose and fructose. Owing to the fact that fructose rotates polarised light more strongly to the left than glucose does to the right, the mixture of the two monosaccharides so obtained is lævo-rotatory. On this account the change to the mixture of monosaccharides is known as *inversion*. With yeast, cane sugar first undergoes inversion by a special enzyme present in the yeast (*invertase*), and the mixture of fructose and glucose is then fermented. Invertase is also present in the intestinal juice.

Maltose is formed during the hydrolysis of starch by acids or by the enzyme amylase, and is the chief sugar in germinating barley or malt. It is α-glucose-α-glucoside :—



Maltose
(abbreviated conventional formula)

It is strongly dextro-rotatory, ferments easily with yeast, and reduces Fehling's solution ; its reducing power is about 70 per cent. of that of glucose. With phenyl hydrazine it gives phenyl maltosazone, which forms characteristic yellow crystals with a melting-point of 206° C. The enzyme *maltase*, of the intestinal juice, converts it to glucose.

Lactose is a constituent of milk. It is much less soluble in water and much less sweet than are the two other disaccharides. It is dextro-rotatory, shows mutarotation and is not fermented by ordinary yeast. Lactose can be split by the agency of an enzyme, *lactase*, which occurs in the animal body and in certain moulds, into glucose and galactose. Lactose reduces Fehling's solution and gives an osazone, which is easily soluble in hot water.

THE POLYSACCHARIDES $(C_6H_{10}O_5)n$

These are complex substances of high molecular weight formed by combination of monosaccharide molecules, with elimination of water. In the animal body the sole significance of polysaccharides lies in their value as foodstuffs. In plants, anhydrides both of hexoses (hexosans $(C_6H_{10}O_5)_n$) and pentoses (pentosans $(C_5H_8O_4)_n$) occur in bewildering variety. Unlike the other carbohydrates, the higher polysaccharides are not destroyed by hot strong alkaline solutions. The chemical constitution of the polysaccharides is a difficult problem because of their complexity and their colloidal behaviour. The methylation methods of Irvine have given us a deeper insight into the manner of combination of the hexoses in a polysaccharide molecule. It appears certain that glycogen and starch are both composed of α-glucopyranose molecules, linked up as maltose units.

The enzymic synthesis of polysaccharides, amylose, starch and glycogen has been effected, the starting-point being glucose 1-phosphate.*

Starch is present in large quantities in nearly all vegetable foods, and is an important constituent of the cereals, as well as of tubers, such as the potato. In the plant cells it occurs as concentrically striated grains, insoluble in water. In hot water the grains swell up and burst, forming a thick paste, which sets to a jelly on cooling. This colloidal solution, as well as the original starch grains, gives an intense blue colour on the addition of iodine. On treating with cold dilute acid, it is converted into a soluble modification, the so-called soluble starch, which also gives a blue colour with iodine. This modification is likewise produced as the first stage of the action of the enzyme *amylase* upon starch. On boiling with dilute acids, starch is converted first into a mixture of dextrins, then into maltose, and finally into glucose.

Natural starch actually consists of two polysaccharides: 25 per cent. of it is *amylose*, giving a blue with iodine, and 75 per cent. is *amylopectin*, which turns purple with iodine. They occur in the ratio 2 : 1, of molecular weights about 60,000 and 300,000 respectively. Each consists of about 24 glucose units, the high molecular weights being due to aggregation. Amylopectin is closely associated with phosphoric acid, with which it may indeed be in combination. On acid hydrolysis both yield glucose; on hydrolysis with barley diastase, amylose yields maltose, but amylopectin is only partially depolymerised, though oat diastase can split it also finally into maltose. On acting upon starch with amylase, such as the diastase of germinating barley, or with the amylase occurring in saliva or pancreatic juice, it undergoes hydrolysis, the final result of the action being a mixture of four parts of maltose to one part of stable dextrin, the latter being derived from the amylopectin. In the intermediate stages in this reaction the first product is soluble starch or *amylodextrin*. This breaks up into a reducing sugar and another dextrin, *erythrodextrin*, which gives a red colour with iodine; and this dextrin, on further hydrolysis, yields reducing sugar and *achroödextrin*, which is not coloured by the addition of iodine. Thus there is a series of successive hydrolytic decompositions of the molecule, each resulting in the splitting off of a molecule of sugar and the production of a lower dextrin.

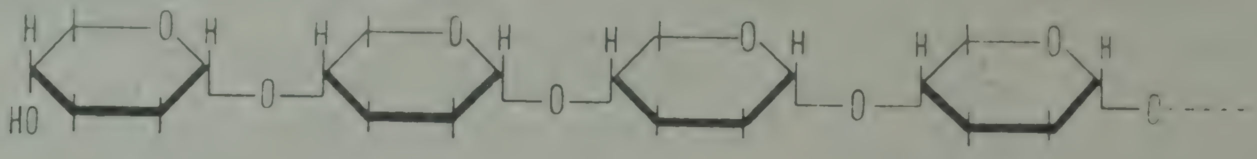
The **Dextrins** are ill-defined bodies which are difficult to separate. They are amorphous white powders, easily soluble in water, forming gummy solutions when concentrated. They are insoluble in alcohol and ether. With cupric hydrate and caustic alkali they form blue solutions, which reduce slightly on boiling. They are not precipitated by saturation with ammonium sulphate. On boiling with dilute acids, they are converted entirely into glucose.

---

* Cori *et al.* *Science,* 1939, **89,** 464. Hanes. *Proc. R. S.,* 1940, **128B**, 421; **129B**, 174.

INULIN, which somewhat resembles starch, occurs in dahlia tubers. It is easily hydrolysed by weak acids into d-fructose.

GLYCOGEN is a polysaccharide which closely resembles starch in structure and properties. It is found in the liver, muscles and other tissues of the body, in all fœtal tissues, and in yeast. It is a white powder forming an opalescent solution in water, and is precipitated from its solution on the addition of alcohol to 60 per cent., by strong acetic acid, by basic lead acetate, or by saturation with solid ammonium sulphate. On boiling with acids, it is entirely converted into glucose. It is affected by amylase in the same way as starch, giving first dextrins and finally maltose. With iodine it gives a mahogany-red colour which, like the blue colour produced in starch, is destroyed by boiling, to return again on cooling. There are two forms of glycogen, one with 12 and one with 18 α-glucopyranose units.



Scheme of portion of glycogen molecule comprising 4 α - glucose units.

THE CELLULOSES. Cellulose is a colourless, insoluble material, or mixture of materials, which forms the cell walls of plants, and is therefore a constituent of most of our vegetable foods. It is insoluble in water or dilute acids or alkalies, but soluble in ammoniacal cupric oxide solution. On boiling with strong acids, it gradually undergoes hydrolysis and yields glucose. In herbivorous animals cellulose is digested by the agency of micro-organisms which swarm in the paunch of ruminants and in the cæcum of other herbivora. By these the cellulose is converted into lower fatty acids, *e.g.* acetic and propionic, which are changed in the body into fats and sugar. In man cellulose undergoes practically no change in digestion, and serves merely by its bulk to promote peristalsis and the normal evacuation of the bowels.

3. THE PROTEINS

The proteins form the most important constituent of protoplasm, and must always be present in a diet. Although characterised by certain chemical tests, it is not easy to give a simple definition in chemical terms of what we mean by the term "protein."

Elementary Composition. All proteins contain oxygen, hydrogen, nitrogen (15–17·6 per cent.), carbon and, usually, sulphur (0·3–2·2 per cent.).

Physical Characters. The proteins are tasteless colloids, many of which can be crystallised. Most of them are soluble either in water, weak salt solutions, or in dilute acids or alkalies. They tend to become insoluble at the iso-electric point, and this change is sometimes found to be irreversible. They are extremely liable to undergo the change called *denaturation*, the nature of which is obscure, as a result of many kinds of chemical or physical treatment. This denaturation may result from shaking, change of temperature, alteration of reaction, or addition of neutral salts. *Coagulation* by heat forms a distinguishing feature of a number of members of this class, which are therefore spoken of as "coagulable proteins." For instance, white of egg is a solution of different proteins. If a strong solution be boiled the whole fluid sets to a solid white mass or *gel*. This change is irreversible, *i.e.* it is not possible by lowering the temperature to bring the white of egg again into solution, and many properties of the protein have been changed in the act of coagulation. A few proteins, *e.g.* gelatin, form gels at lower temperatures which melt reversibly on warming.

THE STRUCTURE OF THE PROTEIN MOLECULE

We can arrive at some idea of the manner in which the protein molecule is built up by breaking it down by hydrolysis.

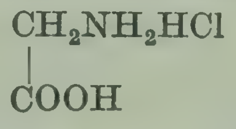
By prolonged acid hydrolysis we obtain a complex mixture of substances, nearly all of which are α-amino-acids, and must be regarded as the proximate constituents of the protein molecule.

A similar hydrolytic change may be effected by the use of digestive enzymes, pepsin, trypsin, erepsin, and so on. These enzymes are all milder in their action than the strong acids. Pepsin for instance effects only a partial decomposition of the protein molecule. Its action results in the formation of substances which still present all the protein reactions and are classified as hydrated proteins or as proteoses and peptones. Trypsin carries the protein a stage further and gives a mixture of polypeptides and amino-acids. Erepsin breaks the polypeptides down to amino-acids.

THE AMINO-ACIDS

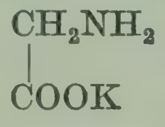
Nearly all the known disintegration products of the main protein molecule are amino-acids. They are soluble in water and easily diffusible. All the amino-acids, except glycine, derived from proteins are optically active, whereas those obtained by synthesis are inactive, or racemic, mixtures of the *d*- and *l*-forms.

The presence in the amino-acids of the basic radical NH_2 and of the acid group COOH lends to these bodies a double character. The monoamino-monocarboxylic acids, possessing neither acid nor alkaline reaction, are able in the presence of strong acids or bases to act either as base or acid. Thus, with hydrochloric acid, glycine forms glycine hydrochloride:



$$\begin{array}{l} CH_2NH_2HCl \\ | \\ COOH \end{array}$$

With bases these amino-acids form salt-like compounds such as potassium amino-acetate



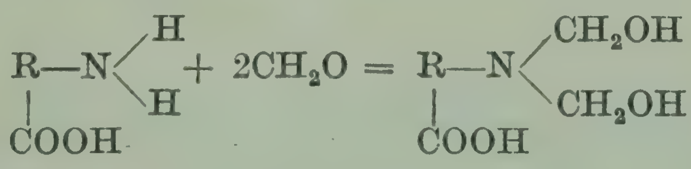
$$\begin{array}{l} CH_2NH_2 \\ | \\ COOK \end{array}$$

On account of the dual nature of the amino-acid molecule, these substances act as feeble electrolytes. Since they may act either as cations or anions, they are spoken of as *amphoteric* electrolytes (*v.* also p. 76).

Amino-acids also combine as acids and bases with one another. This power of combination much increases the difficulty of separating the constituents from a mixture of amino-acids. Amino-acids, which singly are sparingly soluble, are often soluble when in the presence of other amino-acids.

The diamino-acids, having two amino groups, are definitely basic in nature, while the dicarboxylic acids, with two carboxyl groups, are acids.

When an amino-acid is treated with formaldehyde the amino group is attacked, and the carboxyl group then has full acidic power and can be titrated.



$$\begin{array}{l} R\text{—}N\begin{array}{l} \diagup H \\ \diagdown H \end{array} \\ | \\ COOH \end{array} + 2CH_2O = \begin{array}{l} R\text{—}N\begin{array}{l} \diagup CH_2OH \\ \diagdown CH_2OH \end{array} \\ | \\ COOH \end{array}$$

Since each COOH group liberated corresponds to one NH_2 group fixed, this method is often used for estimating the amino-groups in any mixture.

An important property of amino-acids is that of combining with carbon dioxide to form carbamino-acids, *e.g.*:—

$$R.NH_2 + CO_2 = R.NH.COOH,$$

and this property is shared by certain proteins, which are thereby enabled to combine with carbon dioxide.

Since proteins are built up from a large number of amino-acids, it is not surprising to find that they likewise are amphoteric substances. The predominance of acid or basic properties will depend on whether the protein contains a surplus of dicarboxylic acids or of di-amino acids. It follows that the proteins can exist as salts with either acids or bases or in the free state. The factor which determines the condition of the protein is the hydrogen ion concentration. It has been found that the physical properties of protein solutions vary greatly with the hydrogen ion concentration and exhibit abrupt maxima or minima at a definite reaction which is characteristic of the protein. It seems probable that at this point —the *iso-electric point*—the protein is combined neither with acids nor with bases, but exists as a very feebly ionised free protein. On either side of the iso-electric point a highly ionised protein salt of some sort will exist, the nature of which again depends on the hydrogen ion concentration. These characteristic changes of the protein molecule with the reaction of the medium are of considerable importance.

The α-amino-acids which have been isolated from the products of hydrolysis of proteins are so varied that it may be a convenience to append a list of the physiologically important amino-acids which have actually been separated by hydrolysis of proteins. (The commonly used names are given on the left.) *

* For nomenclature *v.* *Biochem. J.*, 1948, **42**, 1. The prefix *d*- or *l*- here refers to the actual rotation. Confusion has sometimes been caused by the use of the Fischer configurative designation, as described for carbohydrates (p. 32). According to this, most of the natural amino-acids belong to the l- series: the actual rotation is then indicated by (+) or (−) following the letter. Thus, natural glutamic acid would be *l* (+), and serine *l* (−), etc., but natural threonine would be *d* (−).

Several of the chemical tests for proteins depend on the presence of specific amino-acids; for example, the Millon's reaction on the presence of tyrosine, the glyoxylic test on the presence of tryptophan, etc.

Under the action of bacteria, amino-acids may undergo a process of deamination which may be accompanied by simple hydrolysis or by reduction. In the former case an amino-acid may be converted into an hydroxyacid, in the latter case into a fatty acid.

---

* Synthesis. *v.* Snyder and Smith. *J. Amer. Chem. Soc.*, 1944, **66**, 350.

On the other hand, some bacteria may split off carbon dioxide from the amino-acids and yield amines. Thus tyrosine becomes *p*-hydroxyphenylethylamine, and histidine becomes *histamine*, a substance having important physiological effects (p. 97).

OTHER CONSTITUENTS OF THE PROTEIN MOLECULE

When we add together the total amino-acids obtainable by the acid disintegration of any given protein, a considerable proportion of the original protein is often unaccounted for. Much of this remainder may represent analytical loss, but some of it may consist of substances not as yet identified. One substance sometimes present is glucosamine. Proteins belonging to the class of mucoids yield on acid hydrolysis from 16 to 30 per cent. glucosamine. Egg albumin, serum albumin and serum globulin all contain in their molecules a complex carbohydrate consisting of glucosamine and mannose.*

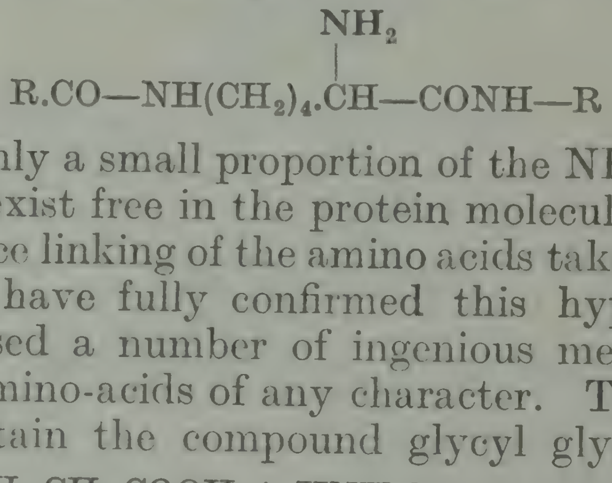
THE BUILDING UP OF THE PROTEIN MOLECULE

The amino-acids are present in different proportions in the individual proteins, so that in many cases a large number of identical amino-acid groups must be present in the protein molecule, with smaller numbers of other groups. One method of linkage of amino-acids to form larger molecules is by condensation of a COOH of one amino-acid and an NH_2 group of another to form the *peptide* linkage :

$$—CO.NH—$$

It is generally believed that, in this manner, molecule can be added to molecule until finally the gigantic molecule of a protein results. In such molecules there is believed to be a regular pattern of amino-acids, each of which recurs with constant frequency at a particular place in the chain.†

Of course, each lysine group in a peptide will give one free NH_2 group :—



$$R.CO—NH(CH_2)_4.\overset{\overset{NH_2}{|}}{C}H—CONH—R$$

but apart from these, only a small proportion of the NH_2 groups present in the separated amino-acids exist free in the protein molecule, and these must be at the end of the chain, since linking of the amino acids takes place by NH groups. Synthetic experiments have fully confirmed this hypothesis. Fischer, and later Bergmann,‡ devised a number of ingenious methods for combining together two or several amino-acids of any character. Thus from two molecules of glycine we may obtain the compound glycyl glycine, as follows :

$$NH_2.CH_2.COOH + HNH.CH_2.COOH =$$
$$NH_2.CH_2.CO.NH.CH_2.COOH + H_2O$$

These compounds were designated *peptides* by Fischer. He distinguished di-, tri-, tetra, etc., or *polypeptides* according to the number of individual amino-acids taking part in the formation of the compound, *e.g.* alanyl leucine, glycyl tyrosine, dialanyl cystine, dileucyl cystine, leucyl pentaglycyl glycine, and so on. The last named would be built up out of one molecule of leucine, and six molecules of glycine. Abderhalden built up a molecule containing eighteen constituent amino-acids. These polypeptides are still very far below the proteins in molecular size, and proteins have not been made artificially. The higher polypeptides closely resemble the peptones. Most of them, even if derived from relatively insoluble amino-acids, are soluble in water, insoluble in alcohol. They dissolve in mineral acids and in alkalies, with the formation of salts, and have a bitter taste. The higher members of the series give certain reactions, such as the biuret reaction, which are regarded as characteristic of peptones, and like the latter are precipitated by phosphotungstic acid. Some are split up by certain proteinases,* and by erepsin, into amino-acids.

* RIMINGTON. *Biochem. J.*, 1929, **23**, 430.

† BERGMANN and NIEMANN. *J. Biol. Chem.*, 1937, **118**, 301 ; 1938, **122**, 577.

‡ BERGMANN. *Science*, 1934, **79**, 439. BERGMANN and ZERVAS. *J. Biol. Chem.*, 1936, **113**, 341.

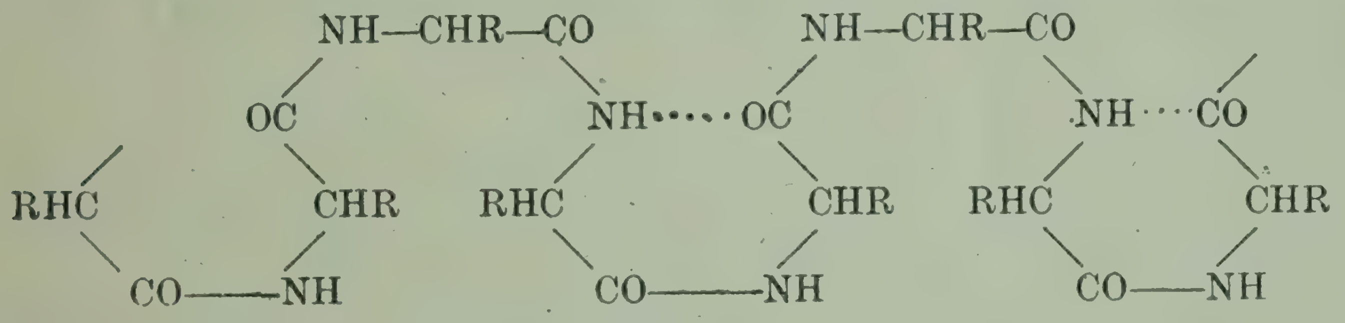
Thus in the building up of the protein molecule there is an almost unlimited capacity for coupling up of numerous amino-acid groups, the link in each case being the nitrogen. Of the two or more possible optical isomers of each amino-acid containing more than two carbon atoms, only one is found in nature.

A still further flexibility in its reactions is conferred on the protein molecule by intramolecular rearrangement occurring with great readiness in its component molecules. As a result of this the protein molecule may not be a single peptide chain, but a system of several chains, differing somewhat in composition, and linked to one another, not by amino groups, but by carboxyl, or imide, or thiol-ester linkages. Thus, according to Chibnall, egg-albumin may consist of at least 4 peptide chains, having free terminal amino-groups (*i.e.* not accountable for from the lysine content), and lactoglobulin may have 9 peptide chains, so explaining the presence of 8 extra free amino-groups, which must presumably be terminal in position.

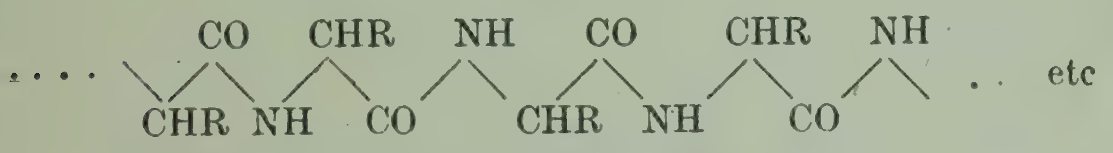
The fact that pepsin will act on proteins, but not on polypeptides, is a further indication that the peptide structure may not be the only type of linkage by which the constituent amino-acids are assembled in the protein molecule. If we consider that perhaps some hundred of the amino-acid groups may go to making up a single protein molecule, it is possible to form some conception of the enormous variability in structure possible to such a compound.

The study of the ultrastructure of proteins by the use of X-ray spectra and by other physical methods, such as the study of thin films, orientation in electric fields, etc., gives another viewpoint from which to study the architecture of their molecules. These investigations show two types of molecular structure, *fibrous* and *globular*.

Among the fibrous proteins are those of myosin, keratin, and fibroin, present respectively in muscle, hair and silk. In these we have essentially a long polypeptide chain. In the normal state the chain is kinked owing to electrostatic attraction between side-chains, *e.g.* in α-keratin :—



α-keratin



β-keratin (stretched)

but when stretched the chain becomes more regular (β-keratin), and if heated in the stretched state this form becomes denatured and permanent (" permanent waving "). The myosin of muscle is probably similar.

In the globular protein molecules, the kinking is exaggerated, so that the molecule folds on itself in a regular pattern. Such proteins are insulin, pepsin, lactoglobulin and hæmoglobin. According to Wrinch,† regular geometrically constructed molecules may result (cyclol structure), containing 6, 18, 30, 42, 54, 66, 72, 90 or more amino-acids, which ultimately form a globular structure. In these molecules it is assumed that some of the peptide linkages are tautomerised to — C(OH) : N — linkages.

THE CONSTITUTION OF DIFFERENT PROTEINS

Nearly all the proximate constituents of the main protein molecule, so far as we know, are amino-acids. Of these the following have been isolated, namely, glycine, alanine, valine, leucine, isoleucine, proline, hydroxyproline, serine, threonine, phenyl alanine, glutamic acid, β-hydroxyglutamic acid, aspartic acid, tyrosine, tryptophan, cystine, methionine, lysine, histidine and arginine.

---

* Bergmann, Fruton and Fraenkel-Conrat. *J. Biol. Chem.*, 1937, **119**, 35.

† Wrinch. *Proc. R. S.*, 1937 (A), **160**, 63 ; **161**, 505.

The question now arises whether all the varieties of protein owe their peculiarities to the presence of different amino-acids, or whether the greater number of the amino-acids above mentioned are present in all proteins, the differences between the latter being determined by differences in the arrangement and relative amounts of these proximate constituents. A large number of analyses of various proteins have been made by Osborne, Dakin, Chibnall and others, utilising the methods for the isolation of amino-acids devised by Fischer and by Dakin. The constitution of some representative proteins as determined in this way is given in the Table below.

These results show that all the proteins contain a very considerable proportion of the total number of amino-acids which have as yet been isolated from acid digests of proteins. The differences in various proteins cannot therefore be determined by qualitative differences in their constituent molecules, but must depend on the relative amounts of the amino-acids which are present and on their arrangement in the whole molecule. As regards relative amounts of amino-acids we find very striking variations. Thus glutamic acid, which forms 16 per cent. of egg albumin and only 1·7 per cent. of globin (derived from hæmoglobin), amounts to 36·5 per cent. in gliadin, the protein extracted from wheat flour. Striking differences are also noticeable in the relative proportions of the diamino-acids, the so-called hexone bases. Whereas in casein they form about 12 per cent. of the total molecule, in globin they form about 20 per cent. ; and in the protamines, salmin and sturin, about 85 per cent. of the total molecule consists of these bodies. On this account the two last-named proteins have a strongly basic character. From these figures it is evident also that certain of the amino-acids must occur many times over in the protein molecule. Thus in globin, if we assume the presence of one tyrosine molecule, there must be at least thirty-two leucine and ten histidine molecules. On these data the minimal molecular weight of hæmoglobin would come out at about 17,000.

THE MOLECULAR WEIGHT OF PROTEINS.—We may arrive at an approximate idea of the minimum size of the protein molecule in various ways, though all our calculations are apt to be vitiated by the difficulty of obtaining a preparation which is chemically pure, and by the ease with which molecules of the size which we must assume for proteins aggregate together or form adsorption combinations in varying proportions with other substances. Some idea of the molecular complexity represented by these weights may be gained by writing out the possible empirical formulæ of the various proteins, *e.g.* :

Egg albumin	$C_{204}H_{322}N_{52}O_{66}S_2$
Hæmoglobin	$C_{712}H_{1130}O_{245}N_{194}S_2Fe$

On the simplest empirical formula, therefore, most of the proteins have molecular weights of several thousand, *e.g.* hæmoglobin is at least 17,000. The application of physical methods, such as the rate of sedimentation at high-speed centrifugalisation, diffusion, viscosity, etc., shows that under most conditions these molecules are aggregated into larger complexes, which, however, can be broken up by altering the conditions. Most of these composite molecules have a molecular weight, according to Svedberg, which is a multiple of 17,600, as *e.g.* :—

Protein.	Molecular weight by sedimentation Velocity.		M(calc.)
Lactalbumin	17,500	...	17,600
Lactoglobulin	41,800	...	2 × 17,600
Insulin	40,900	...	2 × 17,600
CO-Hæmoglobin . . .	69,000	...	4 × 17,600
Serum globulin . . .	167,000	...	8 × 17,600
Hæmocyanin (*Helix*) . . .	6,630,000	...	384 × 17,600

(*v.* also p. 72).

THE CLASSIFICATION OF PROTEINS

At the present time it is impossible to make any classification of proteins based on their constitution, and we have therefore to use an arbitrary classification, based chiefly on the solubilities of the various proteins. Many proteins formerly considered to be chemical individuals have now been separated into various fractions. We shall here only indicate the characters of the main groups.

(1) **The Protamines.** These occur only in combination. They are obtained from the ripe spermatozoa of certain fishes, where they are in combination with nucleic acid. They are of relatively low molecular weight, *e.g.* 2,000, and are characterised by the very large amount of diamino-acids in their molecule. A small proportion of mono-amino-acids may also be obtained from their disintegration (*v.* Salmin, Table, p. 44). They possess strongly basic characters and form well-marked salts, *e.g.* sulphates, as well as double salts with platinum chloride. They contain no sulphur and do not coagulate on heating.

(2) **Histones.** This class of proteins, like the protamines, only occurs in combination with other substances, such for instance as nuclein and hæmatin. They may be obtained from red blood corpuscles, where they form the globin part of the hæmoglobin molecule, or from the thymus gland. The histones are precipitated from their watery solutions by addition of ammonia, but are soluble in excess of this reagent. In the presence of salts they are coagulated on boiling. The most characteristic feature is the high proportion of diamino-acids contained in their molecule, in consequence of which they are strongly basic.

(3) **Albumins.** These are soluble in water and are precipitated by complete saturation with ammonium sulphate or zinc sulphate.

Egg Albumin forms the greater part of the white of egg. It gives the ordinary protein tests, coagulates on heating at about 75° C., and is precipitated from its solutions if shaken with a drop of dilute acetic acid in excess of ether. It is lævo-rotatory, its specific rotatory power being — 35·5°.

Serum Albumins occur in large quantities in the blood plasma, serum, lymph, and tissue fluids of the body. They coagulate at 75° C., and are distinguished from egg albumin by greater specific rotatory power, – 56°, and by the fact that they are not precipitated by ether and acetic acid.

(4) **Globulins.** These bodies are insoluble in water and require the presence of a certain amount of neutral salt to dissolve them. They are precipitated from their solutions by complete saturation with magnesium sulphate or by half-saturation with ammonium sulphate. Important members of this class are:

Crystallin, obtained from the crystalline lens by passing a stream of carbon dioxide through a saline extract of this body.

Serum Globulins, constituents of blood plasma and blood serum.

Fibrinogen, which occurs in blood plasma and is converted into fibrin when the blood clots.

Myogen, a normal constituent of muscle.

Midway between these two groups may be placed the muscle protein, *myosin* (or *myosinogen*) which, though soluble in water, resembles the globulins in the ease with which it is precipitated by the addition of neutral salts.

Proteins allied to this class form an important constituent of plants, and are found in large quantities in many seeds used as articles of food. Prominent members of the vegetable globulins are the *edestins*, from hemp, cotton, and sunflower seeds, *zein* from maize, *legumin* from beans.

(5) **Gliadins,** contained in cereals, and soluble in dilute alcohol.

(6) **Glutelins,** also obtained from cereals, and soluble in weak alkalies or acids.

(7) **Derivatives of Proteins.** When proteins are heated with acids, or acted on at the body temperature by certain enzymes, *e.g.* pepsin, trypsin, or papain, they undergo hydrolysis. This action, when carried to its end, results in the production of the amino-acids which we have already dealt with.

These hydrolytic changes proceed by a series of stages, so that the intermediate products still present many of the protein reactions. These derived proteins are divided into three groups, *metaproteins*, *proteoses* and *peptones*. The formation of these intermediate products is especially marked with the proteolytic enzymes. Pepsin, together with hydrochloric acid, for example, only breaks down the protein molecule into smaller, but still quite large molecules, the proteoses and peptones. It does not liberate any amino-acids. Trypsin gives rise to proteoses, peptones and also amino-acids. In both cases, the peptide linkages are attacked, since equal numbers of NH_2 and COOH groups become free. The action of these enzymes on proteins, in fact, results in the production of a number of derivatives of progressively diminishing molecular weight and complexity by a hydrolytic process :—

$$\ldots \mathrm{R.CO.NH.R} \ldots \quad + \mathrm{H_2O} \longrightarrow \quad \ldots \mathrm{R.COOH} + \mathrm{NH_2.R} \ldots$$

The protein molecule is distinguished by the variety of the groups which enter into its formation, and this renders possible a great variety of intermediate products. Thus a protein molecule may consist of the amino-acids, A, B, C, D, E, F, G, H, etc., arranged in varying order. When hydrolysis occurs it may result in the immediate splitting off, say, of group A, while the residue breaks up into a series of proteoses whose composition may be represented as ABF, ABC, DFG, BDEF, etc. With further hydrolysis these groups are broken into still smaller ones, and the penultimate stages of the hydrolysis will be polypeptides.

No sharp dividing line can be drawn between the metaproteins, proteoses, peptones, and polypeptides. We have at present no satisfactory means of isolating the different members of these groups. Their classification is, therefore, a conventional one, depending on their solubilities and their precipitability by neutral salts. Both proteoses and peptones give reactions common to all proteins and, like these, are precipitated by such reagents as mercuric chloride, or phosphotungstic acid. They give the biuret reaction. Their solutions can be boiled without coagulation. Many of them may be thrown down from their solutions by alcohol.

(*a*) Metaproteins. These are amongst the early products of hydrolysis of the proteins and are little less complex than the proteins from which they are derived.

Acid Metaprotein is formed by the action of dilute acids on any proteins. If a weak alkali be added so as nearly to neutralise the solution of acid metaprotein, this latter is precipitated.

Alkaline Metaprotein is formed by the action of strong alkalies on any protein, or by adding alkali in excess to a solution of acid metaprotein. It is precipitated on neutralisation of its solution.

(*b*) PROTEOSES, *e.g. albumose* from albumin, *caseose* from casein. All of these are precipitated from their solutions on saturation with ammonium sulphate. In the presence of a neutral salt they give a precipitate on the addition of nitric acid. All, with the exception of heteroalbumose, are soluble in water, and all are soluble in weak salt solutions or dilute acids or alkalies. They are slightly diffusible through animal membranes.

(*c*) PEPTONES, *e.g.* fibrin peptone, gluten peptone. These are all soluble in water, diffuse fairly readily through animal membranes, and give reactions similar to those of the albumoses. From the latter they are distinguished by the fact that they are not precipitated on saturation of their solutions, either in acid or alkaline reaction, with ammonium sulphate. Many of them are soluble in alcohol.

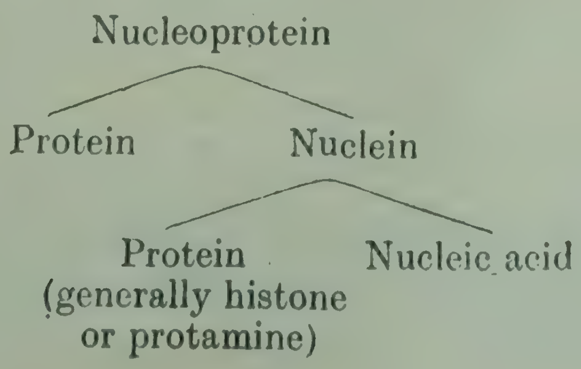
(*d*) THE POLYPEPTIDES resemble peptones, but are more readily diffusible.

(8) **Conjugated Proteins.** Various complex bodies which play an important part in building up cells, and in the vital processes of the body, make up this group of compounds. They resemble one another only in the fact that in each of them a protein molecule is combined with some other body, often spoken of as the *prosthetic* group.

(*a*) THE PHOSPHOPROTEINS. In this class may be included a number of substances of very diverse properties, which, however, resemble one another in containing phosphorus as an integral part of their molecule. The phosphoproteins have markedly acid characters. They are insoluble in water, easily soluble in alkalies, from which the original body is thrown down again on addition of acid. Their solutions in alkali are not coagulated by heating. To this class belong *caseinogen*, the chief protein of milk, and *vitellin*, the main protein in the yolk of egg. The vitellins are generally associated with a large amount of lecithin. The phosphoproteins differ from the nucleoproteins, which also contain phosphorus, in that they are readily decomposed by dilute caustic alkali with the liberation of phosphoric acid, and do not contain purine bases.

(*b*) CHROMOPROTEINS. Of this class, consisting of a colouring matter combined with a protein, the most important is *hæmoglobin*. This substance, which is the red colouring matter of the red corpuscles of the blood, is composed of the protein, globin, united with an iron-containing body, hæmatin $C_{32}H_{32}N_4O_4Fe$. Other very important chromoproteins are the *cytochromes*, which play an important part in the carrying out of tissue oxidations.

(*c*) THE NUCLEOPROTEINS. These are formed by the combination of a phosphorised organic acid, *nucleic acid*, with a basic protein which is usually one of the histones or protamines. If a nucleoprotein be subjected to gastric digestion, a large amount of the protein goes into solution as proteose or peptone, leaving an insoluble remainder. This precipitate still contains a protein group, and is spoken of as *nuclein*. From the latter nucleic acid can be split off by heating with stronger acids or by trypsin. The relation of the two portions of the nucleoprotein may be represented :—



The nucleoproteins are soluble in water, salt solutions and dilute alkalies. They have acid characters and are precipitated by acids. The nucleins, on the other hand, are insoluble in water and salt solutions, but are dissolved by dilute alkalies. Nucleoproteins form the chief constituents of cell nuclei, and the heads of spermatozoa therefore contain a large amount. They also occur in the cytoplasm. Nucleoproteins may be obtained from organs rich in cells, such as the thymus, and from yeast.

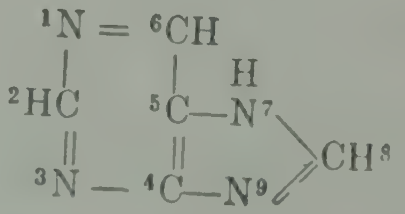
The nucleoproteins are of fundamental importance in all living things. The phenomena of heredity are closely connected with the properties of the nucleoprotein substance chromatin, and the hereditary elements called genes are probably molecules or aggregates of molecules of nucleoproteins. Also the viruses of disease, the simplest living things, are crystallisable nucleoproteins, which, like genes, can reproduce.

Nucleic Acid. By hydrolysis, the nucleic acid may be broken up into its proximate constituents. These differ slightly according to the source of the nucleic acid. Whatever the source, the disintegration products always contain phosphoric acid, purine bases, pyrimidine bases, and a pentose.

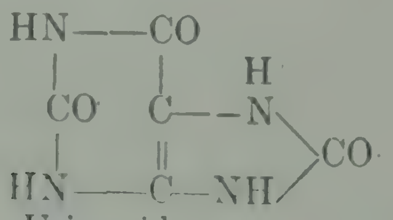
There appear to be two main types of nucleic acid, one present in nuclei, and therefore predominating in thymus nucleic acid, and one in cytoplasm, and especially abundant in yeast nucleic acid. These two differ slightly in their degradation products, yielding different pentoses and pyrimidines.

(1) *Phosphoric Acid.* The proportion of phosphorus in the nucleic acids is about 10 per cent. It represents, so to speak, the combining link for the groups contained in the nucleic acid molecule.

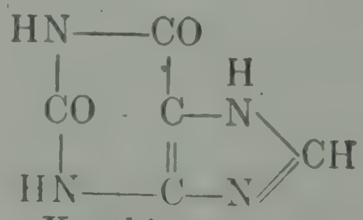
(2) *The Purine Bases.* Among the products of disintegration of nucleic acid we find constantly the bases *adenine*, $C_5H_5N_5$, and *guanine*, $(C_5H_5N_5O)$. These substances, with the products of their oxidation, *xanthine*, $C_5H_4N_4O_2$, *hypoxanthine*, $C_5H_4N_4O$, have long been known to be closely allied to uric acid, $C_5H_4N_4O_3$. According to Fischer they can be all regarded as derivatives of the body *purine* :



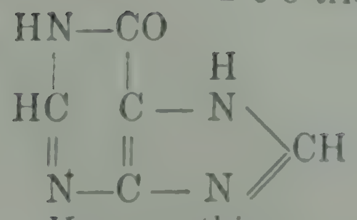
The relation of xanthine, hypoxanthine, guanine, and adenine to uric acid is shown by the following formulæ :



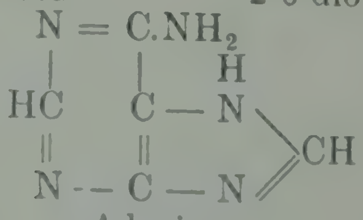
Uric acid
2-6-8-trioxypurine



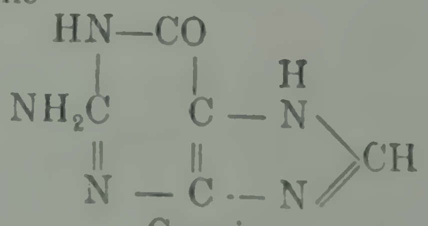
Xanthine
2-6-dioxypurine



Hypoxanthine
6-oxypurine



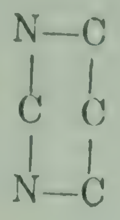
Adenine
6-amino-purine



Guanine
2-amino 6-oxypurine

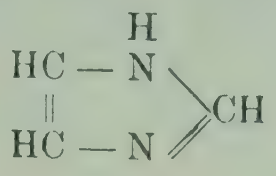
Closely allied to this group of bodies are the active constituents of tea, coffee, and cocoa, namely *caffeine*, which is *trimethyl dioxypurine*, and *theobromine*, which is *dimethyl dioxypurine*.

From the structural formulæ given it will be seen that the purine ring contains two nuclei. The nucleus :



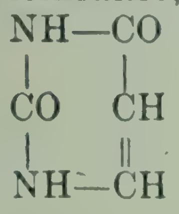
is spoken of as the *pyrimidine nucleus.*

The other is the *iminazol* ring which we have met with already in histidine :

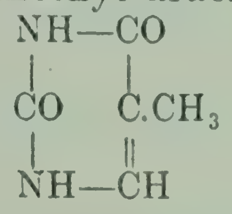


(3) *Pyrimidine Bases.* In addition to the pyrimidine ring contained in the purines, nucleic acids yield a separate series of bases derived from the pyrimidine ring. These are uracil, thymine, and cytosine.

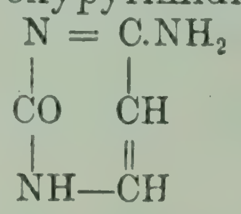
Uracil, 2-6-dioxy-pyrimidine,



Thymine, 5-methyl uracil,



Cytosine, 6-amino-2-oxypyrimidine,



Nucleic acids from nuclei yield cytosine and thymine ; the acids from cytoplasm give cytosine and uracil.

(4) *Pentose.* In the nucleic acids of nuclei this is a desoxypentose ($C_5H_{10}O_4$), viz. *β-d*-2-desoxyribofuranose, but in nucleic acids of cytoplasm and in the mononucleotides of animal tissues, *e.g.* adenylic acid, the carbohydrate group is the ribose, *β-d*-ribofuranose of empirical formula $C_5H_{10}O_5$. In general, the two nucleic acids comprise respectively the following units :

Nuclear.	*Cytoplasmic.*
Phosphoric acid.	Phosphoric acid.
Desoxyribose.	Ribofuranose.
Adenine and guanine.	Adenine and guanine.
Cytosine and thymine.	Cytosine and uracil.

The researches of Levene and of others have thrown light on the manner of combination of these groups in the molecule of nucleic acid. It appears that each purine or pyrimidine group can combine with a pentose to form what is called a "*nucleoside,*" *e.g.* :—

$$\underset{\text{(Adenine)}}{C_5H_4N_5}—\underset{\text{(Ribose)}}{C_5H_9O_4} \text{ is the nucleoside } \textit{adenosine.}$$

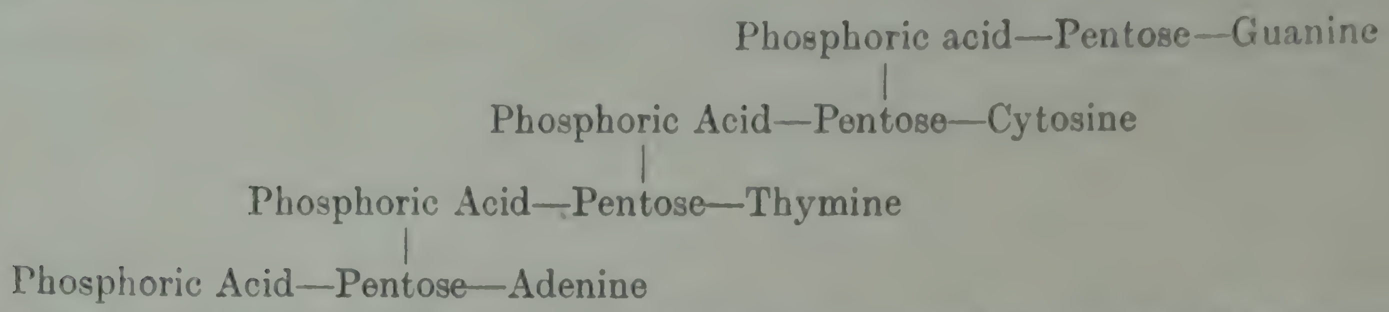
Each nucleoside can be then attached to a molecule of phosphoric acid, this complex being named a "*nucleotide*" and representing a nucleic acid in its simplest form, *e.g.* :—

$$\underset{\text{(Adenine)}}{C_5H_4N_5}—\underset{\text{(Ribose)}}{C_5H_8O_3}—\underset{\text{(Phosphoric acid)}}{PO_3H_2} \text{ is the (mono) nucleotide } \textit{adenylic acid,}$$

or *adenosine monophosphoric acid.*

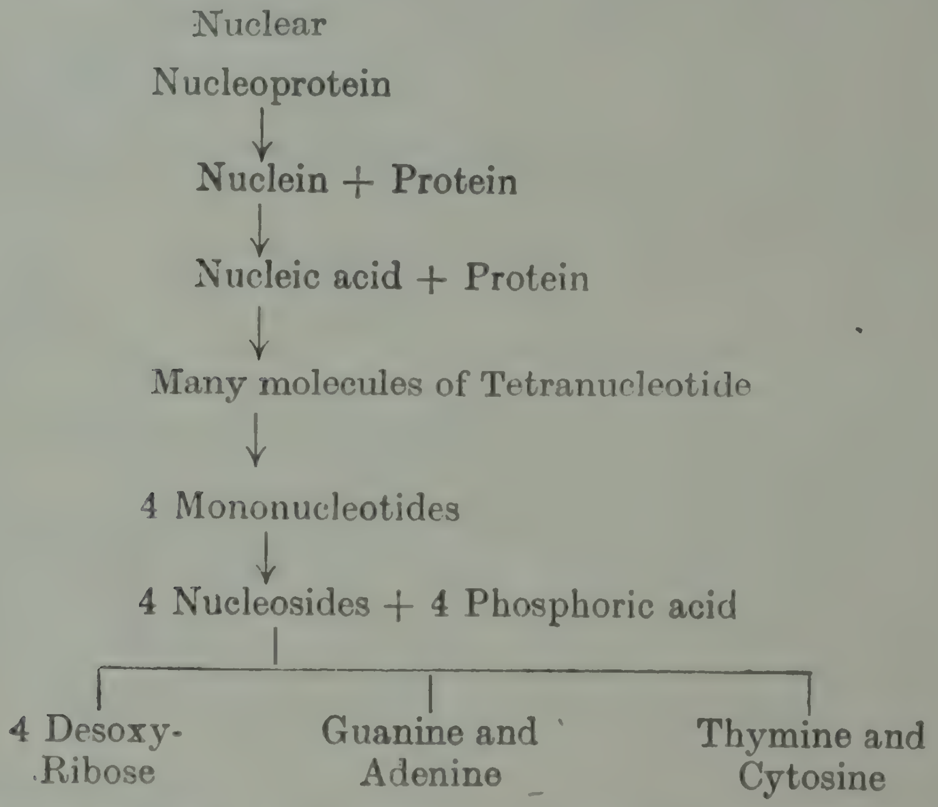
By addition of one and two further molecules of phosphoric acid, we get the *adenosine diphosphoric* and *triphosphoric* acids, which play most important functions as carriers of phosphoric acid radicles in many biochemical processes. Other important nucleotides are *nicotinic amide mononucleotide, flavine mononucleotide* and *adenine-flavine dinucleotide,* all coenzyme components.

In general, nucleic acids are very large molecules, the molecular weight of th smallest probably being about 15,000; these are aggregated into elongate particles of weights ranging from 200,000 to 1,000,000. In structure, th smaller units appear to be chains of relatively small molecules called *tetr nucleotides*, in which four mononucleotides are linked together, possibly throug the phosphoric acid molecule of one and the carbohydrate of the next. Thu thymus nucleic acid would be built up from units, each of them a tetranucleotid which would have the structure



Phosphoric acid—Pentose—Guanine
Phosphoric Acid—Pentose—Cytosine
Phosphoric Acid—Pentose—Thymine
Phosphoric Acid—Pentose—Adenine

The degradation of nucleoprotein may be rendered clearer by the following scheme:



Nuclear
Nucleoprotein
Nuclein + Protein
Nucleic acid + Protein
Many molecules of Tetranucleotide
4 Mononucleotides
4 Nucleosides + 4 Phosphoric acid
4 Desoxy-Ribose
Guanine and Adenine
Thymine and Cytosine

(*d*) THE GLYCOPROTEINS. In the glycoproteins the prosthetic group is represented by a carbohydrate radical, generally containing nitrogen, such as glucosamine or galactosamine. Serum albumin and globulin both contain a carbohydrate consisting of glucosamine and mannose.* The glycoproteins proper are split into their two constituents, protein and carbohydrate, on boiling with dilute mineral acids. The carbohydrate prosthetic group is a tetrasaccharide, derived *e.g.* from two acetylhexosamine molecules joined together by two glucuronic acid molecules. The hexosamine called glucosamine gives a tetrasaccharide called *mucoitin*, while galactosamine yields the tetrasaccharide called *chondroitin*—they occur respectively as mucoitin and chondroitin sulphuric acids. Heparin is a derivative of some such compound as chondroitin sulphuric acid.

The glycoproteins are divided into the two main groups, viz.: mucins and mucoids.

The *mucins* are present in the slimy secretion of the mucous membranes and which is secreted either by goblet cells or by mucous glands. They may be precipitated from their solutions by the addition of acids, and redissolve on addition of alkalies. They are not coagulable by heat. They give the various typical protein tests, such as the xanthoproteic, Millon's, the biuret reaction and so on. Prolonged boiling with acids splits the molecule, with the production of acid metaprotein and mucoitin sulphuric acid.

---

* RIMINGTON. *Biochem. J.*, 1931, **25**, 1062.

The *mucoids* include a number of substances which may be extracted from various tissues by the action of weak alkalies, *e.g.* from tendons, bone and cartilage. Another example of this class of mucoids is *ovomucoid*, which is a constituent of egg-white. A similar body has been prepared from blood serum. The best studied example of this group is the *chondromucoid* which, with collagen, forms the ground substance of cartilage. Chondromucoid on hydrolysis yields a protein, and both mucoitin and chondroitin sulphuric acids.

(9) **The Albuminoids or Sclero-proteins.** Under this heading are grouped a number of diverse substances which play an important part in building up the framework of the body. They play the part in the animal economy which in the vegetable kingdom is filled by the celluloses, lignin, the pentosans, etc. Their value as skeletal tissue seems to be determined by their insoluble character, but on this account it is practically impossible to purify them ; we can simply take the residue of a tissue which is left after extraction of the soluble constituents. When broken down by the action of strong acids, they yield disintegration products which resemble those derived from other proteins.

Collagen forms the main constituent of white fibrous tissue and the ground substance of bone and cartilage. Under the action of acids or when subjected to prolonged boiling with water it is converted into *gelatin*, which forms a colloidal solution setting to a jelly when cold. When subjected to acid hydrolysis it gives a series of amino-acids from which tyrosine and tryptophane are wanting. On the other hand, there is a preponderance of glycine and phenyl alanine. Gelatin is hydrolysed by gastric juice or by pancreatic juice, whereas collagen is unaffected by the latter.

The *Keratins* are produced by the modification of epithelial cells, and form the horny layer of the skin as well as the main substance of hairs, wool, nails, hoofs, horns and feathers. They are distinguished by their insolubility in water, dilute acids or alkalies, and if eaten pass through the alimentary canal unchanged. Although differing in their elementary composition, they are all distinguished by the very large amount of sulphur present in their molecule. The greater part of this sulphur is in the form of cystine, of which keratin contains as much as 10 per cent.

Neurokeratin, which forms the basis of the neuroglia of the central nervous system, is grouped with the keratins. It is extracted from nervous tissues by boiling these with alcohol and ether, and then submitting the tissue to tryptic digestion which leaves the neurokeratin unaffected.

Elastin forms the elastic fibres of the connective tissues. Elastin is insoluble in water, alcohol or ether, or in dilute acids and alkalies. It is slowly dissolved on *prolonged* treatment with gastric juice, but is practically unaffected in the alimentary canal.

Other members of this group are *fibroin*, which forms the main substance of silk; *spongin*, the horny framework of sponges ; *conchiolin*, the ground substance of shells : and perhaps the amyloid substance which we have already mentioned in connection with the mucoids. All these sclero-proteins present considerable differences in their qualitative and quantitative content of amino-acids.

Specificity of Proteins. Although certain proteins may appear to be identical so far as ordinary chemical and physical properties, and even so far as chemical analysis is concerned, they are not necessarily identical in their biological properties. For example, casein from cow's milk and casein from goat's milk, or egg albumin from hen or duck, have certain specific properties by which they are distinguished from one another. This can be shown by *anaphylactic reactions* (*v.* Chapter XXXVII.). Thus, if a guinea-pig is sensitised by injections of hen-egg albumin, administration of egg albumin from another species is not followed by any effects, whereas an extremely small injection of the hen albumin promptly causes death from anaphylactic shock. There is thus a species specificity with proteins which is not seen with other biochemical constituents.

Dudley and Woodman * showed that this is in all probability due to the fact that in the different species there are slight differences in the *arrangement* of the constituent amino-

---

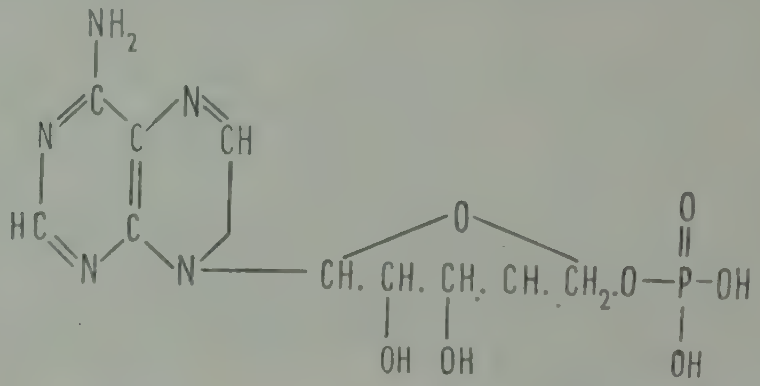
* Dudley and Woodman. *Bioch. Journ.*, 1915, 9, 97.

OOD TECHNOLOGICAL RESEA

acids in the protein molecule. Thus if in one species we have the amino-acids A, B, C, D, . . . arranged in that order, we should have a stereochemically different molecule if t arrangement were B, D, A, C, E . . . . These species differences are of great importance i connection with the subject of immunity; they also explain why, in the construction protein in the body, the protein taken as food must first be thoroughly broken down int its constituent amino-acids.

SOME IMPORTANT PHOSPHORIC ACID DERIVATIVES

It will be useful at this stage to mention some further compounds containin phosphoric acid in the molecule, which play a most fundamental *rôle* in almos all the chemical reactions concerned with energy liberation. The outstandin substance in this respect is *adenosine triphosphate*. The adenosine phosphate are all derived from the nucleoside *adenosine* (p. 49), a compound of th amino-purine adenine with the pentose *d*-ribose; it can combine with one two or three molecules of phosphoric acid to give adenosine mono-, di- o triphosphate, as shown below :—



(*Adenine*) (d-*ribose*) (*Phosphoric acid*)

Adenosine monophosphate

or, for brevity $\textcircled{Ad}$—Ph, where $\textcircled{Ad}$ stands for adenosine and Ph for $-PO_3H_2$

Similarly the diphosphate and triphosphate may be written briefly :—

$\textcircled{Ad}$— Ph $\sim$ Ph *Adenosine diphosphate* (A.D.P.)

$\textcircled{Ad}$— Ph $\sim$ Ph $\sim$ Ph *Adenosine triphosphate* (A.T.P.)

Now the importance of these compounds lies in the fact that the second and third phosphoric groups are bound to the monophosphate phosphoric group by what are called *energy-rich* bonds, indicated above by the wavy bond $\sim$. This means that when these groups are split off a large amount o energy is set free. If the bond is broken by hydrolysis the energy appears as heat and is equal to 12 Cal. per g. molecule :—

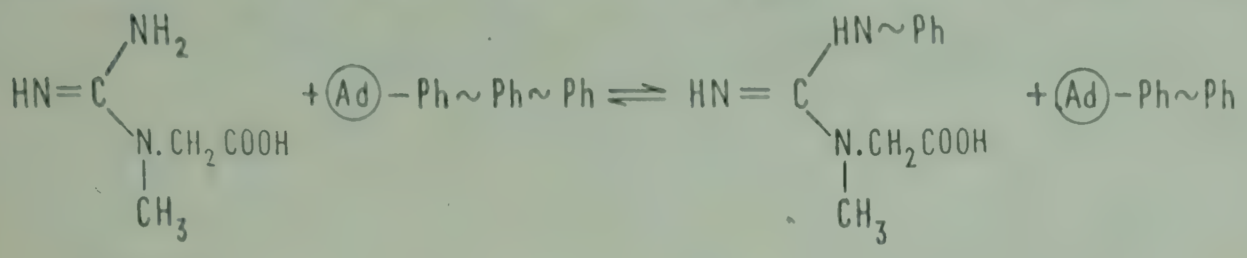
$$\textcircled{Ad}-Ph \sim Ph \sim Ph + H_2O \longrightarrow \textcircled{Ad}-Ph \sim Ph + H_3PO_4 + 12\ \text{Cal.}$$

But what is even more important, 10 Cal. of the energy set free by the liberation of the phosphate group is free energy, *i.e.* it can be directly utilised to do work instead of being converted into heat, and it is probable that all the energy manifestations of living things are derived from the resolution of such energy-rich bonds. One of the uses to which living cells can put such energy is to synthesise new compounds of high energy potential, in which, so to speak, energy is stored up ready for use. It is especially in these syntheses that the energy-rich phosphate groups are concerned, because in such reactions the phosphate group can be added on to other compounds, together with the energy-rich bond, without loss of energy.

Another important phosphoric acid derivative is *creatine phosphate*.* It also contains an energy-rich phosphate group, and its formation is an example of the transference of this group, without energy loss, from A.T.P.

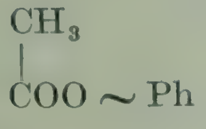
---

* Eggleton. *Physiol. Rev.* 1929, **9**, 432.



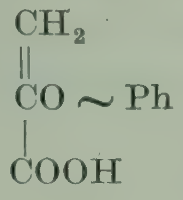
(*Creatine*) (*Creatine phosphate*)

Other compounds with energy-rich phosphate bonds are phosphoacetic acid, phospho-*enol*-pyruvic acid, and 1 : 3 diphosphoglyceric acid.



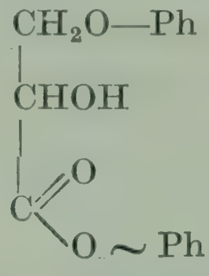
$$\begin{array}{l} CH_3 \\ | \\ COO \sim Ph \end{array}$$

Phosphoacetic acid



$$\begin{array}{l} CH_2 \\ \| \\ CO \sim Ph \\ | \\ COOH \end{array}$$

Phospho-enol-*pyruvic acid*



1 : 3 *Diphosphoglyceric acid*

We shall see later that these various compounds play an important *rôle* in the development of the energy of muscular contraction, and in processes of intermediary metabolism.

C. BIOPHYSICAL PRINCIPLES *

CHAPTER V

THE ENERGY OF MOLECULES IN SOLUTION

WATER forms from 70 to 95 per cent. of the mass of protoplasm. No substance introduced into the protoplasm has any chemical influence on it unless it be soluble, and the first stage in the preparation of foodstuffs for assimilation always consists in a process of solution. It follows that all the energy with which we have to deal is the energy of *molecules in, or in equilibrium with, watery solution.*

DIFFUSION. When a substance (solute) is dissolved in a liquid (solvent), we may regard the molecules of both solute and solvent as being in continual movement within the liquid, very much as the molecules of a gas are in continual motion. In consequence of this state of movement solutes travel by diffusion from places where they are more concentrated to parts where they are more dilute, until finally a uniform concentration obtains throughout the solution. Thus, if a vessel be half filled with a 10 per cent. solution of cane sugar, and be then filled up carefully with water, so as to form a layer on the heavier sugar solution, the sugar gradually diffuses up into the water, and after some weeks there will be the same concentration of sugar throughout all parts of the fluid. Carried out in this way, the process of equalisation is a slow one, but when aided by the production of currents, or when only thin films of liquids are concerned, spread by diffusion may be effected in quite short periods of time.

We also find differences between the rates of diffusion of dissolved substances —determined by the weight and size of the individual molecules, although the relation between molecular weight, or size, and rate of diffusion is not so simple as in gases.

The diffusibility of a substance is given by its *diffusion coefficient.* If we take a cylindrical mass of solution which is one centimetre long and has a sectional area of one square centimetre (Fig. 14), and maintain a constant difference of concentration between A and B = 1, the diffusion coefficient is the amount of substance which diffuses in a unit of time from A to B. Thus the statement that the diffusion coefficient of urea is 0·810 at 7·5° C. denotes that, if A be continually filled with a 1 per cent. solution of urea, while in B a constant current of distilled water is kept up so as to maintain the concentration at zero, in the course of a day, at 7·5° C., 0·810 gramme of urea will pass from A to B through the cylinder of one centimetre in length and one square centimetre in cross section. The determination of these diffusion coefficients is rendered easier by the fact, first ascertained by Graham, that diffusion of salts occurs as rapidly through a solid jelly of gelatine or agar-agar as through water. It is therefore possible to make the cylinder in the diagram solid by the admixture of one of these two substances, and to maintain a constant concentration on the two sides of it by the circulation of fluid without affecting the rate of diffusion through the cylinder by setting up accidental currents.

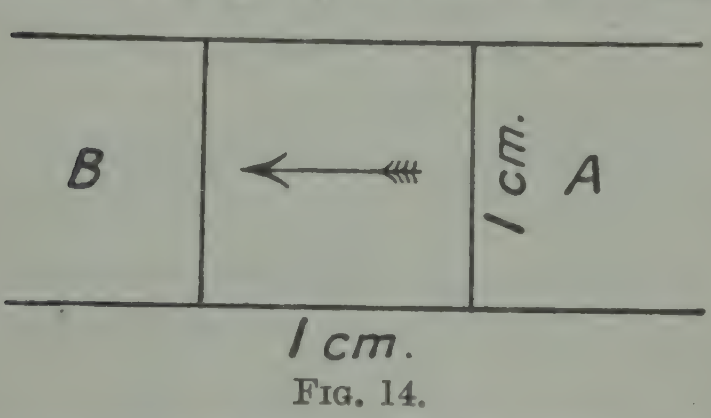

FIG. 14.

Filtration, Ultra-filtration and Dialysis. Filter paper permits the passage both of water and of all dissolved substances. Different kinds of filter paper allow passage with varying degrees of rapidity, depending on the fineness of the holes through which the fluid can pass. The same difference may be observed in porous structures, such as the Berkefeld filter, which allow all dissolved substances to pass but keep back most bacteria. On the other hand the very smallest micro-organisms, the so-called filter-passers, will traverse the pores of a Berkefeld filter. Most gels, such as gelatin and collodion are of porous structure, and collodion membranes may be obtained of varying degrees of permeability according to their mode of preparation * and the concentration of the collodion in the membrane. Such membranes are used for the process known as *ultra filtration*. The membranes of loosest texture will allow proteins such as albumin to pass, in addition to crystalloids. On the other hand the denser collodion membranes, or cellophane, will keep back all colloid constituents and allow only water and crystalloids to pass. If, for instance, serum be placed on one side of such a membrane, under pressure a filtrate will be obtained containing the water, salts, urea and other crystalloid constituents of the serum (Fig. 15).

---

* As with the chapters on Structural and Biochemical Principles, the present chapter can hope to be no more than an outline indicative of the main aspects of the important branch of biology called Biophysics, for further details of which special treatises must be consulted.

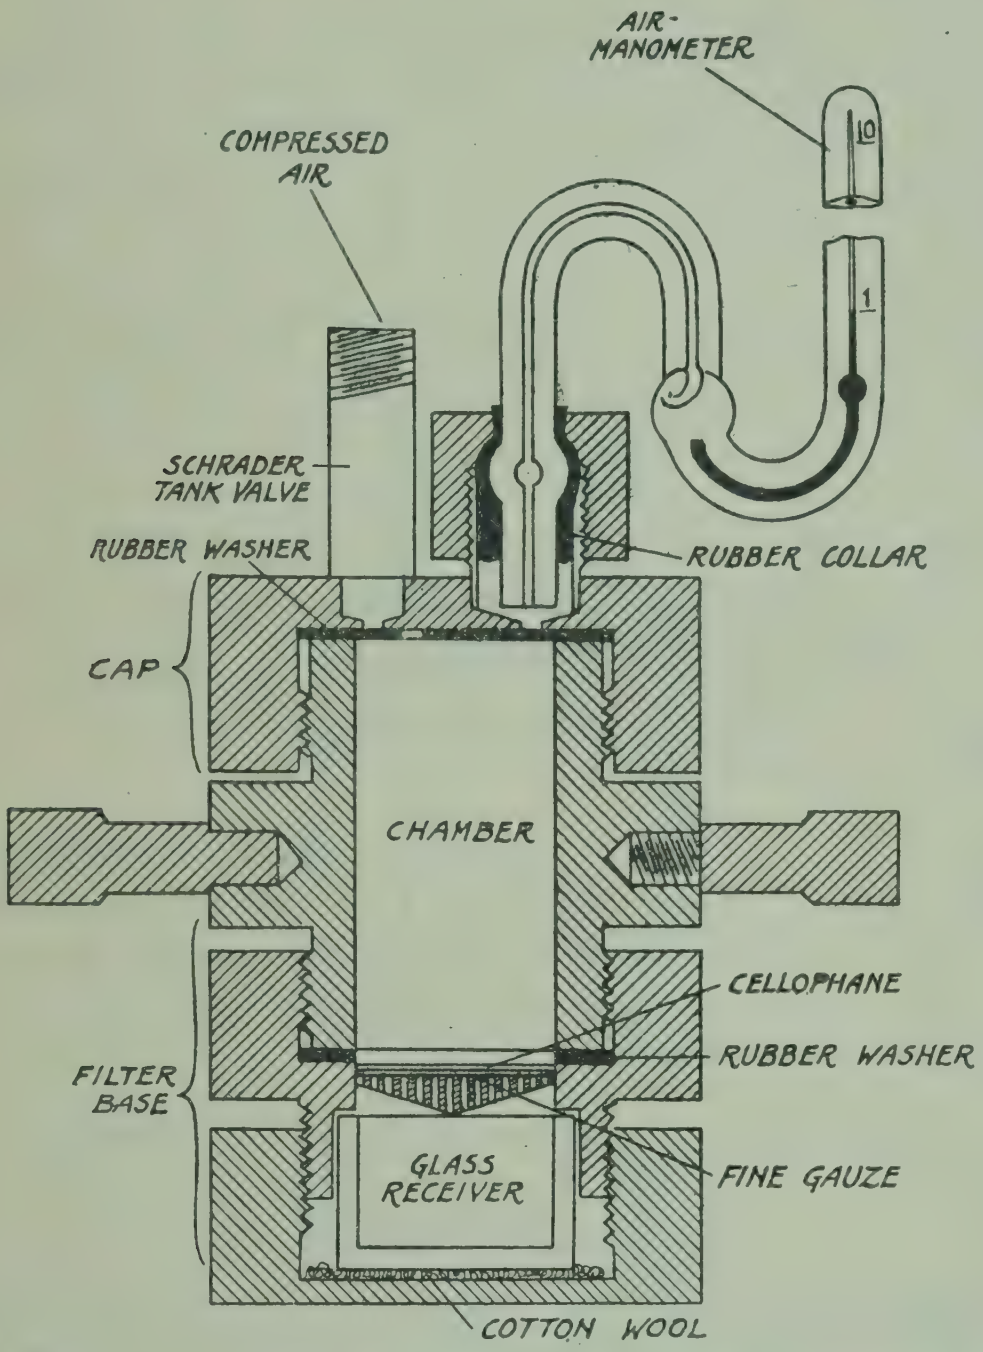

FIG. 15. Apparatus for ultra-filtration. The filtering membrane is cellophane. The upper chamber contains the colloid solution, from which a colloid-free filtrate is forced through into the lower chamber by air pressure. (AITKEN and KAY, *J. Physiol.*, 1927, **62**, Proc. xxix.)

Similar membranes are also made use of when it is desired to free a colloidal solution from salts, in the process known as *dialysis*. If a fluid containing both colloids and crystalloids in solution, *e.g.* blood serum, be enclosed in a tube of vegetable parchment or collodion which is hung up in a large bulk of distilled water (Fig. 16), all the salts diffuse out, and if the water be frequently changed, we obtain finally a fluid within the "dialyser" free from salts and other crystalloid substances, but containing the whole of the colloids originally present. In the process of dialysis, however, not only does solute pass out into the water, but water also passes inwards into the solution, so that this tends to become diluted. These phenomena are easily explained if we remember that molecules of solvent and solute are in constant movement, and if we regard the solution as being weaker in solvent than the pure solvent is. Thus, to consider a strong cane sugar solution and water or a weak cane sugar solution, the former consists of a high concentration of sugar molecules and a lowered concentration of water molecules, while the latter is a high concentration of water molecules and a low (or non-existent) concentration of sugar molecules. Consider that we have a vessel with two such "solutions," A strong and B weak (or B = water), at the same level, and separated by a membrane *pm*, permeable to *both* sorts of molecule, as in Fig. 17 (I). Then solvent and solute can both

---

* PIERCE. *J. Biol. Chem.*, 1927, **75**, 795; DESAI, *Bioch. J.*, 1930, **24**, 1897.

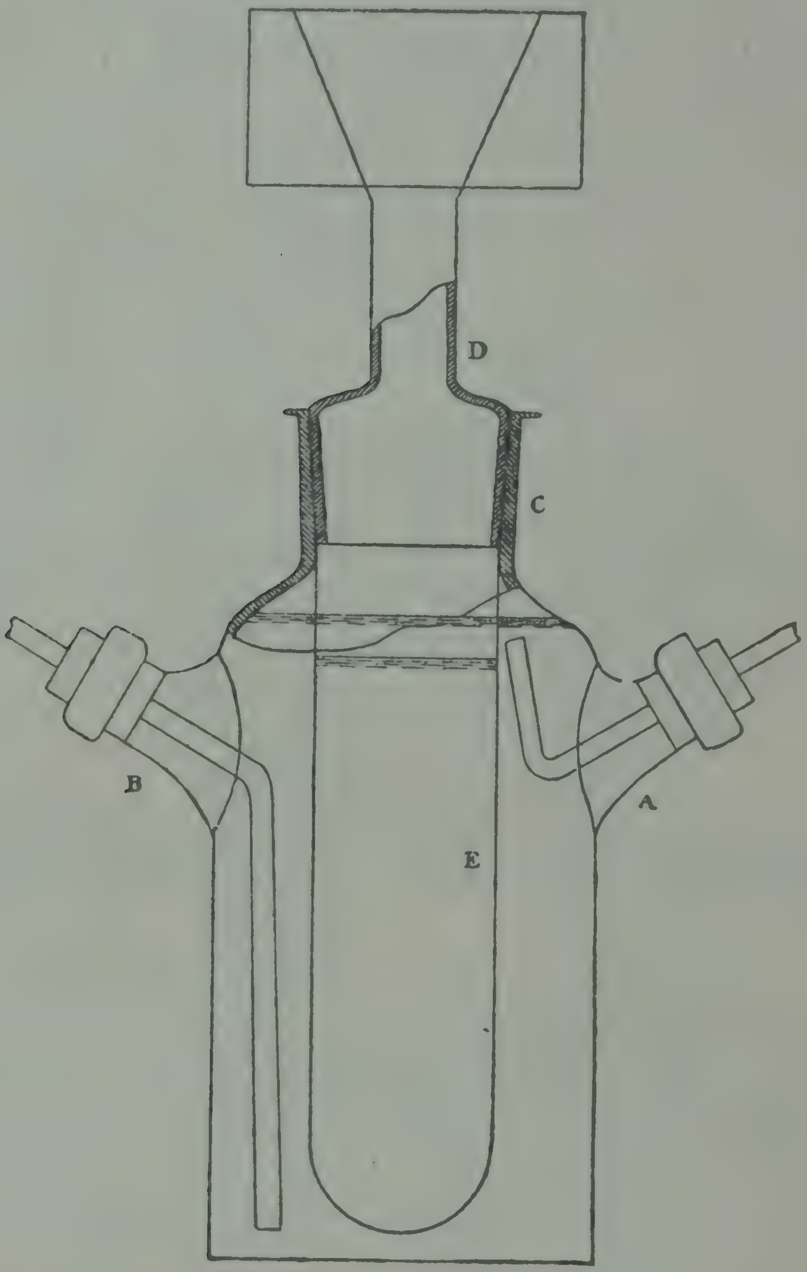

Fig. 16. Dialysing Apparatus. The collodion tube E is fastened to the glass stopper D which fits airtight into the neck of the bottle. Sterile water is introduced into the bottle from a reservoir through B, and the colloid for dialysis poured into E. A partial vacuum is then made in the bottle by exhaustion at A; this opposes the osmotic pressure of the solution in E and so prevents its dilution, or if great enough may even concentrate it by ultra-filtration. (Jessne Hansen.)

move in either direction, but because solute is more concentrated in A and solvent more concentrated in B, there will be a greater passage of solute into B, and of solvent into A, than in the reverse direction. Ultimately, when the two solutions have become uniform in composition, A by losing solute and gaining water, B by gaining solute and losing water, there would at first be a raised level of solution in A as compared with B, Fig. 17 (II). But this difference of hydrostatic pressure, since the membrane is freely permeable to both solvent and solute, causes fluid of the uniform composition to flow from A to B, until it reaches the same level, and true equilibrium is now reached (Fig. 17 (III)).

If a certain pressure is put on the contents of the dialyser, or (as in Fig. 16) suction on the outside, fluid also passes out by ultra-filtration, but there is a certain limiting

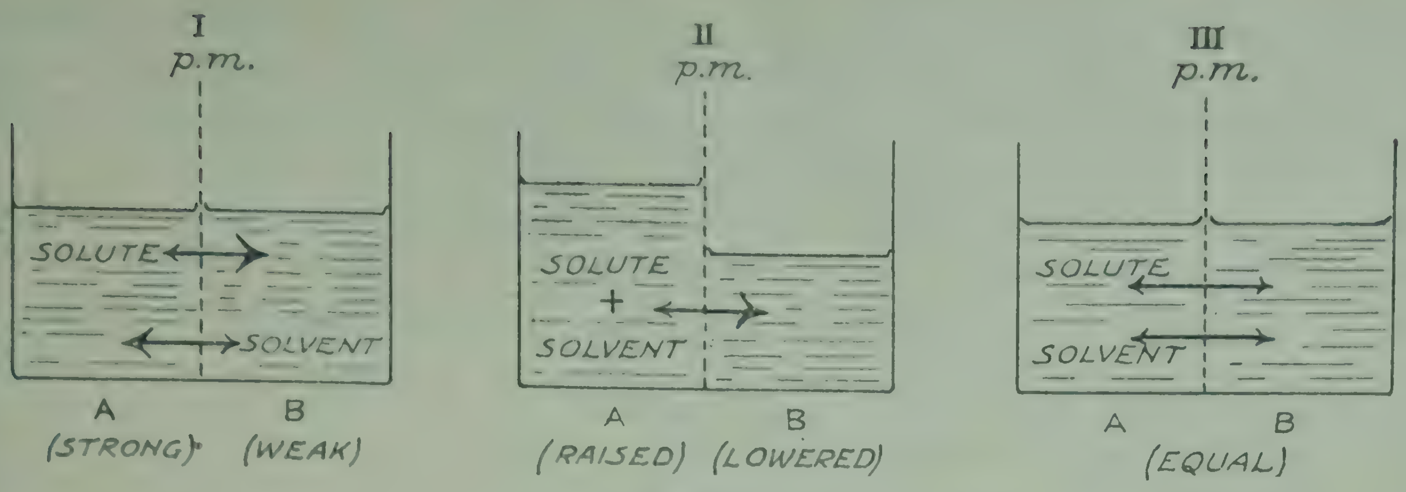

FIG. 17.

pressure below which no filtration will take place. This limiting pressure is equivalent to the osmotic pressure of the colloids in solution, and varies according to the state of aggregation of the colloid, *i.e.* to the number of molecules, simple or compound, of the colloid which is present. In blood serum it is equal to about 30 mm. Hg. If the difference of pressure on the two sides of the membrane is less than this amount, water and salts will pass from the outside to the inside of the membrane and the serum will be diluted.

Semi-permeable Membranes. Membranes may be of different degrees of permeability, according to the sizes of their structural pores, so that some solutes may be let through, but not others of larger molecular size. A special case arises when only the solvent can pass through, while all solutes are held back. This is called a *semi-permeable membrane.* If we consider the case of a solution separated from its solvent by such a membrane, it is clear that if we start with pure solvent on one side, equilibrium can never be established in the sense that the solutions will become of the same composition on both sides of the membrane, because ultimately all the solvent could be absorbed into the solution, since no solute would pass out.

OSMOTIC PRESSURE

This attraction of solvent to a stronger from a weaker solution is known as *osmotic pressure*, or, more correctly, as *osmotic water attraction.* Consider the case of a strong and a weak solution (or pure solvent) separated by a semi-permeable membrane, *s.p.m.* in the vessel A, B (Fig. 18), each limb of which is provided with a watertight piston, bearing a scale-pan *a*, *b*. Left to itself, solvent will pass from B to A, owing to the osmotic pressure, or osmotic water attraction, of the solution in A. If a weight W, be placed on the pan *b*, the rate at which water passes into A will be accelerated, because solvent will be driven through the *s.p.m* by the pressure put upon it. If, instead, the weight be placed on the pan *a*, as in the figure, the rate at which solvent enters A will be reduced, and if the weight placed on *a* be heavy enough, solvent can be driven out of A into B, against the osmotic water attraction of the solution in A. If the weight on *a* be just sufficient to prevent water either entering A or leaving it, a state of equilibrium is reached, the weight just counteracting the osmotic pressure of the solution, and so giving a measure of its magnitude.

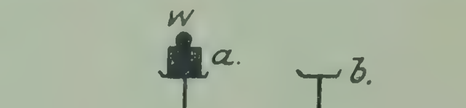

FIG. 18.

Osmotic pressures can only be set up permanently by solutes to which the membrane is impermeable, while permeable to the solvent.

Direct experiment has shown that the osmotic pressure exerted by a solute in a given volume of solvent is the same as the pressure the same weight of solute would exert when in a state of gas occupying the same volume as the solvent, *i.e.* one gramme molecule of solute in 22·4 l. of solvent would have an osmotic pressure of one atmosphere (or 760 mm. Hg). We see that the osmotic pressure of a solution, the measure of its attraction for water, represents a certain amount of potential energy, which can be utilised in an osmotic machine, such as that represented in the diagram, for the performance of work.

The amount of work done in this way can be calculated in exactly the same way as when we are dealing with a gas. To compress a gramme molecule of any perfect gas from volume V_1 to Volume V_2 requires the expenditure of work represented by $W = RT \log e \frac{V_1}{V_2}$. If we take the pressures, and compress from pressure p_1 to pressure p_2, the expression will be $W = RT \log e \frac{p_2}{p_1}$. To convert from natural to ordinary logarithms, we must multiply this expression by 2·303. The numerical value of R depends on the units required, being 1·991 for gramme calories and 0·848 for kilogramme metres. T at 37° C. is 310°. The equation then becomes :

$$\left.\begin{array}{r} W = 1421 \text{ gramme calories} \\ \text{or } 605{\cdot}5 \text{ kilogramme metres} \end{array}\right\} \times \log\frac{p_2}{p_1}.$$

To compress a fluid containing one gramme molecule of solute from osmotic pressure π_1 until it is concentrated to an osmotic pressure π_2, would require $605{\cdot}5 \times \log \frac{\pi_2}{\pi_1}$ kilogramme metres.

It must be remembered that this expression gives the work done in concentrating a solution, whatever method of concentration be applied, (*e.g.* evaporation) at a constant temperature.

THE MEASUREMENT OF OSMOTIC PRESSURE. By a method differing but little from the one just sketched out, it is possible directly to measure the osmotic pressure of aqueous solutions. A semi-permeable membrane is provided when copper ferrocyanide is deposited within the interstices of a clay cell. The cell is then filled with the required solution, connected with a manometer and immersed in distilled water, which passes into the cell until the pressure within the latter is equal to the osmotic pressure of the dissolved substances. By this means Pfeffer obtained the results given in the table below with a 1 per cent. solution of cane sugar at different temperatures.

By Avogadro's hypothesis, equal volumes of gases at the same pressure contain equal numbers of molecules. The figures show that the same laws apply to the osmotic pressure of substances in solution as to the pressure of gases in their free state. It is therefore possible to reckon the osmotic pressure which would be exerted by 1 per cent. sugar in solution at a given temperature.

Temp. °C.	Pressure in atmospheres.	
	Observed.	Calculated.
	Atm.	Atm.
6·8	0·664	0·665
13·7	0·691	0·681
22·0	0·721	0·701
32·0	0·716	0·725
36·0	0·746	0·735

This calculation is carried out as follows : A gramme molecule of any gas at 0° C. and 760 mm. Hg has a volume of 22·4 litres, therefore 342 grammes of cane sugar (one mole), if it could be converted into a gas at 0° C. and 760 mm. Hg, would have a volume of 22·4 litres. In Pfeffer's experiment one gramme of sugar was dissolved in 100 grammes of water making a total volume at 0° C. of 100·6 c.c. The osmotic pressure of the sugar molecules in this solution will therefore amount to $\frac{22400}{342 \times 100{\cdot}6} = 0{\cdot}651$ atmosphere. At a temperature of 6·8° the pressure would be 0·665 atmosphere, as against the observed 0·664 atmosphere.

Pfeffer's method is difficult to carry out and is not applicable to all dissolved substances. Other indirect methods have therefore been applied to the comparison of the osmotic pressures of different solutions.

Determination by Plasmolysis. Solutions which have the same osmotic pressure are spoken of as isosmotic. The method of plasmolysis, which we owe to the botanist De Vries, consists essentially in the comparison of the osmotic pressure of solutions with that of the cell sap of certain plant cells, and depends on the principles already explained viz.: that the superficial layers of cytoplasm behave to many solutes as semi-permeable membranes. If we determine the concentration of a solution at which the *plasmolysis* just occurs, and another smaller concentration at which plasmolysis is absent, we know that the concentration of the cell sap lies between those of the two salt solutions. Thus, if plasmolysis occurs in a solution containing 0·6 per cent. sodium chloride and is absent in a solution containing 0·59 per cent. of the same salt, the concentration of the cell sap must be about equivalent to a 0·595 per cent. NaCl solution. Solutions of different salts, in which plasmolysis just occurs, must also be isotonic with one another. Thus a 1·01 per cent. solution of KNO_3 is found to be isotonic with a 0·58 per cent. NaCl solution.

Determination by Hamburger's Blood Corpuscle Method. The external layer of red blood corpuscles is also impermeable to a number of dissolved substances. If red corpuscles be placed in a solution of such a substance of smaller osmotic pressure than their contents, they will swell up and, since they have no supporting cell wall, the increase in size may go on until the corpuscles burst, and their contained red colouring matter, hæmoglobin, passes into solution in the surrounding fluid. If the corpuscles be then allowed to settle or be centrifuged, the fact that hæmolysis has occurred is shown by the red colour of the clear supernatant fluid. In order to determine the osmotic pressure of a solution, say of sugar or of sodium chloride, these are added in various dilutions to blood corpuscles until we get solutions in which hæmolysis just occurs. These are called *isotonic* solutions. As an example of this method may be adduced the following results :

	Lowest concentration in the solution in which the blood corpuscles do not hæmolyse	Highest concentration of the solution in which the blood corpuscles begin to hæmolyse	Mean concentration
	Per Cent.	Per Cent.	Per Cent.
Potassium nitrate . .	1·04	0·96	1·00
Sodium chloride . .	0·60	0·56	0·585
Cane sugar . . .	6·29	5·63	5·96
Potassium iodide . .	1·71	1·57	1·64
Sodium iodide . . .	1·54	1·47	1·505
Potassium bromide . .	1·22	1·13	1·17

A more accurate approximation can be got by finding the concentration of the given substance at which the red corpuscles remain unaltered in dimensions or in volume.

Isotonic is not necessarily identical with isosmotic. Tonicity has reference to the action of the solution with regard to some cell membrane, and therefore implies the impermeability of the membrane to the substance or substances in solution. Thus equimolecular solutions of urea and of glucose would be isosmotic, yet, tested by the blood corpuscle method, the solution of urea would be found to be isotonic with distilled water, since the outer layer of a blood corpuscle is freely permeable to urea, but not to sugar. Urea is therefore unable to exert any osmotic pressure in relation to blood corpuscles.

Indirect Methods of Measuring Osmotic Pressure. Equimolecular solutions (of non-electrolytes) have the same osmotic pressures. Since the osmotic pressure of such a solution is dependent on the number of molecules of solute in unit volume, any method which will tell us this will also enable us to determine the osmotic pressure. Other properties of solutions which are functions of the number of molecules present, are vapour tension, boiling point, freezing point. The presence of a substance in solution in water diminishes its vapour tension at any given temperature, raises its boiling point, and depresses its freezing point; and the extent of the deviation is proportional to the number of dissolved molecules present. The determination of the rise of boiling point is of very little value in physiology.

The classical method is the measurement of the *depression of freezing point* (generally represented by $\triangle$).

The determination is carried out with a thermometer reading to $\frac{1}{100}$° C. (Fig. 19). The freezing point of a decimolar solution of a non-electrolyte is $-0{\cdot}186°$ C., and that of a molar solution (*i.e.* containing one gramme molecule per litre, in the case of glucose 180 grammes), would have a $\triangle$ of 1·86° C. Since this has, as already explained, an osmotic pressure of 22·4 atmospheres, it is evident that the depression of freezing point can be converted directly into osmotic pressure by multiplying the depression by $\frac{22{\cdot}4}{1{\cdot}86} = 12{\cdot}04$. Thus a 1 per cent. solution of sodium chloride with $\triangle = 0{\cdot}61$ will have an osmotic pressure of $0{\cdot}61 \times 12{\cdot}04 = 7{\cdot}34$ atmospheres, while a 1 per cent. cane sugar solution with a $\triangle = {\cdot}0546$

will have an osmotic pressure of 0·675 atmosphere. This method has the advantage that the fluids are in most cases not altered by freezing. For colloid solutions, since the osmotic pressures are small, the values of $\triangle$ are very small.

A simple and accurate method was introduced by A. V. Hill *; it depends on the determination of the *depression of vapour pressure* by the dissolved substances, by observation of the differences in temperature produced by evaporation. Since it involves the use of thermopiles it is extremely delicate. The method makes use of the fact that if two aqueous solutions of different osmotic (*i.e.* vapour) pressures are placed in a moist atmosphere, water will be evaporated faster (or condensed more slowly) at the surface of the solution having the lower than from the one with the higher osmotic pressure, and hence the solution with the lower osmotic pressure will become cooler than the other. If the two solutions are in contact with the two faces of a thermopile connected with a galvanometer, the difference in temperature produces a deflection proportional to the differences in osmotic pressure. If the osmotic pressure of one of the two solutions is known, that of the other can be deduced. In practice a piece of filter paper is wetted with each of the two solutions, *e.g.* blood on one and 0·92 per cent. NaCl on the other, and these are applied one to each face of the thermopile. This is then placed in a moist chamber kept damp by the known solution and at constant temperature, and connected with the galvanometer. Readings are taken after half an hour. Example: Blood and 0·92 per cent. NaCl. Galvanometer reading = 19·8 mm. Calibration showed that 1 mm. deflection = ·001120 grms. NaCl per cent. Hence difference of V.P. on two sides is = 19·8 × ·001120 = ·0222 grms. per cent., *i.e.* the V.P. and O.P. of blood is equal to that of 0·92 + ·0222 = 0·9422 grms. NaCl per cent.

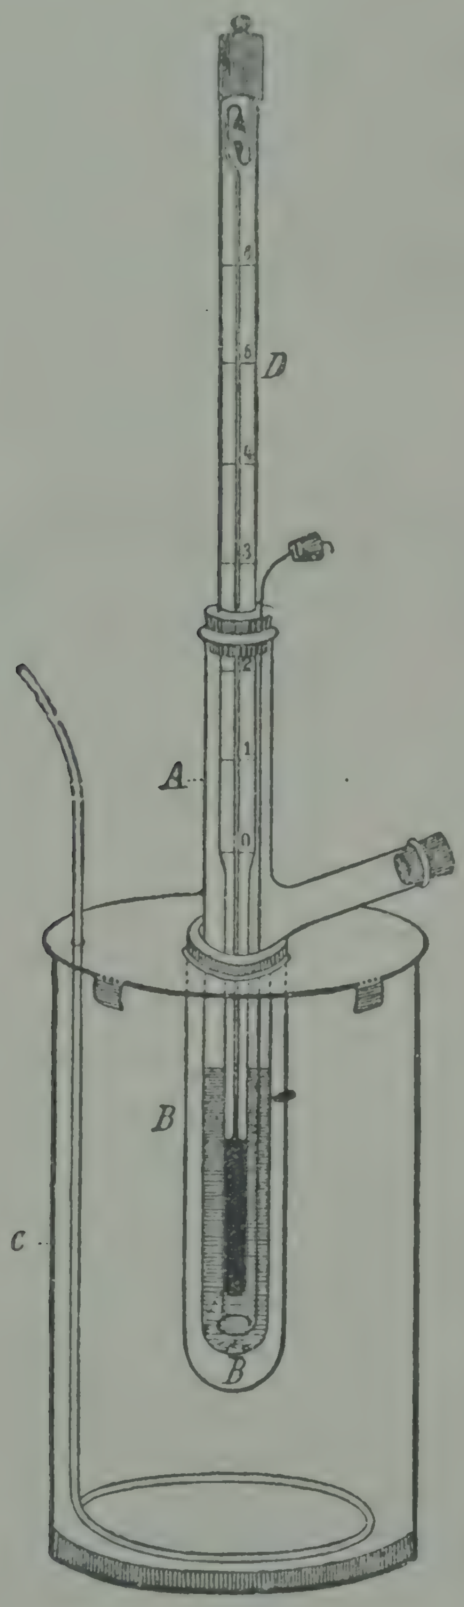

FIG. 19. Beckmann's Apparatus for Determination of Freezing Point.

---

* HILL. *Proc. Roy. Soc. A.*, **1930, 127, 9.**

Barger suggested a simple method * for small quantities of fluids. Drops of the fluid are drawn up into a tube (1·5 mm. in diameter), so as to alternate with small drops of cane sugar of known content (Fig. 20). Water vapour will pass from the solution of which the vapour tension is the higher. By observing the edge of a drop under a microscope, it can be easily seen whether it has grown or diminished in size. If the edge of the drop remains stationary, it shows that the vapour tension and the osmotic pressure of the two fluids are equal. A series of trials is made with different strengths of sugar solution until this equality is established.

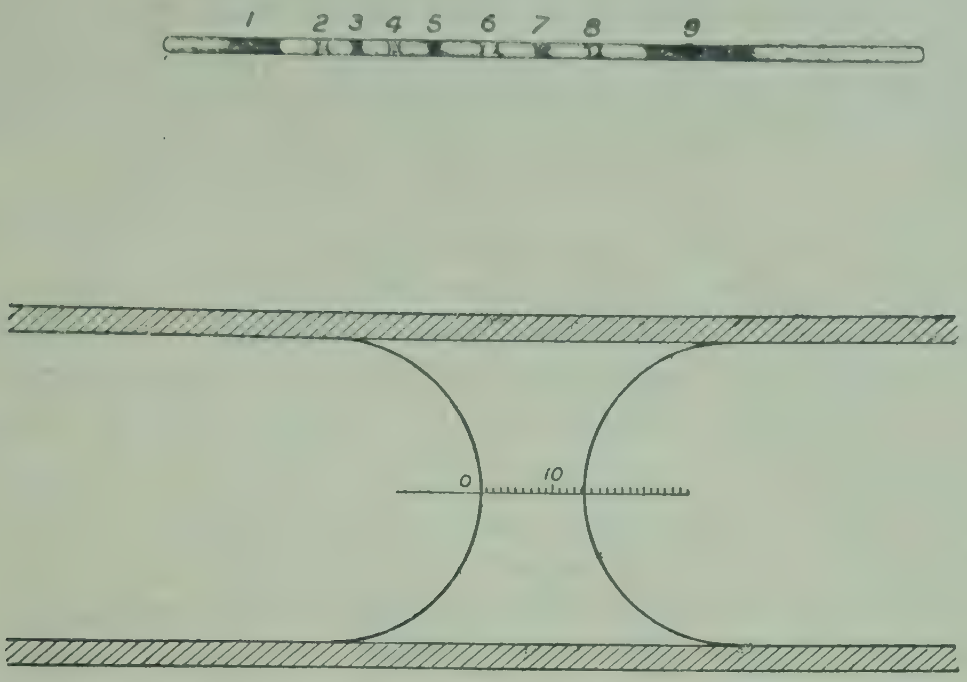

FIG. 20. Diagram to illustrate Barger's Method of Determining Osmotic Pressure. The upper figure shows the capillary tube with nine alternate drops of cane sugar and the substance under investigation.

OSMOTIC PRESSURE OF ELECTROLYTES. The conducting power of electrolytes depends on the fact that their molecules, in the act of solution in water, undergo dissociation into ions which increases with the dilution of the solution. Since each ion, as regards osmotic pressure and the related properties, acts as a whole molecule, the osmotic pressure of a *dilute* solution of NaCl is double that of an equimolecular solution of a non-electrolyte, *e.g.* glucose. Thus 0·58 per cent. NaCl is isosmotic with 3·5 per cent. glucose and not with the molecular equivalent, 1·8 per cent. If the solution is one of sodium sulphate the osmotic pressure is increased three times, since this salt dissociates into two Na ions and one SO_4 ion.

Every substance in solution evidently possesses a certain amount of potential energy in the form of osmotic pressure. This pressure is independent of the nature of the substance dissolved and is determined merely by its molecular concentration and degree of ionic dissociation. It can be used as a force for the attraction of water or, by the use of appropriate mechanisms, for the performance of mechanical work or for the production of differences of electrical potential.

"Normal" Physiological Solutions. Animal cell membranes are freely permeable to water, and hence, in conditions of equilibrium, the total osmotic concentration inside and outside the cell must always be equal. If it is temporarily disturbed, equilibrium is soon restored by passage of water towards the osmotically stronger side, by which process the cells swell or shrink. Using blood corpuscles, we may find a concentration, *e.g.* of sugar at which the corpuscles will neither increase nor diminish in bulk. This concentration varies according to the species from which the corpuscles are derived. Instead of sugar we can use sodium chloride. It is then found that a 0·65 per cent. NaCl solution is isotonic with frogs', and a 0·9 per cent. NaCl solution with mammalian red corpuscles. Since the osmotic concentration is identical in all the cells of the body and is the same as that of the blood, 0·65 per cent. and 0·9 per cent.

---

* BARGER. *Trans. Chem. Soc.*, 1904, **85**, 286.

NaCl solutions have been given the name of "*normal saline*," and are used fo maintaining tissues, respectively of frog or mammal, moist when they are unde experiment.

Since the limiting external layer of most cells seems to resemble bloo corpuscles in being impermeable to sugar and many ions, it might be thought that it was a matter of indifference what salts were used for making norma saline. This is not the case. It was shown by Ringer (Ch. XXXII) that t sodium chloride there must be added traces of calcium and potassium salts in order to obtain a saline solution suitable for keeping the heart alive and beating.

The function of a cell is thus dependent, not only on the nature of its contents and on the osmotic pressure of the surrounding fluid, but also on the nature of the ions which are in contact with its external surface. It should be noted that it is a matter of indifference what salts of calcium or potassium are used, since it is the cations themselves which are responsible for the effect. When we wish to keep a tissue alive, immersed in some solution, we employ a "Ringer's fluid" in which sodium, potassium and calcium ions are present in the proper amounts. It is customary to add also some sodium bicarbonate and sometimes sodium phosphate, so as to imitate the reaction of the normal body fluids. The accompanying table shows the composition of some commonly employed physiological saline solutions.

Physiological Saline Solutions.

NEUTRALITY AND REACTION

Most of the tissues in the human body contain about 80 per cent. of water. In every reaction taking place in the organism water plays an essential part. It is calculated that 1 litre at 22° C. contains 10^{-7} gramme ions of hydrogen, and of course the same number of hydroxyl ions. The temperature coefficient of the dissociation of water is fairly high, so that at 18° C. the hydrogen ion concentration in pure water is only $0{\cdot}78 \times 10^{-7}$, while at 37° C. it is $1{\cdot}76 \times 10^{-7}$.

When a strong acid such as hydrochloric acid is added to a strong base such as NaOH, the hydrogen and OH ions combine to form molecules of water, leaving behind only Na and Cl ions. The actual combination which takes place is thus the same whatever strong acid and strong base are used, namely, a combination of H and OH ions. In a solution containing H and OH ions, the active mass in any reaction which may take place is equal to the product of the

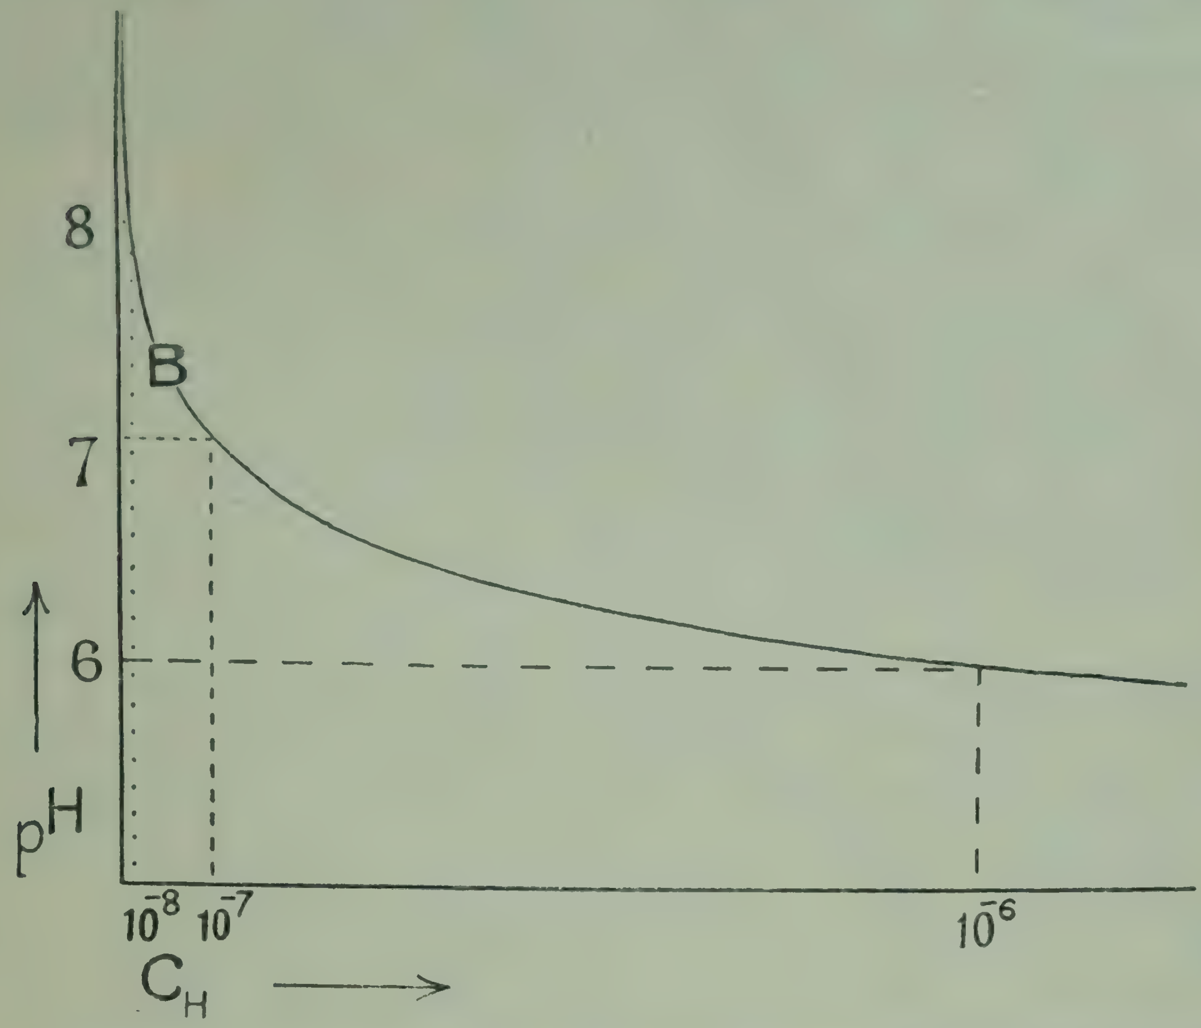

FIG. 21. Diagram to show the Relation between the two Methods of Registering Hydrogen Ion Concentration. (D. T. HARRIS.)

two concentrations H × OH. In a watery solution this is constant for any given temperature and amounts at 22° C. to 10^{-14}, increasing with the temperature; (at 37° it is $3{\cdot}1 \times 10^{-14}$). Thus the more H ions are present in a solution the fewer will be the OH ions, and the shift is considerable, since it is the product of the two and not the sum which remains constant.

The behaviour of a living cell bathed in any solution in which H ions are concerned will be determined, not by the total titratable acid or base, but by the actual concentration or activity of the H ions in the solution. It is therefore of importance to express the reaction of the body fluids in terms of H ion concentration, denoted by cH, or of H ion activity *ca*H.

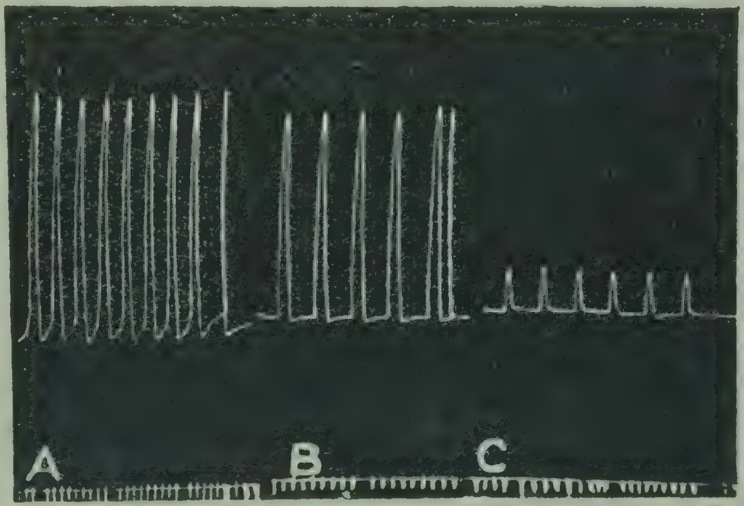

FIG. 22. Effect of Acid on the Isolated Heart of the Frog. (CLARK.)

A. Perfused with Ringer's solution with H' ion concentration of pH 7·7.

B. After perfusion for 20 minutes with faintly acid Ringer's solution, H' ion concentration, pH 6·5.

C. After perfusion of the acid solution for 80 minutes.

Owing to the inconvenience of expressions such as $1{\cdot}05 \times 10^{-7}$, $1{\cdot}3 \times 10^{-6}$, etc., it has become customary to use, not the cH figure directly, but the negative exponent of 10 as a positive number, calling it the hydrogen ion exponent or pH. Thus 5×10^{-6} is the same as $10^{-5{\cdot}3}$, and a solution having this concentration in H ions would be described as having a pH of 5·3. It must be remembered that the pH falls as the acidity increases. Moreover the change expressed by a unit difference in pH is much greater than that expressed by a unit difference in cH. Thus, while it is easy to see that the cH of 4×10^{-6} is double that of 2×10^{-6}, it is not at once obvious that a pH of 5·398 signifies an acidity which is double that of 5·699. The relation between the values of cH and of pH between cH 10^{-8} and cH10^{-6} is shown in Fig. 21.

Since H and OH ions are involved in all the chemical processes which go o in the living cell, it is not surprising that the cell functions are profoundl modified by differences in reaction. In Fig. 22 is shown the effect of a chang from $10^{-7\cdot7}$ to one of $10^{-6\cdot5}$ on the isolated heart of the frog. This change woul be produced by the addition of 0·036 milligrammes of HCl to 1 litre of distille water. A slightly higher degree of acidity, *i.e.* one of 10^{-6}, would kill th heart altogether.

“Buffer” Systems. The changes of reaction which would be caused by production of minute quantities of acid or alkali in the various chemica processes continually taking place in the cell are minimised by the presenc of certain substances in the protoplasm and fluids of the body in which the cells are bathed. These substances function as “buffers” in taking up $H^{\cdot}$ or OH' ions without a corresponding change in the reaction of the medium.

As an example of buffer action, we may consider the pH titration curves obtained by addition of NaOH to acetic acid, as compared with the curves obtained by adding NaOH to water rendered equally acid with HCl (Fig. 23). It will be seen that, whereas the addition of 0·2 c.c. of NaOH raises the pH of the water from 3·5 to 10, the pH of the acetic acid is only raised to about 3·6, and even 2·5 c.c. of alkali only raises it to about 5·5. Conversely, if we started with sodium acetate and added HCl, the pH would only slowly alter between pH 6·5 and 3·5, as compared with the alteration which would be caused by the same additions to water.

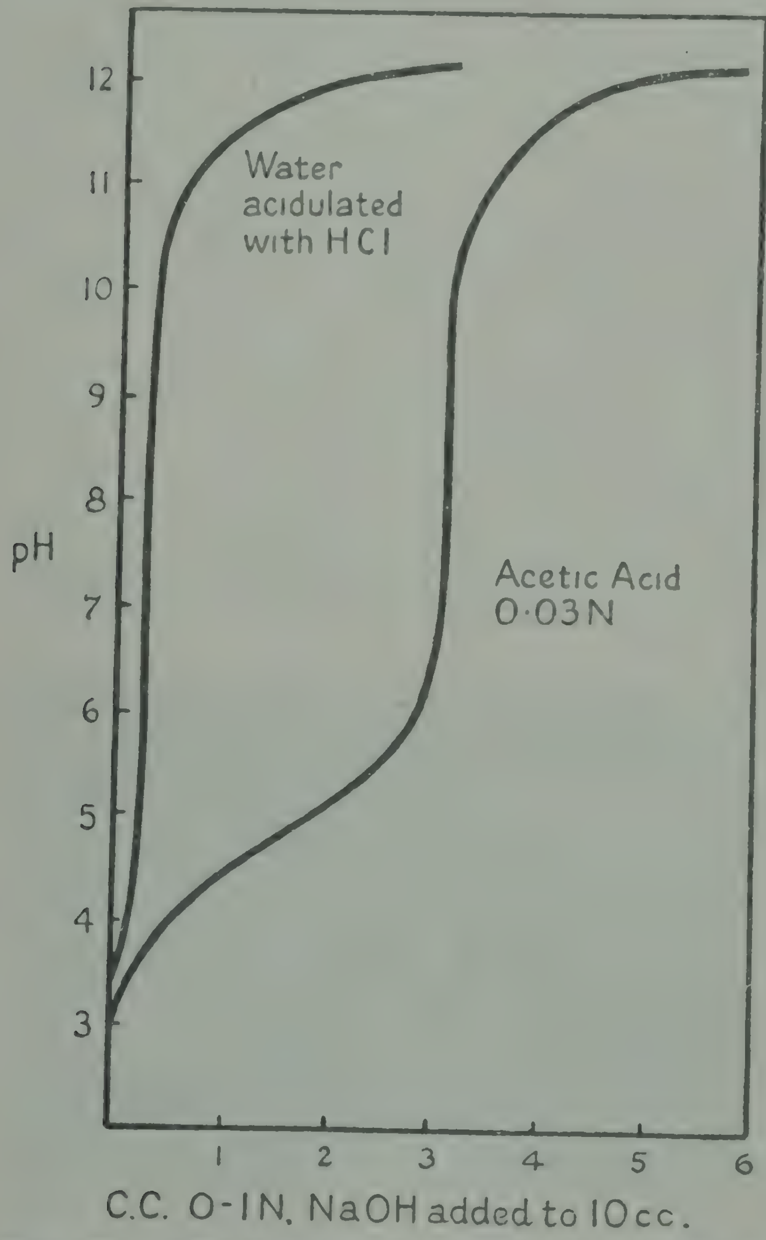

FIG. 23. pH titration curves, showing effect of adding stated amounts of 0·1N. NaOH to 10 c.c. of 0·03N. acetic acid, and to 10 c.c. water acidulated to pH 3·5 by HCl.

Two important salt buffers are the bicarbonate system and the phosphate system, the former of chief importance in the fluids of the body, the latter in the cells. The phosphate system is made up of the two phosphates NaH_2PO_4 and Na_2HPO_4. In a watery solution of NaH_2PO_4 there are present, besides the $H^{\cdot}$ and OH' ions from the water, $Na^{\cdot}$, H_2PO_4', $H^{\cdot}$, and HPO_4'' ions from the phosphate. The $H^{\cdot}$ ions are therefore present in greater quantity than in pure water, and the reaction is slightly acid. In a solution of Na_2HPO_4, the ions resulting from dissociation of the phosphate are $Na^{\cdot}$, $Na^{\cdot}$, and HPO_4''. The HPO_4'' ions combine with some of the $H^{\cdot}$ ions derived from the water to form H_2PO_4', leaving an excess of OH' ions, so that the reaction is slightly alkaline. Since it will require an equivalent weight of NaOH to convert 1 gramme molecule of NaH_2PO_4 into Na_2HPO_4, and 1 gramme molecule of HCl to effect the reverse change, a mixture of the two phosphates will absorb relatively large quantities of acid or base with but slight changes in the resulting reaction.

The acidity (*i.e.* the hydrogen ion concentration) of a mixture of the two phosphates will be proportional to $\frac{NaH_2PO_4}{Na_2HPO_4}$. When this proportion equals $\frac{1}{2\cdot5}$ the reaction will be neutral.

A still more perfect buffer system is afforded by $NaHCO_3$, when the solution is maintained in equilibrium with an atmosphere containing a constant proportion of CO_2. The solution will contain the following ions produced by dissociation.

$$\begin{aligned}
&NaHCO_3 && \rightleftharpoons Na^{\cdot} + HCO_3'.\\
&H_2CO_3 && \rightleftharpoons H^{\cdot} + HCO_3'.\\
&H_2O && \rightleftharpoons H^{\cdot} + OH'.\\
&HCO'_3 + H_2O && \rightleftharpoons H_2CO_3 + OH'.
\end{aligned}$$

H_2CO_3 is a very weak acid, so that only few hydrogen ions are produced. If an acid be added to the solution, a certain amount of the $NaHCO_3$ is decomposed with the formation of CO_2 and a neutral salt. But the CO_2 escapes from the solution, so that the only result is a diminished concentration of the $NaHCO_3$.

The cH of the solution will be proportional to $\frac{H_2CO_3}{NaHCO_3}$, and the reaction will be neutral when $\frac{H_2CO_3}{NaHCO_3} = \frac{1}{3{\cdot}75}$.

The salts of any weak acids (*e.g.* boric, acetic, etc.) or weak bases, *e.g.* ammonia, may act as buffers, and we may have complex systems in which these substances are present. Such buffer mixtures are of great value in physiological work because, by mixing two such substances in known proportions, solutions of definite hydrogen ion concentration may be prepared; such solutions only slowly change their H-ion concentrations when acids or bases are added to them. Examples of such buffer mixtures are given below.

Range of Buffer Mixtures

Mixtures of	Range of *p*H obtained.
Glycine and HCl	1·15 — 3·68
Acid K. Phthalate and HCl	2·2 — 3·8
Acid K. Phthalate and NaOH	4·0 — 6·2
Acetic acid and sodium acetate	3·24 — 6·55
$K_2HPO_4 + KH_2PO_4$	5·19 — 8·21
Boric acid, HCl and NaOH	7·8 — 10·0
Glycine + NaOH	8·58 — 12·97

Among other important buffers present in cells the proteins must be mentioned. Like the amino-acids, *e.g.* glycine shown above as a laboratory buffer, the proteins can function as either weak bases or weak acids and so absorb considerable amounts of either acid or alkali, so helping to stabilise the H-ion concentration of cells.

THE MEASUREMENT OF HYDROGEN ION CONCENTRATION

The Hydrogen Electrode. This is the classical method, and is still the standard of reference. Its use in biological material is restricted owing to the necessity for complete absence of oxygen.

The Glass Electrode. The method depends on the fact that a potential difference is set up between two solutions of different hydrogen ion concentrations, when these are separated by a very thin glass membrane. If the hydrogen ion concentration of one of the solutions is known, that of the other can be calculated from the difference of electrical potential. The method * has certain advantages, one of which is that it is not necessary to de-oxygenate the solution. It is now the most generally used method.

Indicators. In some cases the estimation can be made rapidly by means of *indicators.* These are dyes which change colour at definite values of hydrogen ion concentration. They are chiefly salts of either a very weak acid or a weak base, or the free acid or base itself, the change of colour being due to the electrolytic dissociation of the salt with the production of an ion which has a different colour from that of the undissociated acid o base. Some of the most useful indicators, and the range of their concentrations, are give in the accompanying table. In determining the hydrogen ion concentration of fluids suc as the blood, the reaction may be tested in the dialysate obtained by placing the blood in thimble of collodion, which is immersed in a small quantity of 0·85 p.c. NaCl solution,

COMMON INDICATORS FOR *p*H DETERMINATIONS.

Indicator.	Range, *p*H.	Acid Colour.	Alkaline Colour.
Methyl violet	0·1– 3·2	Yellow	Violet.
Thymol blue (acid range)	1·2– 2·7	Red	Pale yellow.
Bromphenol blue	3·0– 4·6	Yellow	Blue.
Methyl orange	3·2– 4·6	Red	Yellow.
Congo red	3·5– 4·7	Blue	Red.
Bromcresol green	4·0– 5·6	Yellow	Blue green.
Methyl red	4·3– 6·3	Red	Yellow.
Neutral red	6·5– 8·4	Red (blue in strong acid solutions).	Yellow.
Bromcresol purple	5·2– 6·8	Yellow	Purple.
Phenol red	6·8– 8·4	Yellow	Red.
Cresol red	7·2– 8·8	Reddish	Orange.
a-Naphthol-phthalein	7·6– 8·5	Yellow	Blue.
Thymol blue (alkaline range)	8·0– 9·6	Pale yellow	Blue.
Phenol-phthalein	8·3–10·0	Colourless	Red.
Thymol-phthalein	9·3–10·5	Colourless	Blue.
Nitrothymolsulphonephthalein	9·2–11·5	Violet	Yellow.
Alizarin yellow	10·2–12·1	Yellow	Orange.
Tropaeolin O	11·1–12·7	Yellow	Orange.

care being taken to avoid loss of carbon dioxide. The dialysate acquires the same reaction as the blood, which is determined by adding a suitable indicator (neutral red or phenol red) and matching against standard buffer solutions to which the same indicator has been added.

SURFACE ENERGY

The forces at the surface of a liquid differ from those in its interior. At the surface, any molecule, instead of being subject to the attraction of the other molecules on all sides, is exposed only to those attractions which tend to draw it inwards, so that as a result the surface is always the least possible and is in a state of tension. This *surface tension* can be measured, and is expressed in dynes per centimetre. To stretch the surface requires the expenditure of energy, while work may be done if the surface is diminished. It is surface tension which causes water to rise in capillary tubes, and the height to which the water rises may be used as one means of measuring surface tension. If, as in the case of mercury, a fluid does not moisten the capillary tube, there is a depression of the meniscus. Any substance which lowers the surface tension of water will tend to spread over its surface until it is one molecule thick. This is the case with oil dropped on water, the spreading of the oil being due to the expansion of the surface of water at the part where its surface tension is diminished by contact with oil. Wherever we have two immiscible fluids there will be a surface tension, and in the same way there will be a surface tension between liquids and solids.

The fact that protoplasm consists largely of colloids involves a heterogeneity of structure, and hence large areas of surfaces. The tension at the cell surface has been measured in various ways and found to lie usually between 1·0 and 0·1 dyne/cm. This value is very much lower than would be expected if the surface layer consisted of lipoid alone, and is explained as being due to the presence of an adsorbed layer of protein covering the lipoid membrane.[†]

The surface tension of a liquid is altered by dissolved substances. Inorganic salts cause a slight rise of surface tension of a solution in contact with air. Most organic substances

[*] DALE AND LOVATT EVANS. *J. Physiol.*, 1920, **54**, 167.

[†] NEWTON HARVEY and DANIELLI. *Biol. Rev.*, 1938, **13**, 319.

cause a diminution of surface tension. It was shown by Gibbs and Thomson that dissolved substances which lower surface tension tend to concentrate at the surface, on account of he fact that the free energy of the system is thereby lessened. In many cases this concentration at the surface may be so marked that the substance forms a solid pellicle (p. 15).

When we are dealing with an interface between liquid and liquid or between liquid and solid, this concentration of solute or dissolved substance at the surface is equivalent to a deposition on the other substance with which the solution is in contact. It is responsible for many cases of concentration at surfaces, for which the name *adsorption* is used (*v.* p. 74). The marvellous power of adsorption of gases by charcoal is due to the very large surface presented by this substance. In the dyeing of stuffs and the staining of sections adsorption is the chief factor involved. On chemically active solutes this process of adsorption will have a two-fold effect: that part which is adsorbed at the surface is taken out of the main solution and loses, for instance, its osmotic effect. On the other hand, the concentration of two reactive substances in the same surface may bring about their interaction, so that chemical changes are furthered which without this concentration would have gone on much more slowly.

Many surfaces such as glass, paper, or wool, in water are negatively charged. This charge affects the type of adsorption at the surface of such particles, and will tend to favour the concentration of electro-positive as against electro-negative molecules at the interface. A charge on a surface implies a diminution of the surface tension, and this is the principle of the capillary electrometer.

Since electrolytes may augment or diminish the charge at a surface, we see how important may be the constituents of a solution to the living cells with which it has to come in contact.

HEAT FORMATION AND FREE ENERGY

Living cells utilise energy for a variety of purposes—for chemical synthesis, osmotic work, movement, etc. This energy is obtained, in nearly all cases, by oxidative processes, the net result of which is that foodstuffs of high potential energy content are converted into end-products of low energy content, the difference in energy content appearing as kinetic energy, one form of which is heat.

Absolute values of the internal energy of molecules are unknown: we can only measure changes, the difference appearing as heat or work. By convention it is usually expressed in calories (but 1 large calorie = 427 Kg. m.).

When a foodstuff is oxidised in the body, the amount of heat ultimately produced is the same as would be evolved if it were oxidised to the same end-products in any way, *e.g.* by burning it, outside the body. The heat evolved per mole, the difference between the potential energy of the initial substances and the final end-products, is called ΔH and is given a negative sign. Thus for the combustion of glucose:—

$$C_6H_{12}O_6 + 6O_2 = 6CO_2 + 6H_2O$$
$$\Delta H = -674 \text{ Cals.}$$

The second law of thermodynamics tells us that the cell cannot utilise heat for doing work, and if an energy change leads to work being done, the heat liberation must be proportionately less. For study of the work available, a knowledge of the change in *free energy* or ΔF is more useful than ΔH, since free energy is energy in a form capable of doing work.*

If a reaction involves a decrease in free energy (*i.e.* if ΔF is negative in sign) then that reaction *could* occur spontaneously, and could then do work, and the maximal amount of work theoretically possible would be deducible from, and n many cases approximately equal to, ΔF. It cannot be predicted that the eaction *will* occur, any more than it can be predicted that a car at the top of hill will run down—the brakes might be on! The value of ΔF is often about

---

[*] Without a knowledge of thermodynamics this must be accepted on faith. It would e pointless here to attempt to introduce the conception of entropy or other thermodynamical theory.

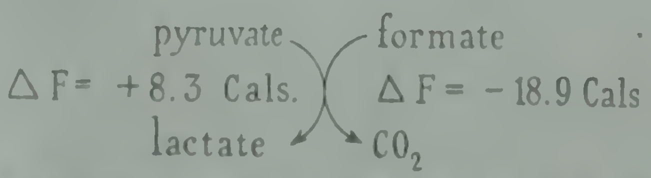
the same as ΔH, but not necessarily so. Thus for combustion of glucose, $\Delta F = -686$ Cals. Many synthetic processes that occur in living cells have a large *positive* ΔF, *i.e.* they involve *absorption* of energy and *cannot* be spontaneous reactions; just as a car at the bottom of a hill cannot get to the top without energy being expended on it. Such a reaction can only occur if coupled thermodynamically with another reaction of suitably large negative ΔF. For example, lactic acid can be oxidised to pyruvic acid with liberation of energy :—

$$\text{CH}_3\text{CHOH.COO}' \longrightarrow \text{CH}_3\text{CO.COO}' + 2\text{H}^{\cdot}$$
$$\Delta F = -8{\cdot}3 \text{ Cals.}$$

But the reverse reaction cannot occur spontaneously since ΔF would be positive. But by coupling it with a reaction that has a large negative ΔF, viz. oxidation of formate to CO_2 :—

$$\text{COOH}' + \text{H}_2\text{O} = \text{HCO}_3' + 2\text{H}^{\cdot}$$
$$\Delta F = -18{\cdot}9 \text{ Cals.}$$

the enzymes of *B. coli* can simultaneously reduce pyruvate to lactate in the coupled reaction :—



with a net change in free energy of $(-18{\cdot}9 + 8{\cdot}3) = -10{\cdot}6$ Cals. which is evolved as heat. This may be compared with a funicular railway, in which a heavy car at the top can lift a light one at the bottom, if the two are linked by a cable.

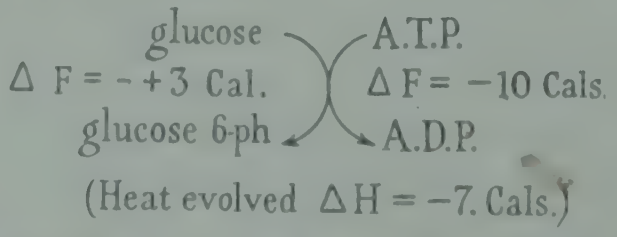
Energy-rich bonds. One of the most important substances in nature is a compound of adenosine with phosphoric acid (*v.* p. 52). It probably plays a part in all biological synthesis involving large energy changes as well as in disintegrative changes such as glycolysis and oxidation. Adenosine triphosphate (A.T.P.) may be represented diagrammatically,

$$\textcircled{\text{Ad}} \underset{(i)}{-} \text{HPO}_3 \underset{(ii)}{\sim} \text{HPO}_3 \underset{(iii)}{\sim} \text{H}_2\text{PO}_3$$

The phosphate groups can be split off one at a time and those at (iii) and (ii) carry with them about 10 Cals. of energy per mole, which can be transferred without apparent loss to other compounds.* Scission at bond (i) only carries about 2 Cal. These energy-rich groups are often designated $\sim$ Ph, and the one most frequently exchanged is the terminal one, with formation of adenosine diphosphate (A.D.P.), or the reverse.

$$\underset{\text{(adenosine triphosphate)}}{\textcircled{\text{Ad}} - \text{HPO}_3 \sim \text{Ph} \sim \text{Ph}} \rightleftharpoons \underset{\text{(adenosine diphosphate)}}{\textcircled{\text{Ad}} - \text{HPO}_3 \sim \text{Ph}}$$
$$\Delta F = -10 \text{ Cals.}$$

For example, glucose can by the appropriate enzyme be converted into glucose 6-phosphate in the coupled reaction :—



Further examples of these important reactions are given in Chapter X.

CHAPTER VI

THE PROPERTIES OF COLLOIDS

The term colloid, from κσλλη, glue, was first introduced in 1861 by Thomas Graham, Professor of Chemistry at University College. Graham divided all substances into two classes, viz. *crystalloids*, including such substances as salt, sugar, urea, which could be crystallised with ease, diffused rapidly through water and were capable of diffusing through dead animal membranes; and *colloids*, which included substances such as gelatin, gum, egg-albumen, starch and dextrin, were non-crystallisable, formed gummy masses when their solutions were evaporated to dryness, diffused with extreme slowness through water and would not pass through animal membranes. The process of *dialysis* was therefore introduced by Graham for the separation of crystalloids from colloids. Although the broad distinction drawn by Graham between colloids and crystalloids still holds good, some of the criteria by which he distinguished the two classes are no longer strictly applicable. For instance, it has been shown that many typical colloids, such as proteins, can be obtained in a crystalline form. On the other hand all gradations exist between substances, such as egg-albumin, which are practically indiffusible, and those, such as common salt, which are very diffusible. Colloids exist under two conditions:

(1) In a state of solution or pseudo-solution, in which they form *sols*, and are distinguished as hydrosols when the solvent is water; and

(2) In a solid state, in which a relatively small amount of the colloid sets with a large amount of a fluid, such as water, to form a jelly. This solid form, *e.g.* gelatine, is known as a *gel*. Such a watery jelly is known as a *hydrogel*.

A number of these colloidal substances can be shown on purely chemical grounds to consist of monstrous molecules. Thus the molecular weight of hæmoglobin is at least 64,000, and one must ascribe similar high molecular weights to such substances as egg-albumin and globulin. Still greater must be the molecular size of such substances as the cell proteins, which may form a gigantic complex, to which it would probably not be an exaggeration to ascribe a molecular weight of over 100,000. Chemical complexity is not, however, a necessary condition of the colloidal state, as is shown by the existence of colloidal silica, and, indeed, of colloidal solutions of practically any given substance, including many elements.

All so-called colloidal solutions are in reality suspensions of particles, the so-called *disperse phase*, in a fluid or *continuous* phase. The fluid may be any liquid or solution whatever. Thus, milk is a suspension of oil droplets in a watery phase, and butter is a colloid consisting of water suspended in a continuous phase of oil. The conversion of milk into butter is an example of phase reversal.

Of special interest are the hydrosols of the metals. Faraday long ago pointed out that, on treating a weak solution of gold chloride with phosphorus, it underwent reduction with the formation of metallic gold. The gold was not precipitated, but remained in suspension or pseudo-solution, giving a deep red * or a blue liquid, according to the conditions under which the reaction was affected. This solution was homogeneous in that it could be filtered without change and could be kept for months without deposition of the gold. The latter was, however, thrown down on addition of mere traces of impurity, though greater stability could be conferred on the solution by adding to it a little gelatin. In 1899 Bredig showed how similar hydrosols might be prepared from a number of different metals, viz. by the passage of a small arc or electric sparks between metallic terminals submerged in distilled water. If for example the terminals be of platinum, the passage of the current is seen to be accompanied by the giving off of brown clouds, which spread into the surrounding fluid.

---

* Ruby glass is a colloidal "solid" solution of gold in a mixture of silicates.

These clouds consist of particles of platinum of all sizes; the smaller—which are ultr microscopic in size, *i.e.* from 5 m.μ to 40 m.μ—remain in suspension, and we obtain a brow fluid which can be filtered through paper or even through a Berkefeld filter without losing i colour. It may be kept for months without any deposit taking place. The addition minute traces of electrolytes precipitates the platinum particles, leaving a colourless flui

Colloidal solutions or sols may be divided into two classes, *emulsoids* an *suspensoids*, according as they may be regarded as suspensions of liquid, or a suspensions of solid particles, in liquid.

Most protein solutions are emulsoids, while the metallic sols are suspensoid Dilute egg-white is an emulsoid, but if it be boiled, although no visible precipitation is produced, the fine particles are coagulated and it behaves as a suspensoid

Properties of Gels. The firm mass to which a solution of gelatin sets o cooling is a typical hydrogel. It is clear, hyaline, apparently structureless an elastic. It may be regarded as formed by the separation of the warm pseudo solution of gelatin into two phases: first, a solid phase, rich in gelatin an forming a tissue or meshwork in the interstices of which is embedded th second phase, consisting of a very weak solution of gelatin.

In many cases the more fluid part of the gel is practically pure water. I a dry atmosphere the gel loses water and becomes shrivelled and dry, but i some cases, *e.g.* gelatin, it can resume its former size and characters on immersion in water. Other gels, such as silicic acid or ferric hydrate, lose the power o swelling up after drying. The change in them is therefore irreversible. A ge adheres to the last traces of water with extreme tenacity. In consequence o its structure, it presents an enormous extent of surface on which adsorption ca take place. At this surface the vapour tension of fluids is diminished, as wel as the osmotic pressure of dissolved substances.

Many colloids, even those such as starch or gelatin which are insoluble i cold water, absorb water and exhibit a phenomenon, viz. "*Quellung*" o imbibition, which in some cases it is impossible to distinguish from the process of solution. When soaked in aqueous solutions, the amount of water taken up varies inversely with the osmotic pressure of the solution. In many respects the insoluble emulsoid colloids when soaked in aqueous solutions, behave as though they were osmotic cells with boundaries capable of expansion. Indeed, we may regard them as such cells filled with colloid to which their surfaces are impermeable. When dry, colloids can exert a considerable force when caused to swell up by moistening.

The huge aggregates of molecules, which distinguish the colloidal state, form a system with considerable inertia, so that there is a tendency to the establishment of conditions of false equilibrium. Once a state is established, it is necessary to overstep widely the conditions of its formation in order to destroy it. Thus a 10 per cent. gelatin solution sets at 21° C. but does not melt until warmed to 29·6° C. Solutions of agar in water set at about 35° C. but do not melt under 90° C. A gel of gelatin takes twenty-four hours after setting to attain a constant melting point. This phenomenon is called *hysteresis*.

On account of the extent of surface it is practically impossible to wash out the inorganic constituents from a gel. The diminution of the osmotic pressure of many dissolved substances at surfaces causes the concentration at the surface of the solid phase to be greater than that in the surrounding medium. Thus, if dry gelatin be immersed in a salt solution it will swell up, but the solution which it absorbs will be more concentrated than the solution in which it is immersed, so that the proportion of salt in the latter will be diminished. When, however, equilibrium is established between a gel and the surrounding fluid, it is found to present no appreciable resistance to the passage of dissolved crystalloids. Thus salt or sugar diffuses through a column of solid gelatin as if the latter were pure water. But gels are impermeable to other colloids in solution. This impermeability is made use of in the separation of crystalloids from colloids by dialysis, membranes used in this process being generally irreversible gels (*e.g.* vegetable parchment, animal membranes, collodion or cellophane). Othe gels, such as tannate of gelatin or copper ferrocyanide, are not only impermeable to colloids, but also to many crystalloid substances. These membranes can therefore be used for the determination of the osmotic pressure of those crystalloids.

Properties of Hydrosols. Hydrosols of substances such as dextrin or egg-albumin may be made of almost any concentration. If a solution of egg-albumin be concentrated at a low temperature, it becomes more and more viscous and finally solid. But there is no distinct point at which the fluid passes into the solid condition. Much discussion has arisen whether hydrosols are to be regarded as true solutions or as suspensions. The homogeneity or heterogeneity of a solution is clearly a matter of degree. In a true solution the molecules of the solute are equally diffused throughout the molecules of the solvent, and it is impossible, without the application of energy, to separate one from the other. Thus filtration or sedimentation leaves the composition of the solution unchanged. It is true that by the employment of the semi-permeable membrane, it is possible to separate solute from solvent, but in this case the force required to effect the filtration may be enormous. The measure of the force required is the osmotic pressure of the solution.

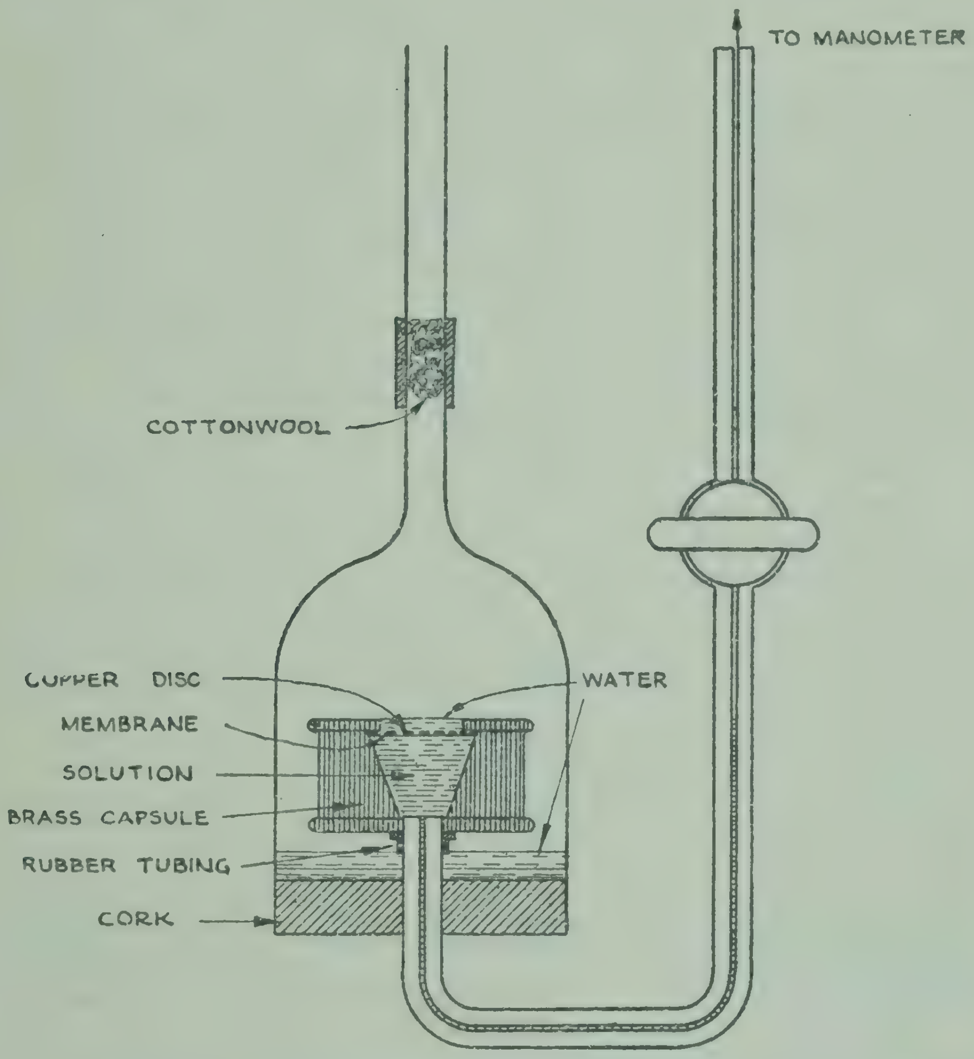

Fig. 24. Govaerts' Osmometer (Verney's modification). (Kerridge.)

Osmotic Pressure. Starling * showed that it is possible to determine the osmotic pressure of colloidal solutions directly, taking advantage of the fact that colloidal membranes, while permitting the passage of water and salts, are impermeable to colloids in solution. In this way it was found that blood serum, containing 7 to 8 per cent. of proteins, had an osmotic pressure of 25 to 30 mm. Hg, which would correspond to a molecular weight of this protein, of about 30,000.

A convenient osmometer for this purpose is illustrated in Fig. 24. The membrane is of cellophane. The serum or other solution is placed in the brass capsule, and water on the upper surface of the membrane. The level of serum in the glass capillary is kept constant by applying counter-pressure from a manometer, to balance the osmotic pressure, and this counter pressure is read off when equilibrium is reached.†

* Starling. *J. Physiol.*, 1895, **19**, 323; 1899, **24**, 317.

† A simpler form is described by Keys and Taylor. *J. Biol. Chem.*, 1935, **109**, 47.

The existence of an osmotic pressure in colloidal solutions was established by Moor and Roaf[*] in the case of hæmoglobins, proteins and soaps, and by Bayliss in the case c colloidal dyes.[†] The osmotic pressure of hæmoglobin has been found by Adair[‡] to correspond to a molecular weight of about 68,000, *i.e.* about 4 times as great as the minima molecular weight deduced from its combining power with oxygen. The osmotic pressur is often smaller than would be expected from the molecular weight of the substance, owin to molecular aggregation. Thus the aggregate of colloidal silica must be many, probabl thousands of, times larger than the molecule as represented by H_2SiO_3. The osmoti pressure being proportional to the number of separate molecules or groups of molecules in given volume of solution, to which a given membrane is impermeable, the larger the aggregate the smaller would be the osmotic pressure of the solution.

It is in consequence of the huge size of the molecular aggregates that colloida solutions, such as starch or glycogen, display such a trivial osmotic pressure We can divide colloidal solutions into two classes, viz. those which almost form true solutions and present a feeble osmotic pressure, and those which form suspensions and therefore exert no osmotic pressure. In inorganic colloids such as arsenious sulphide, Picton and Linder have shown that all grades exis between true solutions and suspensions. With increasing aggregation of the molecules, the suspension becomes coarser and coarser until finally the sulphide precipitates.

Heterogeneity. We have every reason to believe that the very complex molecules forming the cell proteins may have molecular weights even greater than 30,000. When, however, we arrive at molecular weights of these dimensions, the disproportion between the size of the molecules and those of the water becomes so great that a homogeneous distribution of the two substances, solute and solvent, is no longer possible. The size of a molecule of water has been reckoned to be $0{\cdot}7 \times 10^{-8}$ mm. A molecule 10,000 times as large would have a diameter of $0{\cdot}7 \times 10^{-4} = 0{\cdot}07\mu$, a size just within the limits of microscopic vision. Long before molecules attained such a size they would no longer react according to the laws of solutes, but would possess the properties of matter in mass. They have a surface of measurable extent, and their relations to the molecules of solvent will be determined by the laws of adsorption at surfaces. As a matter of fact we find that such solutions present an amazing mixture of properties, some of which betray them as mechanical suspensions, while others show them to be capable of participating in chemical reactions such as those studied in the simpler compounds in solution usually dealt with by the chemist.

THE ULTRA-CENTRIFUGE. It has been found by Svedberg[§] that protein solutions and other colloids show partial sedimentation when submitted to extremely rapid centrifugalisation, and he has calculated the apparent molecular weights of various proteins from their observed speeds of deposition. It would appear from his researches that most proteins have molecular weights of 17,600 or approximate multiples of this, *e.g.*:

Egg albumin	43,800
Hæmoglobin	69,000
Serum albumin	70,200
Serum globulin	167,000
Nucleic acid	15,000 to 1,000,000
H-Hæmocyanin	6,630,000

Optical Behaviour of Hydrosols. Nearly all colloidal solutions present what is known as the Faraday-Tyndall phenomenon. When a beam of light is passed through an optically homogeneous fluid, the course of the beam is invisible. A beam of sunlight falling into a dark room is rendered visible by impinging on and illuminating the dust particles in its course. Each of these particles, being illuminated, acts as a centre of disperson of the light, so that the course of the beam is apparent to a person standing on one side of it. Tyndall showed that, if the particles were sufficiently minute, the light dispersed by them at right angles to the beam was polarised. This can be easily tested by looking at the beam through a Nicol's prism. The Tyndall phenomenon may be regarded as a test for the presence of ultra-microscopic particles, varying in size from 5 to 50 mμ. The phenomenon is perhaps too sensitive to be taken as a proof that a fluid presenting it is a suspension rather than a solution. It is shown, for instance, by solutions of many bodies of high molecular weight, such as raffinose (a trisaccharide) or the alkaloid brucine (Bayliss).

A particle having a diameter less than half the wave-length of light, *i.e.* about 300 λ o 0·3 μ, cannot be clearly distinguished under any power of the microscope. The fact that a ultra-microscopic particle may serve as a centre for dispersal of light may be used fo endering the *position* of such particles visible under the microscope. For this purpose a trong beam of light is passed in the plane of the stage of the microscope through a cell ontaining the hydrosol, which is then examined under a high power. On examining a ilute gold sol with this apparatus, we see a swarm of dancing points of light, "like gnats in he sunlight," which move rapidly in all directions, rendering it almost impossible to count heir number in the field. The coarser particles present slight oscillations similar to those ong known as the Brownian movement. The smallest demonstrable particles show a ombined movement, consisting of a translatory movement, in which the particle passes apidly across the field in one-sixth to one-eighth of a second, with one of oscillation of much horter period. The representation of the course of such a particle is given in Fig. 25.

---

[*] MOORE AND ROAF. *Bioch. J.*, 1907, **2**, 34.

The size of the smallest particles revealed in this way may amount to 0·005 μ. Not all colloidal solutions show these particles in the ultra-microscope. In some cases this is due simply to the small size of the particles, and the addition of any substance, which causes aggregation and therefore increase in the size of the particles, will bring them into view. In others the absence of optical heterogeneity may be due to the coincidence of the refractive indices of the two phases of the hydrosol, or to the absence of any clear dividing surfaces between the two phases. In any case it is not the particle itself which is thus rendered visible, but only the light scattered from it.

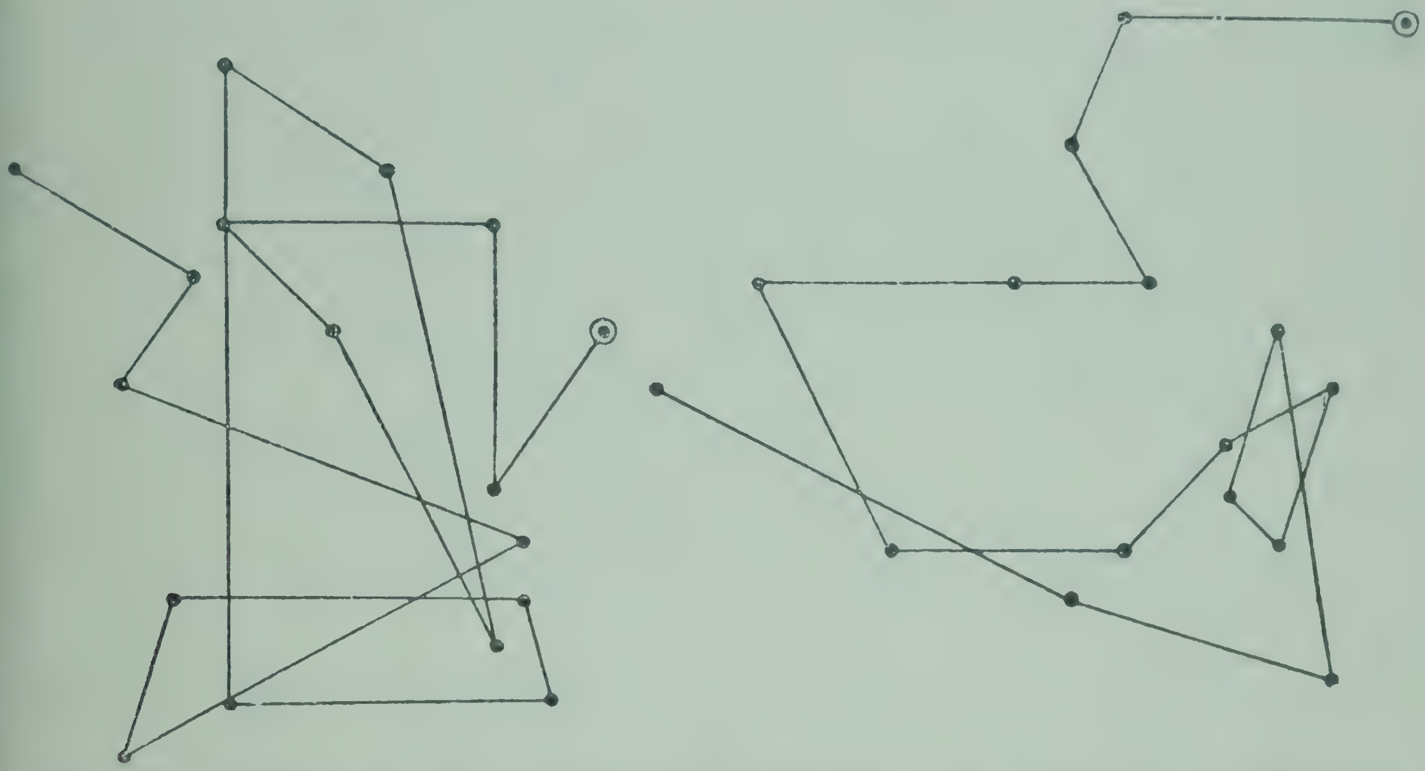

FIG. 25. Movements of two Particles of India-rubber Latex in Colloidal Solution, recorded by cinematograph and ultra-microscope. (HENRI.)

ELECTRICAL PROPERTIES OF COLLOIDS

In the case of many hydrosols the ultra-microscopic particles of which they are composed carry an electric charge which, according to the nature of the solution, may be either positive or negative. On this account the particles move if placed in an electric field, and the direction of their movement reveals the nature of their charge. Thus colloidal ferric hydrate is electro-positive and travels to the cathode. The presence of a charge is not, however, a necessary condition for the stability of a colloidal solution. Thus the proteins of serum globulin in a neutral saline solution, or of gelatin, present no drift when exposed to a strong electric field.* In certain colloids, the proteins for instance, the charge varies according to the conditions under which they are brought into solution. At a particular hydrogen ion concentration, differing for different proteins, and called the *isoelectric point*, the protein is uncharged and does not migrate in an electric field. Moreover, at the isoelectric point, proteins show minimal solubility, viscosity, osmotic pressure, etc. Advantage is often taken of this to separate or purify proteins by precipitation at the isoelectric point, or *isoelectric precipitation*. When in solution on the acid side of their isoelectric points protein particles carry a positive charge, whereas on the alkaline side (and at most physiological pH values) their charge is negative.

---

* HARDY. *J. Physiol.*, **1905, 33, 251.**

The iso-electric pH of some important proteins are given below :—

Edestin	6·9
Reduced hæmoglobin	6·8
Oxyhæmoglobin	6·6
Serum globulin	5·4
Egg albumin	4·8
Serum albumin Casein Gelatin	4·7

The charged condition of these particles must play a considerable part in keeping them asunder and therefore in preventing their aggregation and precipitation. This is shown by the fact that any agency which will tend to discharge them will often cause precipitation and coagulation. Among such agencies is the passage of a constant current and the coagulative effects of neutral salts. Thus, any of the colloids we have mentioned, ferric hydrate, silica, gold or boiled albumin, are thrown down by the addition of traces of neutral salts, and it is found that in this process they carry with them some of the ion with the opposite charge to that of the colloidal particle. Thus in the precipitation of the electro-positive ferric hydrate, the negative ion of the salt is the determining factor, the coagulative power increasing rapidly with the valency of the acid. On the other hand, in the precipitation of a gold sol, the electro-positive ion is the effective agent, and here again the coagulative effect is enormously increased by a rise in valency. This is shown by the fact that in the coagulation of gold, barium chloride with the divalent $Ba^{\cdot\cdot}$ is 7 times as powerful as K_2SO_4 containing the univalent $K^{\cdot}$; whereas, in the precipitation of the electro-positive ferric hydrate, K_2SO_4 with a divalent SO_4'' is 400 times as effective as $BaCl_2$.

Electrophoresis. The mobility of protein molecules in an electric field, *i.e.* the velocity with which the protein molecules move (in cm./sec. per unit gradient in potential, *i.e.* per volt/cm.) can be measured by putting a known potential between electrodes, at a measured distance apart, dipping into the solution of protein, and then, after a measured interval of time, determining the concentration of protein at various distances from the electrodes. By this method Tiselius has shown that mixtures of proteins can be separated, without chemical interference.

Other Forces. In addition to the electrical forces related to ionisation, there are other less well understood forces that may play a part in determining colloidal behaviour.

Long-range colloidal forces, probably electrical, but of unknown origin, can operate over distances of the order of 500 A. Enzymes can act when separated from their substrates by films 100 A. or more in thickness, perhaps due to such forces.

Hydrogen bonds can form connections with other atoms, *e.g.* N or O, and such bonds certainly occur in proteins.

The Hofmeister Series. The action of ions on emulsoid colloids, *e.g.* proteins, is somewhat more complex than that described above, since both positive and negative ions exert an influence which is dependent on the nature of the ions. When gelatine is immersed in aqueous solutions, for example, its swelling is hastened by NaCl, NaBr, KCl, NH_4Cl and $NaNO_3$ and retarded by sodium sulphate, tartrate, citrate and acetate. It is possible to arrange certain ions in the order of their efficacies in affecting this and certain other properties of emulsoid colloids. This series, called the *Hofmeister series*, runs :—

$$\text{Sulphate, Tartrate} < \text{Acetate} < \text{Cl} < \text{NO}_3 < \text{I} < \text{SCN}$$

which exert a tendency, in the order shown, to precipitate positively charged (*i.e.* acidified) protein, while the cations

$$\text{Li} > \text{Na} > \text{K} > \text{NH}_4$$

favour precipitation of positively charged protein in the order shown. In alkaline solutions the order of each series is reversed. According to Loeb, if attention is given to hydrogen ion concentration, the series becomes altered and is then simply one of valencies. But it is probably important that the Hofmeister series also holds good for many aspects of the physiological effects of various ions in the tissues.

Adsorption. The charged condition of a colloidal particle makes it behave in an electric field in much the same way as a charged ion of an electrolyte, and this similarity extends also to its chemical behaviour, so that we can have a class of combinations formed resembling in many respects chemical compounds, but differing from them in the absence of definite quantitative relations between the reacting substances. This class of compounds of varying composition has been designated *adsorption complexes.*

The factors involved in the formation of adsorption combinations are :

(1) Extent of surface. In a colloidal solution this is enormous in proportion to the mass of substance in solution. Thus a 10 c.c. sphere with a surface of 22 sq. cm., if reduced to a fine powder consisting of spherules of 2·5 $m\mu$ in diameter, will have a surface of 20,000,000 sq. cm., *i.e.* nearly half an acre. At the whole of this surface adsorption may take place, involving the concentration of dissolved electrolytes, ions or gases.

(2) Chemical nature of particle, residual valencies, etc.

(3) Electric charge and other forces on the surface. The sign of this may be determined by the chemical nature of the colloid and its relation to the electrolytes in the surrounding medium.

The conditions which determine the formation of these adsorption complexes can be studied in their simplest form on the adsorption of dyestuffs by substances such as paper. If we take a series of solutions of a dye, such as Congo red, in progressively diminishing concentration, and place in each solution the same amount of filter-paper, we find that a part of the dye is taken up by the paper, and the proportion taken up is larger the more dilute the solution. This relation is in accordance with what Bayliss called the *law of adsorption.** This is illustrated by the following Table :

Concentration of Solution.		Proportion of Dye in Solution.	Proportion of Dye in Paper.
Initial.	Final.	Per cent.	Per cent.
0·014	0·0056	40	60
0·012	0·0024	20	80
0·010	0·0009	9·3	90·7
0·008	0·0003	4	96
0·006	0·00008	1·3	98·7
0·004	—	trace	practically all
0·002	—	trace	practically all

If put into the form of a curve, where the ordinates represent the percentage of dye left in solution and the abscissæ the original concentration of the solution, the curve only approaches the axis (*i.e.* zero concentration) asymptotically. In other words, the more dilute the original solution the more firmly the dye is adsorbed. A consequence of this is that when we attempt to wash out an adsorbed substance by the pure solvent, the removal (or *elution*) gets slower and slower. Elution can be hastened by the use of another solvent, of a nature that reduces adsorption. Similar relations are found to exist between proteins and electrolytes. By continuously washing a protein, *e.g.* gelatin, with distilled water, the removal of electrolytes becomes slower and slower, and it is impossible within finite time to get rid in this way of the last traces of ash.

CHROMATOGRAPHY.† An interesting application of the phenomena of adsorption is the technique of chromatography, first introduced by Tswett, by which dissolved substances can be separated from one another. A column of a powdered adsorbent is packed into a vertical glass tube, and the solution to be analysed poured on and allowed to percolate ; if the components to be analysed are coloured (*e.g.* plant pigments dissolved in petroleum ether) and the adsorbent white (*e.g.* calcium carbonate) it is seen that different coloured layers

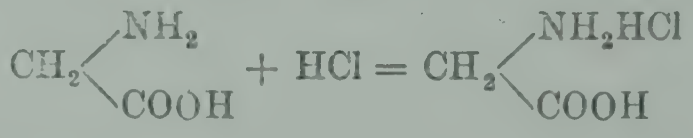
---

* **BAYLISS, W. M.** *Bioch. J.*, **1906, 1, 175.**

† WILLIAMS. An Introduction to Chromatography. 1946. (Blackie & Son Ltd.)

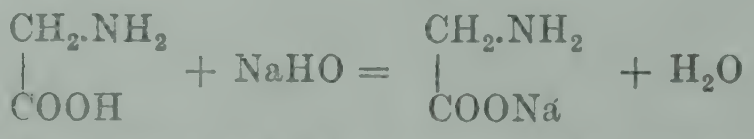
are formed owing to varying intensity of adsorption of different pigments. I
now the solution is followed through by pure solvent (*e.g.* petroleum ether) th
different bands move further apart and are separated by white intervals. Th
coloured zones can now be removed separately and the pigments eluted (*e.g.* b
alcohol). Modifications of this method allowing of the separation also o
colourless substances from one another have been developed, and have prove
to be of great value.

Colloidal Ions. Although the chemical behaviour of colloids is largel
determined by surface phenomena, it is also conditioned by the chemical structur
of the colloid molecule and by the charge carried by the latter. A good exampl
of these combinations is presented by globulin, the behaviour of which has bee
studied by Hardy.* Four states can be recognised both in the solid conditio
and in solution, viz. globulin itself, compounds with acid or with alkali, an
compounds with neutral salt. The amount of acid and alkali combining wit
the globulin is indeterminate, the effect of adding either acid or alkali to th
neutral globulin being to cause a gradual conversion of an opaque, milk
suspension into a transparent solution. On drying HCl-globulin, the solid is
found to contain all the chlorine used to dissolve it. The acid may therefore b
regarded as being in true combination. Both acid and alkali globulins act as
electrolytes, the globulin being electrically charged and taking part in the
transport of electricity. It is, in fact, present as an ion, charged positively or
negatively, according to the reaction. In order to produce the same degree of
solution, the concentration of the alkali added must be double that of the acid.
The relation of globulin to acids and alkalies is similar to that of the so-called
ampholytes or amphoteric substances, such as the amino-acids. An amino-acid
such as glycine can react as a basic anhydride with other acids thus :



$$CH_2\begin{cases}NH_2\\COOH\end{cases} + HCl = CH_2\begin{cases}NH_2HCl\\COOH\end{cases}$$

or as an acid with bases :



$$\begin{matrix}CH_2.NH_2\\|\\COOH\end{matrix} + NaHO = \begin{matrix}CH_2.NH_2\\|\\COONa\end{matrix} + H_2O$$

Like these, too, globulin forms soluble compounds with neutral salts. An
amphoteric electrolyte thus acts as a base in the presence of a strong acid and
as an acid in the presence of a strong base.

According to later developments of physical chemistry, amino-acids more probably have what is called a *zwitterion* structure : $^+NH_3.R.COO^-$. If this is so, then the action of acids and alkalies differs from that previously accepted, for the zwitterion forms a "dipole," positive at one end and negative at the other. Addition of a strong acid therefore acts, not by enhancing the basic property of the NH_2 group, so causing the molecule to acquire a positive charge, but by depressing the ionisation of the carboxyl, *i.e.* the negatively charged group :

$$^+NH_3.R.COO^- + H^+Cl^- = {}^+NH_3.R.COOH + Cl^-$$

The zwitterion theory can also be applied to polypeptides and proteins.†

From true electrolytes, colloidal solutions differ in the fact that their particles are of varying size according to the conditions in which they exist, and carry varying charges of electricity, whereas an ion such as $Na^{\cdot}$ or Cl' has a mass which is constant for the ion in question and always carries the same electric charge. The charged particles of an acid- or alkali-globulin may be distinguished therefore as *colloidal* or *pseudo-ions*. Whether a protein has a positive or a negative charge depends chiefly on the hydrogen ion concentration of the medium. At the *isoelectric point* it carries no charge (or, according to the zwitterion theory, there is complete ionisation of both groups).

COMBINATIONS BETWEEN COLLOIDS. Besides the compounds between colloids and electrolytes, combination, or at least interaction, takes place between different colloids. Many colloids are precipitated by other colloidal solutions. This effect is always found to occur when the colloidal solutions carry opposite charges. Thus ferric hydrate in colloidal solution is precipitated by colloidal silica or colloidal gold, both colloids being thrown out of solution. On the other hand certain colloids may exercise a protective influence on other colloidal solutions. Thus, as Faraday first showed, colloidal gold is much more stable in the presence of a little gelatin. The colloids of serum can dissolve a considerable amount of purified globulin. Although the latter alone shows a drift in the electric field, the resulting solution is quite unaffected by the passage of a current through it. In these cases the protective colloids carry no charge, but the same protective effect may be observed if a large excess of *e.g.* an electro-positive colloid be added to an electro-negative colloid. This interaction between different colloids probably plays an important part in many physiological phenomena. We have reason to believe that the reactions between toxin and antitoxin and between enzyme and substrate, which we shall study later, are of this character, and that the compounds formed belong to the class of adsorption combinations.

In these combinations, although the chemical nature of the colloidal molecules is concerned, there is an absence of definite equilibrium points such as we are accustomed to in most chemical reactions. The inertia of the system and the large size of the molecules determine the occurrence of false equilibria and of delayed reaction, so that the condition and behaviour of a colloidal system at any moment are determined, not only by the quantitative relations of its components but also by the past history of the system.

THE COAGULATION OF COLLOIDS

Most colloidal solutions are unstable, and the relations between the suspended particle or molecule and the surrounding fluid may be upset by slight changes of reaction or the presence of minute traces of salts. As a result the hydrosol is destroyed, the suspended particles aggregating to form a precipitate or gel, the result varying according to the nature of the colloid and its concentration. Thus gelatin changes from the condition of hydrosol to hydrogel with fall of temperature. On the other hand, by adding calcium chloride to an alkaline solution of casein, we obtain a mixture which sets to a jelly on warming but becomes fluid again on cooling. Other agencies may lead to the production of changes which are irreversible.

If a solution of egg-albumin or globulin be heated in neutral or slightly acid medium and in the presence of neutral salt, the whole of it is thrown down in an insoluble form. This coagulated protein is insoluble in dilute acids or alkalies and is said to be *denatured.* With concentrated solutions of protein, heat coagulation results in the formation of a gel. In dilute solutions the result is the production of a flocculent precipitate.

Another method is the so-called mechanical coagulation. If a solution of globulin or albumin be violently shaken, a shreddy precipitate makes its appearance in the solution, and by prolonged shaking it is possible to throw down 80 or 90 per cent. of the dissolved protein in the coagulated form. Ramsden showed that this mechanical coagulation is a surface phenomenon. In the case of proteins the molecules at the surface are so closely packed together that they form an actual solid pellicle. When the solution is violently shaken, new surfaces are constantly being formed, and as the older surfaces are withdrawn into the fluid, the solid pellicle on them is rolled up into a fine shred of coagulated protein.

CHAPTER VII

THE PASSAGE OF WATER AND SOLUTES THROUGH MEMBRANES

The heterogeneous structure of the body involves the presence of surfaces of separation, which may be of any order of size, molecular, microscopic, or evident on simple dissection. In the single cell the membrane bounding the cell and separating it from its environment is as a rule invisible under the microscope. Similar membranes must be assumed to be bounding the cell nucleus. In other cases the membrane is of a definite thickness: it may be apparently structureless and homogeneous such as the elastic lamina in the back part of the cornea of the eye, or it may be made up of cells of various shapes. The bounding membrane of the blood capillaries or of the lung alveoli is composed of very thin flat cells; or the membrane may consist of cubical or columnar cells, as in those forming the lining membrane of the small intestine or the essential part of secreting glands. In such a cellular membrane any transference across the membrane may be regulated by the cells themselves, taking up a substance on one side and turning it out on the other, in many cases after having undergone modification. It is impossible, however, to investigate the part played by these cells in the transference of substances across a membrane unless we know what factors determine the passage of water and dissolved substances across membranes which do not take an active part in the process of transference. Such a membrane we can imagine of any thickness, from one molecule upwards since the thickness will affect only the rate of passage of substances across it. Surface films, one molecule in thickness, are readily formed on liquids, *e.g.* when fatty acids are placed on water. In such a case the molecules are arranged vertically, with the carboxyl groups next to the water.* Similar *mono-molecular films* are also in all probability formed at the surface of colloid solutions and, as a general case, at surfaces where adsorption occurs.

The following factors may be concerned in causing the movement of water or dissolved substances across a membrane :—

(1) **Hydrostatic Pressure.** The significance of this is familiar in the ordinary process of filtration. A filter pump merely increases the difference of pressure between the two sides of the filtering membrane. The denser the membrane the greater will be the difference of pressure required to effect a passage at a certain rate.

(2) **Diffusion and Osmosis.** This has already been discussed in Chapter V.

The physico-chemical conditions for passage of water and salts across membranes have been studied in detail by Schreinemakers † and found to be complex, since when two solutes are present together in the solution on either side of a given membrane, the resultant transfer of water or of either solute depends on many factors. If the membrane is truly semi-permeable in the classical sense, *i.e.* is only permeable for water, equilibrium between two-solute mixtures will be reached when the two solutions have the same osmotic pressures, but their composition will probably not be the same. If the membrane is permeable to both solutes as well as to water, then when equilibrium is reached the composition on both sides will be identical, though the changes undergone in reaching such equality (or the "osmotic path") will be complicated and not predictable on general theoretical grounds, though modified by the properties of the membrane and the original composition and amounts of the solutions. A substance may at one phase of the diffusion pass in one direction and afterwards in the opposite one. In general terms, when n substances can pass a membrane, then there will be 2^n different types of diffusion, of which one is impossible, and

---

* ADAM. The Physics and Chemistry of Surfaces. 1930. (Clarendon Press, Oxford) LEATHES. *Lancet*, 1925, **103**, (1), 853.

† SCHREINEMAKERS. *J. Gen. Physiol.*, 1928, **11**, 710; 1929, **12**, 555; 1930, **13**, 335.

$2^n - 1$ possible. For instance, if there are six substances, there will be $2^6 - 1 = 63$ actually possible types of diffusion (*i.e.* when each substance may move either to right or to left that is counted as two types). Which of the possible types will actually occur depends on the properties of the membrane, and these cannot be predicted.

(3) **Electrical Difference of Potential.** This factor probably plays an important part in the transference of dissolved substances across membranes in the body. Just as differences of hydrostatic pressure determine movements of a fluid *en masse*, differences of electric pressure will serve as a driving force for the charged constituents of fluids. These may be actual particles, *e.g.* oil droplets or bacteria, the ultra-microscopic particles of colloids or the ions derived from the electrolytic dissociation of dissolved molecules. The passage depends on the fact that any charged particle will move towards the pole of opposite charge in an electric field. The electricity passing through the fluid is in fact carried by the particles which are thus set into movement. If a current is passed across a membrane immersed in an electrolyte, the final result will be a chemical difference on the two sides and therefore a permanent difference of potential which will tend, on breaking the current, to drive the ions in the opposite direction and to re-establish equilibrium on the two sides. The process of passage of a current across a membrane is said thus to give rise to *polarisation*, and after the passage of the current the membrane is polarised, *i.e.* presents a difference of potential between its two sides.

The presence of a membrane impermeable to the colloidal constituent of an ionised colloidal salt will affect the passage of a current through the membrane in one direction, so that the phenomenon of "irreciprocal conductivity" is presented. Thus if one side, A contains the potassium salt of hæmoglobin and the other side, B contains KCl, a current can pass from A to B, since it is carried from A to B by the potassium ions which can pass freely through the membrane, and from B to A by the electro-negative ions, namely, chlorine. An application of this method called *electro-dialysis*, is in fact one of the best ways of freeing protein solutions from adsorbed basic ions. If, however, B be made the positive pole, no current can pass because the electro-negative ion, namely hæmoglobin, cannot pass through the membrane. If we take an arrangement with three compartments A, B and C, of which only B contains a protein salt, the passage of a current will be hindered in both directions, since, whichever the direction of the current, the protein molecule will be required to carry the negative electricity either into A or into C. This resistance to the passage of a current will be still more marked if the membrane is impermeable also to certain inorganic ions. It is on this account that whole blood presents a greater resistance to the passage of a current than does the serum, each of the red blood corpuscles serving as a non-conductor and therefore diminishing the total area through which the current can pass.

In nearly every case the hindrance to migration of one or more ions by the membrane will prevent the passage of other associated ions to which by themselves the membrane would be freely permeable. These ions will travel an infinitesimal distance into the membrane, till they are held back by the electrostatic attraction of the oppositely charged ions which cannot pass. This electrostatic tension will give rise to a charge on the surface of the cell, and in nearly every case free swimming cells such as red blood corpuscles are found to be charged differently from the solution in which they are suspended. In most cases this charge is negative, so that, if a current be passed through blood, the red blood corpuscles will tend to travel towards the positive pole.

A charge on a membrane may also cause water to pass with an electric current through the membrane. This may be explained as follows: A charged particle, if free to move, will travel to the pole with the opposite charge; thus clay is negatively charged and migrates to the anode. Suppose now the membrane is made of clay and that electrodes are immersed in the fluid, the anode in A and the cathode in B. Now since the clay partition is fixed the water moves instead, viz. to the negative pole, so that the volume in B is increased. This phenomenon is called *electro-endosmosis*. With a gelatine membrane, the charge depends on the reaction of the solution. If this is alkaline, the gelatin is, like clay, negatively charged, but if acid it is positively charged and the direction of the flow is reversed.

(4) **Permeability of the Membrane.** In its relation to permeability, an animal membrane may be either passive or active.

(*a*) *Passive Permeability.* For this it makes no difference whether the membrane is dead or alive. The nature of the membrane cannot add to the force concerned in the transference of water or dissolved substances across it: it can only serve as a limiting condition for the action of the forces just enumerated. How these forces will act in regard to different kinds of membrane will depend on the permeability of the membrane, and this again on its physical and chemical structure. The membrane may be absolutely impermeable, as in the case of those surrounding certain eggs, and in plants as a means of protection for seeds. In most cases, however, the permeability is relative. Sometimes there is permeability to all crystalloids, as in a dialyser (*v.* Chapter V).

Some animal cells have a permeability of this dialyser-membrane type. Examples are the endothelial cells of capillaries in most parts of the body: the membranes formed by continuous sheets of such cells even allow a slight passage of the proteins of smaller size, especially when the endothelium is damaged. The clearest example of ultra-filtration is seen in the glomerular epithelium of the kidney. The capillaries of the central nervous system lie at the other extreme, and show a selective permeability towards many dissolved substances: water- and lipoid-soluble substances pass easily, anions, cations, glucose and urea only slowly.

A still greater restriction of permeability is obtained with "semi-permeable" membranes. No completely semi-permeable membrane is known, *i.e.* one which allows the passage of water but is impermeable to all dissolved substances. Such membranes are of much interest since, as already mentioned, the surfaces of all cells show in greater or less degree the phenomenon of semi-permeability. Thus, red blood corpuscles are only slowly permeable to most kations, such as Na and Ca, but allow the passage of K, urea, CO_2, chlorine, OH ions, as well as NH_4 and glucose (slowly).* To anions the order of permeability is $NO_3 > Cl >$ acetate > oxalate > sulphate > citrate, *i.e.* in order of increasing hydration.

Finally, we may have a form of permeability which depends on the solubility of the solute in the membrane itself, or on the formation of reversible compounds between the solute and the membrane. If a rubber balloon containing air be placed in a vessel filled with carbon dioxide, the balloon rapidly expands and may even burst. The carbon dioxide molecules are dissolved in the rubber and diffuse from the other side into the air inside the bag. The molecules of nitrogen and oxygen cannot pass in the reverse direction, so that the balloon expands. It has been supposed that phenomena of a similar nature may play a part in determining the peculiarly specific permeability of cell membranes. Cell surfaces are freely permeable to a number of organic substances, such as the alcohols which are soluble in lipides. It was suggested that the limiting membrane is lipoidal in nature, and hence allowed easy passage to lipoid-soluble substances, as already discussed on p. 16.

(*b*) *Active Permeability.* In many instances the plasma membrane is able to transport ions, and also non-ionised substances, from one side where a low concentration is present to the other side, where there is a high concentration. This transport, against the gradient of concentration must involve the utilisation of energy, provided by the metabolism of the cell contents, and is therefore dependent upon the life of the cell.

One way in which transport could be effected is by change of the material transported into some other substance, which is not diffusible, *e.g.* if a cell can convert glucose into glycogen, or phosphate ion into creatine phosphate or A.T.P. This would, however, although dependent on the metabolism of the cell, be a different case, and not an example of transport against a gradient.

It is different with most inorganic ions, for these are apparently all present in the free state within the cell as well as in its environmental fluid. Yet in almost every type of cell, plant or animal, we find that the ionic contents of the cell differs widely from that of the fluid outside it in which it has grown and lived. Thus the Cl ion in the frog muscle fibre is only 1·2 m Eq/l, while that in blood serum is 74·3 m Eq/l. The red blood cell is another example of different ionic distributions inside and outside, as shown in the table (p. 82).

In each case the concentration of K is higher, sometimes very much higher, and that of Na lower, inside the cell than outside. It has often been supposed that, because this difference is maintained, the cell membranes must be impermeable to one (Na) or both ions. But experiments with the radio-active isotopes ^{42}K and ^{24}Na do not support this view. During muscular work some K leaves the muscle fibres and is replaced by Na. Also, in absence of glucose, K leaves the red blood cells and returns again when glucose is added. We must

* Hsu. *J. Physiol.*, 1935, **84, 29P**.

Cell.	Concentration in mm/1. of Fluid.			
	Potassium.		Sodium.	
	Inside.	Outside.	Inside.	Outside.
Dog, red blood cell .	9	5·5	145	147
Man, red blood cell .	125	5·9	36	160
Frog, muscle . .	126	2·6	15·5	103·8

conclude, therefore, that these ionic transportations are effected as a result o the expenditure of energy by the cell.

The permeability of living membranes often shows peculiarities, which depend on thei being alive. For instance, Reid * found that fresh frog's skin allows water to pass only from without inwards, and Wertheimer,† found that in frog's skin sodium salts and acid dyes only pass from without inwards, while glucose and basic dyes only pass outwards.

The explanation of irreciprocal permeability probably varies from instance to instance, but is mostly unexplained. As regards water, it is thought to be related to the so-called anomalous osmosis which depends on the membrane being electrically charged. Thus, the frog skin has a negative charge outside and a positive one within : this charge is dependent on the metabolism of the skin, as a result of which H′ and HCO_3′ are kept at a high level on the inside. The resultant water movement is probably due to electro-osmosis.

The surface membrane of a cell differs, moreover, from artificial semi-permeable membranes in that its permeability varies according to the state of the cell itself. Thus, activity of a cell is always attended with an increased permeability of its surface membrane, and this change may be an important factor in the execution of its functions.

Not only does the function of the cell determine the properties of its surface, but the reverse holds true. Cell activities seem to be determined to a very large extent by alterations in the amounts of substances in the surrounding medium even though they cannot penetrate the limiting membrane of the cell. This is especially well marked in the case of contractile tissues, such as the heart, where the normal beat depends on the presence in the surrounding fluid of K, Na and Ca ions. None of these can penetrate the cell membrane : they can merely be adsorbed on the cell surface, and it is their presence there which in some way or other modifies all the functional activities of the muscle cell.

(5) **Membrane Equilibria.** If a colloid is in the form of a compound with either acid or base, which undergoes ionic dissociation, certain interesting results are possible.‡ For instance, Congo red is a sodium salt of a colloid acid. If this be placed in an osmometer which is immersed in water, a certain osmotic pressure is developed. Although sodium ions can pass readily through the membrane of the osmometer, they carry a positive charge, so that if they broke away from their combination with Congo red acid, the fluid in the osmometer would become negatively charged. The sodium ions are thus held in the immediate neighbourhood of the membrane by the electrostatic attraction between Congo red acid ions and the sodium ions. If we add sodium chloride to either the inner or outer fluid, the osmotic pressure is found to fall if time be allowed for equilibrium to be established between the two sides of the membrane. At this point the outer fluid, which is free from dye, contains a larger percentage of chloride than the inner fluid. This difference is permanent and is more marked the greater the concentration of the dye. In the following Table are given the concentrations of the two fluids with different percentages of salt, the numbers indicating the litres to which each gramme molecule of the salt is diluted (i.e., the *reciprocals* of the the concentrations).

Dye.	Chlorine.		
	Inside.		*Outside.*

* Reid. *J. Physiol.*, 1890, **11**, 312.

† Wertheimer. *Pfluger's Arch.*, 1923, **199**, 383.

‡ Bayliss, W. M. *Proc. Roy. Soc.*, 1909, **81B**, 269 ; 1911, **84B**, 229.

Donnan * independently showed that these results must occur from thermodynamic considerations, so that their general statement is spoken of as the "Donnan equilibrium."

When a saline solution contained in a collodion sac is suspended in distilled water, the simple laws of diffusion suffice to explain the final equal concentrations of salt reached on both sides of this permeable membrane. If, however, a sodium salt of a non-diffusible anion (R′) be placed on one side of a dialysing membrane and water on the other side, simple osmosis does not suffice to explain the final state of equilibrium. The Na will tend to pass through the membrane, but this can only take place if an equivalent quantity of OH (from the water) diffuses in the same direction. Thus :

Initial State		*Final State*	
$Na^{\cdot}$	H_2O	$Na^{\cdot}$	$Na^{\cdot}$
R'		$H^{\cdot}$	OH'
		R'	

The water will become alkaline, while the solution in the left compartment will become less alkaline. If, on the other hand, a salt, say a chloride, of a non-diffusible kation, were placed on the left-hand side, then the water outside would become acid, and the solution on the left less acid.

Again if NaR be placed on one side of the membrane and NaCl on the other side, equilibrium will be attained only when the products of the concentrations of [Na] and [Cl] are the same on opposite sides of the membrane.

Initial State		*Final State*	
$Na^{\cdot}$	$Na^{\cdot}$	$Na^{\cdot}$ Cl'	$Na^{\cdot}$ Cl'
R'	Cl'	R'	

$$[Na]_1 \times [Cl]_1 = [Na]_2 \times [Cl]_2$$

This can only occur if $[Na^{\cdot}]_1 > [Na^{\cdot}]_2$ and $[Cl']_1 < [Cl']_2$.

This difference in the concentration of the diffusible ions on opposite sides of the membrane gives rise to a potential difference which is equal to

$$58 \log. \frac{[Cl']_1}{[Cl']_2} \text{ millivolts.}$$

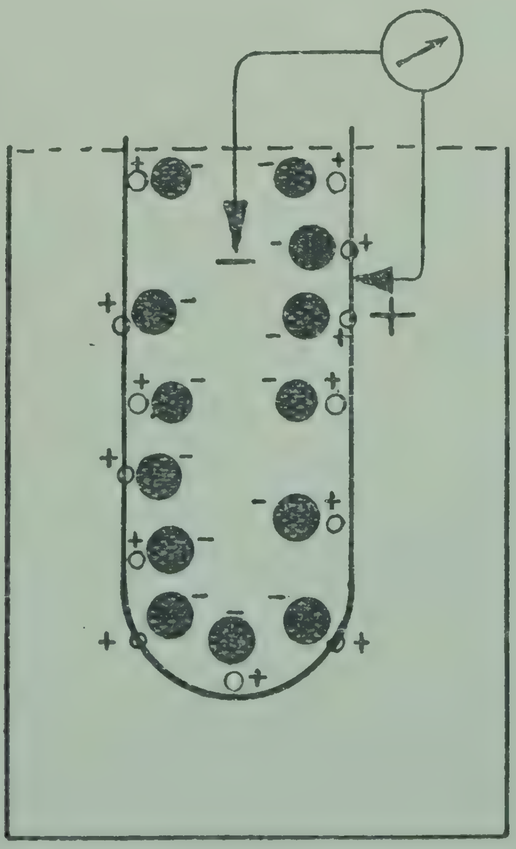

FIG. 26.

---

* DONNAN. *Ztschr. f. Elektrochem.*, 1911, **17**, 572.

Thus, suppose we have, as in Fig. 26, a collodion sac filled with an alkalin solution of a protein, *i.e.* with the protein in the form of a salt with a base, an immersed in water or saline solution.

The proteinate solution will be ionised into the basic ion B^+ and the larg protein acid ion Pr^-, and the latter cannot pass through the collodion therefore, although the collodion is permeable to the basic ion, this cannot pas through it either, because it is kept back by the attraction of the oppositel charged protein ion. But, owing to the tendency of the B^+ ion to penetrat the membrane, the two ions are arranged in an orderly fashion, the negativel charged ones innermost and the positively charged ones next to the membran or perhaps just within its substance. The membrane is thus *polarised* o charged, the outer surface positively, so that if we lead off from its outer an inner surfaces a potential difference can be demonstrated and shown to agre with theoretical calculations.

Since living cells are likewise filled with protein and other colloidal substance in combination, partially ionised, and the living tissues abound in membrane impermeable to colloids, Donnan's theory of "membrane equilibria" must have a wide application in physiology. But the effects are modified, and often obscured, as a result of other properties of the cell membranes, *e.g.* that of being permeable to some ions and not to others. Thus red blood cells are permeable to anions but not to cations ; their surface is negatively charged.

CHAPTER VIII

BIOELECTRIC POTENTIALS

It has long been known that all living tissues, animal and plant, are capable of showing developments of electric potential. In the exceptional cases of the electric fishes potential differences of several hundred volts, capable of stunning a horse, can be generated, but in most cases the potential is measurable in millivolts, and rarely exceeds 100 mV. Nevertheless these potentials are easily measured and recorded and have been the subject of much attention for many decades. They are of especial interest in connection with the active state of tissues, *e.g.* contraction of muscle, impulse transmission in nerve, secretion of gland cells, and are believed to be fundamental phenomena of the excitatory state to which those activities are due.

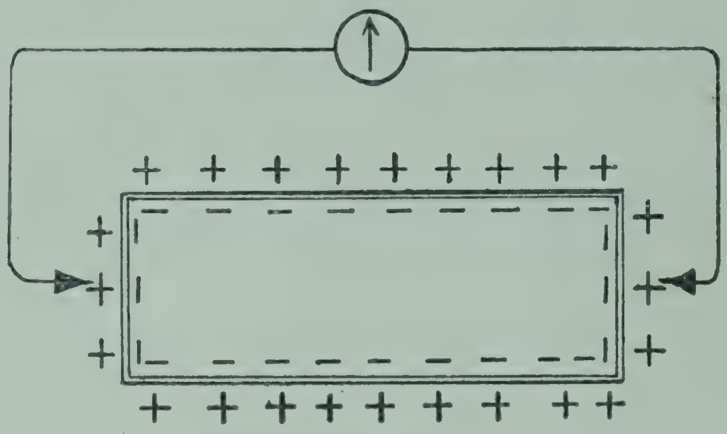

Fig. 27.

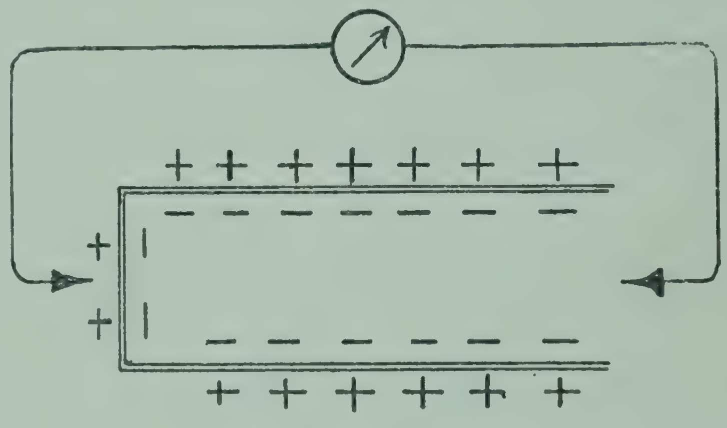

Fig. 28.

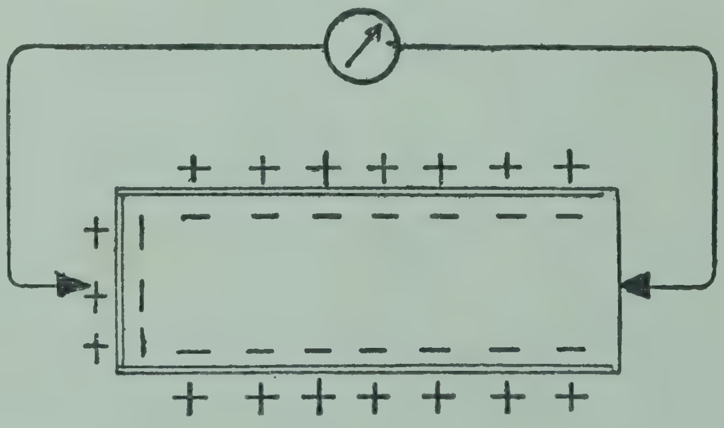

Fig. 29.

Figs. 27, 28, 29. To show the origin of bioelectric potentials. The double line round the cell indicates a polarised membrane, the single line in Fig. 29 a depolarised one.

In general, any two points at the surface of a resting cell are at the same potential, and the resting cells in a tissue all have the same surface potential. When a cell, or part of it, is excited, however, the surface of that part which is excited becomes negative to the resting surface, so that if contact between active and resting surfaces is made through a galvanometer, a current will flow from the resting to the active tissue, as long as the activity lasts. Further, if the surface of a resting cell is broken at any point, a lead-off from the damaged area, which is equivalent to a lead-off from the cell contents, will show this also to be negative to the resting and uninjured outer cell surface.

These potential differences must be due to unequal distribution of ions, and much convergent evidence leads us to regard the plasma membrane as the principal theatre of this ionic orientation : the bioelectric potentials are hence often spoken of as *membrane potentials*, and are considered as being due to *polarisation* of the plasma membrane. By this we mean that attached to, or incorporated in, the inner surface of the membrane is an excess of negatively charged anions, while on the outer surface are either very few anions, or else an excess of cations. Hence the membrane somewhat resembles a charged condenser, with the electrons accumulated on the inner surface, but itself of high insulating power so that the charge is maintained (Fig. 27). Damage to the membrane enables the two surfaces to be connected through a galvanometer, so that current flows (Fig. 28). But it is a continuous, not a brief current, that the charge on the membrane must be maintained in some way, and t analogy with a condenser can only be a partial one.

When a part of the cell becomes active, current also flows in a simil direction, *i.e.* from the resting to the active surface (Fig. 29), and it can be show that at the same time the resistance of the membrane at the active part

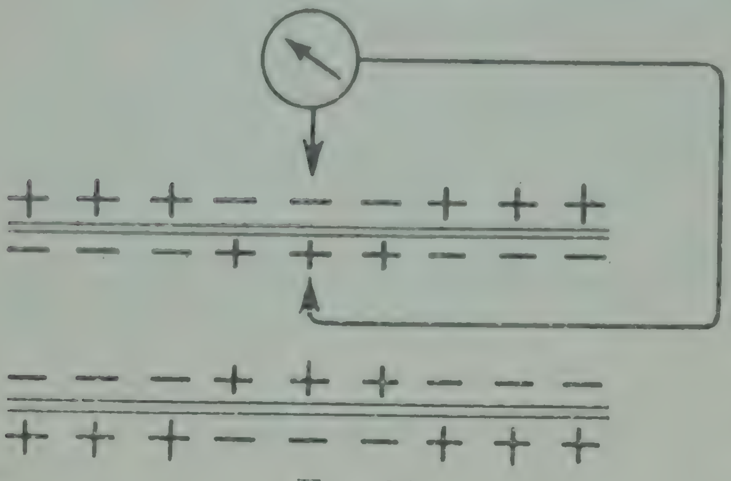

Fig. 30

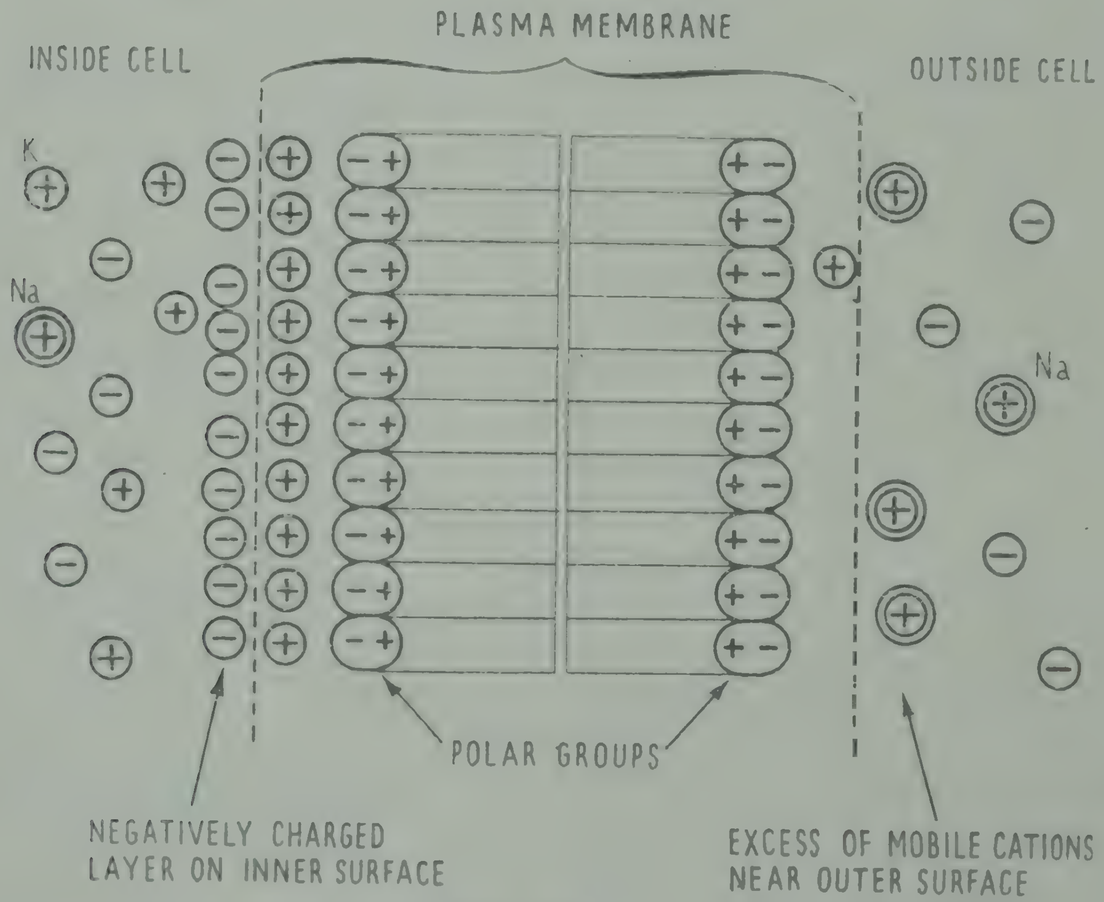
suddenly lowered to about $\frac{1}{40}$ of i resting value, allowing the current flow. Activity has thus been regarde as due to local depolarisation of th plasma membrane. But it now appear that it is something more than mer local *de*polarisation, and that, in fac the polarity of the membrane, is actuall *reversed*, *i.e.* there is a local excess o negatively charged ions on the *outsid* instead of on the inside of the membrane; this has been shown, as i Fig. 30, by leading off from both sides of the membrane with micro-electrodes, avoiding all short circuiting.

The cause of the polarisation of the resting plasma membrane is not exactly known, but is probably related to a specific ionic permeability, due to the molecular structure of the membrane. The potassium ion is small, and can enter the membrane; the sodium ion is hydrated and thus is too large to penetrate. We have seen (p. 17 and Fig. 9) that orientated lipoid molecules are probably the basis of the plasma membrane: the orientation is such that the polar groups of the lipoid molecules are at or near the surfaces and are so turned that their negatively charged ends are at the surfaces and the positively charged poles within the membrane as in Fig. 31. These negative charges attract the cations in the aqueous phase, of which potassium only can penetrate, however: the potassium does not pass right through the membrane, but merely enters the surface layer next to the negative charge on the dipole, and when it does so the anion is left behind, but remaining at or near the surface owing to the attraction exercised by the adsorbed cations. The surface of the membrane thus acquires a negative charge, the value of which depends on the concentration



PLASMA MEMBRANE
INSIDE CELL
OUTSIDE CELL
K
Na
Na
POLAR GROUPS
NEGATIVELY CHARGED LAYER ON INNER SURFACE
EXCESS OF MOBILE CATIONS NEAR OUTER SURFACE

Fig. 31

of potassium in the solutions on the two sides. In the excitable tissues, there is a high concentration of K inside the cell and a low one outside, where Na replaces it (for squid fibres the potassium ratio is 279 m Eq/l. in axoplasm to 10 m Eq/l. in sea-water (and tissue fluid) *) ; hence the inside of the membrane is negative to the outside, as we have seen.

The maintenance of the high concentration of K ions and the low level of Na ions inside the cell is due to the expenditure of energy by the cell, and ceases when the cell dies, or when it is deprived of oxygen. It is therefore the result of metabolic changes taking place in the cell.

During the state of excitation the permeability of the plasma membrane is altered. According to the classical theory it now becomes freely permeable to both anions and cations, as a result of a molecular breakdown, and hence the active region of the membrane loses its charge ; it is then *relatively* negative to the resting surface. But, as stated above, more recent work has shown that, at all events in some instances, the charge on the membrane is not merely lost but reversed, so the depolarisation theory now appears inadequate. What actually happens is a matter for further conjecture. An attractive suggestion is that the inner one of the two orientated lipoid layers becomes disorientated, leaving the outer layer unopposed and therefore with a considerable negative charge at the surface.

CHAPTER IX

ENZYMES AND ENZYME ACTION

Most of the phenomena of life are accompanied and conditioned by chemica changes, both of synthesis and of disintegration, of the most varied character Synthesis by ordinary laboratory methods falls far short of the process as i actually occurs in the living cell, both in completeness of the reaction and in th ease with which it can be effected. Many of the chemical transformation effected by living cells we have so far been quite unable to imitate. Th distinguishing characteristics of the net chemical changes wrought by th living cell are :

(1) The rapidity with which they are effected at relatively low temperatures.

(2) The specific direction of the process, which is therefore almost complete, with a surprising absence of side reactions. This characteristic may, however, be regarded as a consequence of the first, since an increase in the velocity of any given reaction will determine a preponderance of this reaction over all others.

(3) The usage, or production, of optically active substances when possible.

All chemical changes in living beings take place in a watery medium. But water plays a direct part in many of the reactions which take place. Apparently the molecule may act as a whole, or the H and OH ions may be separately involved. When the molecule acts as a whole, *e.g.* in hydrolysis, the water is added to the molecule on which it acts, with the production of a hydrated product or with a splitting of the original molecule into two parts as a result. The rapidity with which these changes occur in the body is very striking. A solution of boiled starch in water may be left for many months without undergoing change, but if we take the solution into the mouth, keep it there for twenty seconds and then eject it, the fluid is found to contain no starch but to contain maltose. In this case there has been a taking up of water molecules by the starch, so that the interaction of water appears in the equation—

$$2\ (C_6H_{10}O_5)_n + nH_2O = nC_{12}H_{22}O_{11}$$

This change, which would never occur spontaneously, is due to the action of a catalytic agent present in the saliva. Such agents are given the general name of *enzymes*, and they play a dominant part in the carrying out of the varied chemical changes which occur in all living things.

ENZYMES

After 1857, when Pasteur showed that the process of alcoholic fermentation, by which glucose is converted into alcohol and carbon dioxide, was apparently inseparable from the presence and growth of living yeast cells, it became customary to suppose that most of the chemical changes which took place in all living things were in some similar way dependent upon the activity and structural integrity of living cells. But in 1897 the Buchner brothers showed that a cell-free juice obtained from yeast could effect an identical fermentation of glucose. We now know that this yeast juice contains a mixture of enzymes by which the chemical reactions known as fermentation are catalytically promoted ; the present-day view is that nearly all the chemical reactions of life are similarly promoted by enzymes, which, when isolated, can perform the same catalyses *in vitro*. Minimal quantities of enzyme can induce chemical changes involving almost unlimited quantities of other substances, the only result of increasing the quantity of enzyme being to quicken the rate of the change. They are, in fact, *catalysers* or *catalysts*. A catalyser is a substance which will increase the velocity of a reaction without adding in any way to the energy changes involved n the reaction, or taking any part in the formation of the end products. The eactions catalysed by each enzyme are very restricted in character, *i.e.* each nzyme is specific. The reactions are usually reversible.

Enzymes of various kinds occur in the digestive juices. Others may often e extracted from the tissues with water, glycerol, salt solutions, or dilute lcohol. Others are insoluble, either because they are bound chemically to the ell cytoplasm, or because they are adsorbed to a constituent of the cytoplasm. he difficulty in their isolation is increased by the fact that all of them are olloidal, and present the tendency common to all colloids of being adsorbed o other colloidal matter as well as to precipitates. A common method of btaining a concentrated preparation of an enzyme is to add to its solution strongly adsorbing colloidal precipitate, such as alumina or kaolin. Kaolin, eing negatively charged, adsorbs those enzymes which have basic characters, while alumina, a positively charged colloid, adsorbs acid substances. The nzyme is carried down on the adsorbent and may be obtained in solution by "elution" with water or dilute acid or alkali. By fractional adsorption with different adsorbents, enzymes may be greatly concentrated and also separated from one another. In this way many enzymes formerly considered s entities have been shown to consist of mixtures of two or more enzymes, and some have been obtained in a pure crystalline state.

All the known enzymes are proteins, or conjugated proteins.

The substance which is chemically altered as a result of enzyme action is called the *substrate.*

It is important to note that nearly all the changes brought by enzymes can be effected by ordinary chemical means. Thus the disaccharides can be made to take up a molecule of water and undergo conversion into monosaccharides. A solution of maltose at ordinary temperatures undergoes practically no change. If the solution be warmed, a slow process of hydration takes place which is quickened by rise of temperature, so that if the solution be heated under pressure to, say, 110° C., hydrolysis occurs with considerable rapidity. If, however, a little maltase be added to the solution, the change of maltose into glucose takes place rapidly at a temperature of 30° C. The action of the enzyme is to quicken a process of hydrolysis which without its presence would take an infinity of time for its accomplishment.

A very large number of enzymes are now recognised, and new additions are constantly being made to the list as our knowledge of cellular metabolism expands.

The enzymes are often remarkably specific in the substrates on which they can act. Whereas all the disaccharides are converted by acids into the corresponding monosaccharides, the enzyme invertase acts only on cane sugar and has no action on maltose or lactose, each of which requires a specific enzyme (maltase, lactase) to effect its hydrolysis. But we can also find examples of a restricted action even among inorganic catalysers.

In the chemical transformations of cellular metabolism each reaction is usually the result of the action of a specific enzyme which catalyses that reaction, and that reaction alone. This high specificity represents an organisation of the functions of the living cells at the molecular level. It is clear that the chemical changes which take place in the course of metabolism must be the result of the action, in an ordered sequence, of large numbers of enzymes.

Absolute specificity is shown as between enzymes of different groups : *e.g.* lipases will not act on proteins. In other directions, within their groups, the specificity is variable, and is probably related to particular chemical groups in the substrate : thus lipases will also hydrolyse many other esters besides fats. It has been found that, whereas maltase splits up all the α-glucosides, it has no power on the β-glucosides : that is to say, maltase will fit into a molecule of a certain configuration, but is powerless to affect a molecule which differs from the first only in its stereochemical structure. On the other hand emulsin which breaks up β-glucosides, has no influence on α-glucosides. This specific affinity of the enzymes for optically active groups of bodies suggests that the operative groups of the enzyme itself may be optically active.

THE NATURE OF ENZYMES. By the use of selective adsorption, enzymes may separated from one another and from many accompanying impurities, and obtained i state of great concentration. Crystalline preparations of several enzymes, *e.g.* urease pepsin[†], chymotrypsin, trypsin[‡], amylase, catalase, etc., have been obtained.

All enzymes are colloidal; some at all events consist of two parts closely associat viz., a colloidal "carrier" which is non-specific, and one or more specific active groups, which union with the substrate is effected. This union takes place with definite groups the substrate molecule, and the specific action of the enzyme is determined by the natu and position of the receptor group to which the specific group of the side chain becom attached. Thus, in the enzymes of the peptidase class the imino group is one point attachment. The purest enzymes, crystalline pepsin[§], trypsin[‖], urease[¶] and amylase are proteins, and probably all enzymes are of protein nature, or contain a protein as essential constituent. Some (*e.g.* urease, dehydrogenase, lipase, phosphatase) depend f their activity on possession of an SH group; such enzymes are inactivated by oxidisi agents which convert the SH groups to S–S groups, or by iodoacetates, which combine wi the SH group; others, *e.g.* pepsin depend on the intactness of the hydroxyl groups tyrosine residues. Many enzymes can exist in an inactive form which is convertible, slight molecular rearrangement, into the active form, the conversion in some cases, *e.g.* the activation of trypsin, being autocatalytic, *i.e.* it is started by a minute trace of t active form, and proceeds with rapidly augmenting velocity as the active form increas in amount.[††]

Enzymes as Catalysers. The subject of thermodynamics teaches tha no reaction can be brought about through the agency of a catalyst unless it accomplishment is attended by a diminution of free energy (*v.* p. 67) of th whole system under consideration. The matter may perhaps be illustrated by mechanical analogy. Suppose a 100 g. weight to be placed at one end of a shee of glass, which is sloped so that the weight is 10 cm. from the table surface an the other end is at the table surface level. Friction, let us suppose, prevent the weight sliding down the inclined surface, although the weight has potentia energy capable of doing 1,000 g.-cm. of work, *i.e.* if it did slide down ΔF woul be negative. If now a little oil is placed beneath the weight, it slides down t table level, and in so doing could perform work and/or generate heat which together would be equivalent to 1,000 g.-cm. This energy liberation would b the measure of the diminution in the free energy of the change, and the oil which merely removes the frictional resistance to it, corresponds to the catalyst. (If the weight then rolled on to the floor, there would be a further liberation of free energy, and if it next rolled down the staircase there would b a still further diminution in free energy. But we are only concerned here with the move down to table level. In other words we are only concerned with *changes* in free energy in particular reactions.)

Now it is self-evident that if we want the weight to go up the inclined plan we must push or lift it up, *i.e.* we must add energy to the system in some wa or the reaction will never occur, oil or no oil (*i.e.* ΔF is positive, *v.* p. 67).

Enzyme and other catalysed reactions are similar; they will not occur unles accompanied by a diminution of free energy. The catalyst, like the oil, merely hastens or makes possible a reaction which is possible on energy grounds, an at the end is unchanged itself. Whereas the influence of most catalysers o the velocity of a reaction increases rapidly with rise of temperature, in the cas of enzymes this increase occurs only up to a certain point (the temperatur coefficient varying, up to this point, from 1 to 2). This point is spoken of as th *optimum temperature* of the enzyme action. If the mixture be heated above thi point, the action of the enzyme rapidly slows off and then ceases, owing t denaturation of the enzyme.

All enzymes are very sensitive to changes of hydrogen ion concentration and there is an optimum *p*H at which each enzyme is most active, *e.g.* for pepsin

*p*H 1·5, for trypsin *p*H 8·3, etc. The optimal *p*H, however, depends very much on other conditions, *e.g.* in the presence of impurities it may be considerably altered.

Many enzymes are easily inhibited or destroyed by certain substances, *e.g.*, by the salts of Hg, Cu, Pb, by iodine, some by HCN, etc., in very small concentrations.

KINETICS. Since the action of enzymes consists in the quickening up of processes which would otherwise occur at an infinitely slow rate, many investigations have dealt with the velocity of the reaction induced by the action of an enzyme. It has been found that the velocity of an enzyme action is accelerated by rise of temperature (up to the optimum) by an optimal *p*H, and by increase in concentration of substrate or of enzyme. Conversely it is inhibited by accumulation of the end-products of the reaction, and hence the action is probably a special case of the laws of mass-action ; it may also be slowed down by inactivation of the enzyme.

Enzymes, which are all colloidal, cannot be dealt with in the same way as the simpler catalysts. In many cases the substrate, *e.g.* starch or protein, is also colloidal, and the combination therefore falls into the class of combinations between colloids. In this we have an interaction between two substances in which the adsorption by the surfaces of the molecules of one or both substances plays an important part.

A variety of methods are available for studying the kinetics of enzyme action. The general principle of these is that the amount of substrate broken up by the enzyme is determined by some appropriate chemical or physical method which measures either the concentration of the substrate or of one of the products at a given time after the enzyme and substrate were brought together. Factors which may be varied are concentration of enzyme and of substrate, time of action, temperature, H-ion concentration, and presence of various other substances.

By such methods it has been found in the simplest case, when the substrate is in true solution, that, when the quantity of enzyme employed is very small in comparison with the *substrate* (the substance acted upon), the *amount of change in a given time is proportional to the amount of enzyme* present, and is (within limits) independent of the concentration of the substrate. This is well shown by the two following Tables representing the action of lactase upon lactose (E. F. Armstrong *) :

PROPORTIONS HYDROLYSED IN 100 C.C. OF A 5 PER CENT. SOLUTION OF LACTOSE. ENZYME VARIED.

Solutions containing—	1·5 hours	20 hours	45 hours
1 c.c. lactase . . .	0·15	2·2	3·9
10 c.c. ,, . . .	1·6	23·3	38·6
20 c.c. ,, . . .	3·2	45·8	—

20 ,, ,, .	7·0	1·40	10·9	2·18
30 ,, ,, .	4·8	1·44	7·7	2·21

---

* E. F. ARMSTRONG. *Proc. Roy. Soc.*, 1904, **73**, 500.

Moreover if we take only the earlier stages of the enzyme action, it is found that, wi small proportions of enzyme, equal amounts of substrate are changed in successive interva of time until about 10 per cent. has been hydrolysed. This is shown in the followi Table :

2 PER CENT. LACTOSE WITH LACTASE

Time	Amount hydrolysed
⅓ hour	3·2
⅔ ,,	6·4
1 ,,	9·6
2 hours	16·4
3 ,,	20·8

These results can best be interpreted by assuming that the first stage in the reaction is combination of enzyme with substrate. Bayliss believed the combination to be an adsorp tion, whereas Michaelis thought it to be a reversible combination of the ordinary chemic equilibrium type. In either case, it is the concentration of this combination which represent the active mass of the molecules, *i.e.* the molecules of substrate which are undergoin change. This compound, as soon as it is formed, takes up water and breaks down, settin free the hydrolysed substrate and the enzyme, which is at once ready to combine with further portion of the substrate. In such a case the velocity of reaction must be directl proportional to the amount of enzyme, and the same absolute quantity of substance wi continue to be changed in succeeding units of time. Supposing, for instance, we had a the bottom of a hill a load of bricks which had to be transferred to the top, and some men t effect the transference. The rate of transference would be directly proportional t the number of men employed ; we could double the rate by doubling the men. Moreove the number of bricks carried in each unit of time would be the same. Five men would carry as many bricks in the second ten minutes as they would in the first, and so on. On the othe hand, the velocity with which the transference was effected would be independent of the number—that is, the *concentration*—of the bricks at the bottom of the hill. The *active mass* of bricks could be regarded as that number carried at any moment by the transferring factor, namely the men. The equation of change would be $\phi = KC$, where C is the concentration of the enzyme. This concentration is always being renewed and kept constant by the breaking down of the intermediate product, so that the rate of change would be continuous throughout the experiment.

On the other hand when the amount of enzyme is relatively large, the rate of change, though at first very rapid, tends continuously to diminish. This is shown by the following Table representing the rates of change (K), during succeeding intervals of ten minutes, in a caseinogen solution to which a strong solution of trypsin had been added (Bayliss).

VELOCITY OF TRYPSIN REACTION

3rd ,,	0·0032
4th ,,	0·0022
5th ,,	0·0016
6th ,,	0·0009
&c.	&c.

In this retardation of the later stages of enzyme action, the end products are concerned in some way or other, and the retardation can be augmented by adding to the digesting mixture the boiled end products of a previous digestion. The retarding effect of the end products resembles in many ways that observed in reversible reactions and is most simply regarded as being due to the fact that the enzyme reversibly combines not only with the substrate, but also with the end products, tending to reverse the reaction, or to prevent enzyme from combining with substrate, or both.

In general, however, reversal of enzyme actions, though theoretically sound, is not easily attained, so that probably a more important factor in slowing the enzyme action in its final stages is the preliminary combination of the enzyme itself with the end products and the consequent removal of the enzyme from the sphere of action. Several facts speak for such a mode of explanation. Thus the action of lactase on milk sugar is not retarded by both its end products, glucose and galactose, but only by galactose. In the same way the action of invertase on cane sugar is retarded by the end product fructose but not by glucose. These are examples of "*competitive inhibition*," one sugar seizing the enzyme and excluding the other.

So far, therefore, a study of the velocity of enzyme actions would lead us to suspect that the enzyme in the first place combines with the substrate, and that this combination is a necessary step in the alteration of the substrate. In the second place, the enzyme is taken up, to a certain extent, by some or all of the end products, and this combination acts in opposition to the first combination, tending to remove the enzyme from the sphere of action, and therefore to retard or even reverse the whole reaction.

Activators and Co-enzymes. Some enzymes are quite inactive except in the presence of some other substance or substances, which are called *activators* or *co-enzymes*, the differences between the two being rather vague. Thus salivary amylase is inactive in absence of chloride or bromide ions, and such simple accessories are commonly called *activators*.

A different kind of activation is that known as "*unmasking*." For instance, pancreatic juice contains a precursor of the proteolytic enzyme trypsin, but it will not act on proteins until mixed with intestinal juice. This contains a substance called *enterokinase*, which appears to remove part of the large trypsinogen molecule and so expose the enzyme trypsin ready for action.

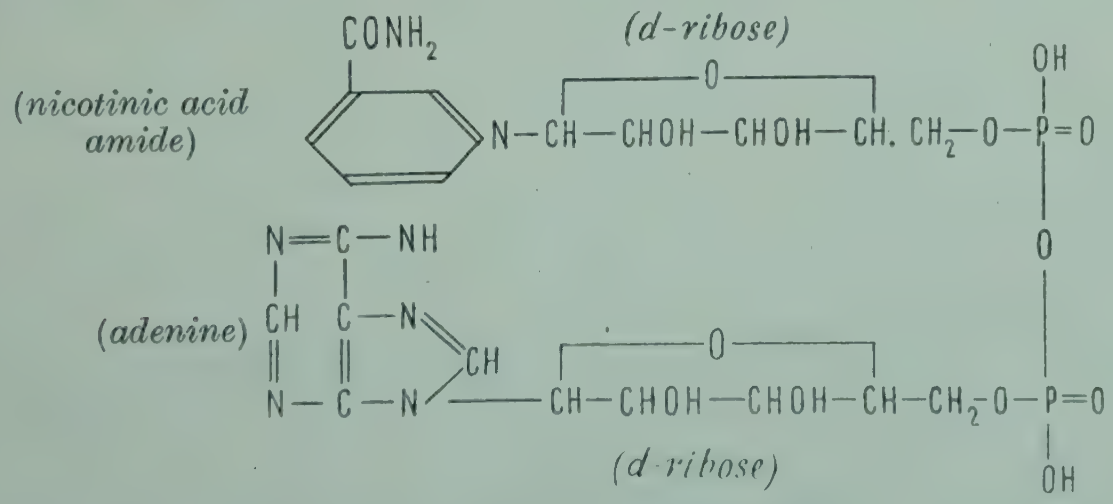
Yet another type of activation is seen in the operation of co-enzymes. For example, an extract of muscle can be made containing various enzymes which, acting together, can convert glycogen into lactic acid. But if the extract is dialysed it will not do this. Addition of the dialysate, or of boiled extract, restores the property : there is evidence that the essential substances removed by dialysis play a *rôle* in the reactions carried out by the enzymes, and such participants are called *co-enzymes*, the complete system consisting then of enzymes and co-enzymes. Sometimes more than one accessory substance is essential, and these together are then called a *co-enzyme system*. Enzymes may usually be freed from their co-enzymes, or from the various components of their co-enzyme systems, by dialysis. The co-enzymes are usually thermostable. There is evidence that the co-enzyme combines with the enzyme, either temporarily, much in the way that the substrate does, or more permanently in the form of the prosthetic group of a conjugated protein.

The following are important co-enzymes of known constitution :—

Co-enzyme		*Example of Enzyme using*
(1) Co-enzyme I	Phospho-pyridino-nucleotides.	Lactic dehydrogenase.
(2) Co-enzyme II		*iso*-citric dehydrogenase.
(3) Flavine nucleotides.		some Reductases.
(4) Thiamine pyrophosphate.		Carboxylase.
(5) Iron-porphyrin compound.		Cytochrome oxidase.

It is of interest to note that most of these co-enzymes contain well-known vitamins of the B group as part of their molecules. Thus Co-enzymes I and II are derivatives of nicotinic acid, one of the B_2 vitamins, the flavine nucleotides contain riboflavine, one of the B_2 vitamins, and thiamine pyrophosphate is the pyrophosphate of vitamin B_1.

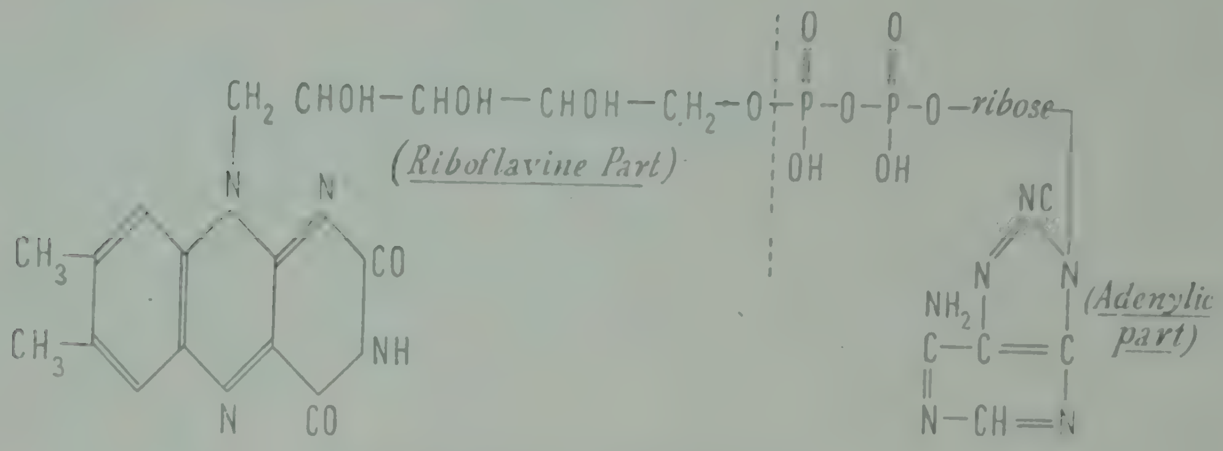
The Phospho-pyridino-nucleotides. There are two of these, viz. a Diphospho-pyridino nucleotide, called for short D.P.N. or "Co-enzyme I," and a Triphospho-pyridino-nucleotide, or T.P.N. or "Co-enzyme II." Of these Co-enzyme I, is probably more important in animal tissues. This co-enzyme is a compound of nicotinic amide, adenine, two molecules of d-ribose, and one of pyrophosphoric acid, and has the probable formula :—



Co-enzyme I (D.P.N.).

The compounds can also exist in a reduced form by introduction of t H- atoms near the N of the nicotinamide. For brevity it is customary to wri oxidised and reduced forms as D.P.N. and D.P.N.H_2, or Co.I and Co.I. respectively.

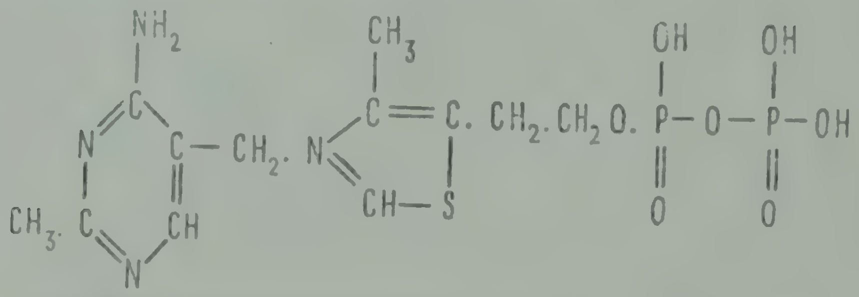
There are various *flavine nucleotides*, the dinucleotide having t structure :—



Flavinadenine dinucleotide.

This compound can also be reversibly reduced by taking on 2H into th rings of the riboflavine part of the molecule.

Thiamine pyrophosphate has the structure :—



Thiamine pyrophosphate (Co-carboxylase)

Enzymes as Synthetic Agents. Theoretically all enzyme actions are reversible, since the end-point represents an equilibrium in which free energy is at the minimum. In most cases, however, this equilibrium represents almost complete reaction in one direction, so that the energy of reversal is slight. But some enzymes have been found capable of catalysing reactions in the reverse direction and forming the original substrate, or, more often, a substance closely resembling it. This happens most readily if the concentration of normal end products is very great. Croft Hill * showed that if maltase were added to a 40 per cent. solution of glucose, a change took place in the reverse direction, which proceeded until 85 per cent. of the glucose was left. The sugar formed, a disaccharide, is not maltose, but the stereoisomeric sugar, iso-maltose.

In the same way it was found by Castle and Loewenhart that the hydrolysis of esters by lipase is a reversible reaction, the action of lipase being simply to hasten the attainment of the equilibrium point between the four substances—ester (or neutral fat), water, fatty acid and alcohol. It has been shown † that " plastein " resembling a protein can be resynthesised from protein hydrolysis products by the action of pepsin at a *p*H of 4·0 and at a relatively high temperature, *e.g.* 70° C. Addition of protein delays the synthesis. A similar synthesis is effected by trypsin at *p*H 5·7.

Perhaps the clearest example of enzymic synthesis is that of starch or glycogen. Peas and liver both contain a phosphorylase which can act on α-glucose-1-phosphate, to produce the polysaccharides starch and glycogen respectively.

If, as is believed, all enzyme actions are reversible, a possibility is opened of regarding the synthetic processes occurring in the living cell, as well as the processes of disintegration, as determined by the action of enzymes. It must be noted that actual reversal of a given enzyme action is only obtained with distinctness when dealing with concentrated solutions. The degree of synthesis, which would be produced in the very dilute solutions of glucose, etc., occurring in the animal cell, would therefore be infinitesimal. But if a mechanism were provided for the immediate removal of the synthetic product from the sphere of reaction, either by its being insoluble, by removing it to a different part of the cell or by building it up into some more complex body which was not acted on by the enzyme, the process of synthesis might go on indefinitely, and the infinitesimal quantities be summated to an appreciable amount. Further it should be noted that synthesis and breakdown of a given substance often occurs by different paths and under the influence of different enzymes.

CLASSIFICATION OF ENZYMES

The names of enzymes are usually made by adding the suffix *-ase* to the name of the substrate, *e.g.* a peptidase acts on peptides: other names describe what the enzymes do, *e.g.* dehydrogenases remove hydrogen from their substrates. Several classifications have been proposed, but none of them are entirely satisfactory. A convenient provisional one, adapted from Baldwin, is given here, and illustrated by examples in the Tables below. Three main groups, each subdivided into sub-groups and classes are :—

- I. ***Splitting Enzymes***
  - (1) Hydrolases.
  - (2) Phosphorylases.
  - (3) Adding Enzymes.
- II. ***Transferring Enzymes***
  - (1) Oxidising and Reducing Enzymes.
  - (2) Other Transferring Enzymes.
- III. ***Isomerases***
  - (1) Simple Isomerases.
  - (2) Mutases.

EXAMPLES OF SOME IMPORTANT ENZYMES (after Baldwin)

I. SPLITTING ENZYMES

Group.	Class.	Example	Substrate	Products
(1) *Hydrolases*	Esterases	Lipase	Fat	Fatty acids and glycerol.
,,	,,	Phosphatase	Phosphoric esters	H_3PO_4 and alcohol.
,,	Carbohydrases	Amylase	Starch	Maltose.
,,	,,	Maltase	Maltose	Glucose.
,,	Peptidases (Endo-peptidases).	Pepsin	Proteins	Proteoses and peptones.
,,	,,	Trypsin	Proteins	Peptones and amino-acids.
,,	Exo-peptidases	Carboxypeptidase	Peptides	Amino-acids.
,,	,,	Dipeptidase	Dipeptides	Amino-acids.
,,	Deaminases	Adenase	Adenine	Hypoxanthin $+ NH_3$
,,	Deamidases	Urease	Urea	$CO_2 + NH_3$
(2) *Phosphorylases*	Amylophosphorylases	Liver phosphorylase	Glycogen and phosphate.	glucose-1-phosphate.
(3) *Adding enzymes*		Catalase	H_2O_2	$H_2O + O_2$
,,		Carbonic anhydrase	H_2CO_3	$H_2O + CO_2$

II. TRANSFERRING ENZYMES

Group 1. Oxido-reducing Enzymes (Transfer 2H)

Class	Example	H-donator[*]	H-acceptor
Anaerobic dehydrogenases	Succinic deh.	Succinate	Cytochrome *c* (or MB
,, ,,	Lactic deh.	l-lactate	Co I.
Aerobic dehydrogenases	Amino-acid oxidase	Amino-acids	O_2 (or MB).
	Xanthine oxidase	Xanthine, etc.	O_2 (or MB).
Flavoprotein	Cytochrome reductase	Reduced Co II	Cytochrome *c* (or MB
Aerobic oxidases	Cytochrome oxidase	Cytochrome *c*	O_2.
,, ,,	Tyrosinase	Phenols	O_2
Peroxidases	Cytochrome peroxidase	Reduced Cyt. *c*	H_2O_2.

Group 2. Other Transferring Enzymes

Group transferred	Class	Example	Group donator	Group acceptor
H_2PO_3—	Transphosphatases	Hexokinase	A.T.P.	Glucose.
,,	,,	Lohmann enzyme	A.T.P.	Creatine.
—NH_2	Transaminases	Glutamic Tr-am	Glutamic acid	α-Keto acids.
—CH_3	Transmethylases	Unnamed	Methionine	Ethanolamine.

III. ISOMERASES

	Example	Reaction
Group 1. Simple isomerases	Oxoisomerase	Glucose 6-phosphate ⇌ fructofuranose 6-phosphate.
Group 2. Mutases	Phosphoglucomutase	Glucose 6-phosphate ⇌ glucose-1-phosphate.

I. Splitting Enzymes. These catalyse the breaking up of a larger molecule into two or more smaller ones.

(1) HYDROLASES. These enzymes bring about *hydrolysis* of the larger molecules on which they act, by the general reaction :—

$$RR' + HOH \rightleftharpoons ROH + R'H$$

Thus, the enzyme maltase catalyses the hydrolytic breakdown of maltose into two molecules of glucose

$$C_{12}H_{22}O_{11} + H_2O = 2C_6H_{12}O_6$$

The digestive enzymes acting on carbohydrates, proteins and fats all belong to this class.

The reverse change, that of dehydration, is also effected apparently with equal facility by the living cell ; thus the amino-acids are built up, first into polypeptides, and these again into the complex proteins of the cell.

Besides the reactions in which there is a difference in the amount of free water on the two sides of the equation, it seems probable that hydrolysis and simultaneous dehydration at different parts of the molecule determine a number of chemical transformations, which at first sight seem to involve a simple splitting of the molecule.

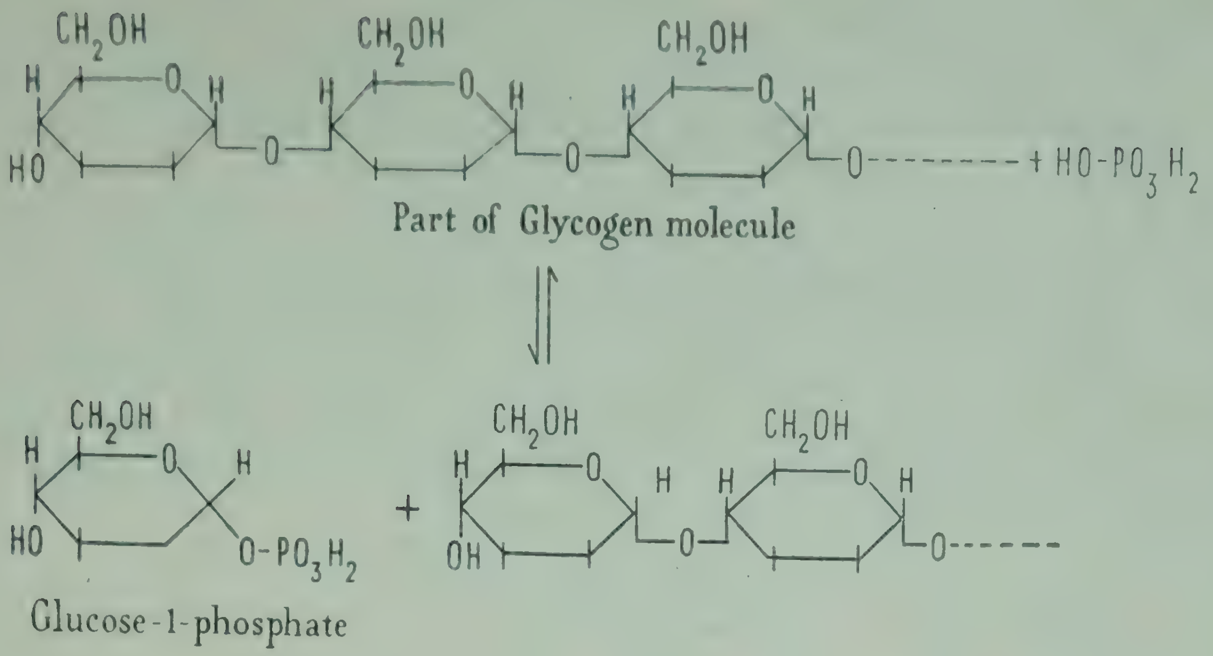
(2) PHOSPHORYLASES. With these enzymes the larger molecule is broken up by reaction with phosphoric acid, thus :—

$$RR' + H\,\vdots\,OPO_3H_2 \rightleftharpoons ROPO_3H_2 + HR'$$

so that a phosphoric group is introduced into one of the products. Thus a phosphoryl group can be introduced from phosphate into glucose, cut off from a glycogen molecule.

---

[*] MB. = Methylene blue.



(3) ADDING ENZYMES. Merely split a molecule into two parts,

$$RR' \rightleftharpoons R + R'$$

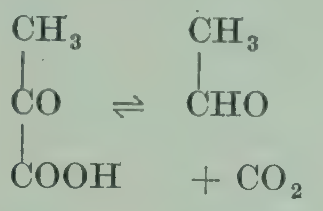
or, when acting in reverse, cause the two smaller parts to unite to form the larger molecule. Thus the simplest case is that of the enzyme *catalase*, which splits hydrogen peroxide into water and oxygen (but not reversibly) :

$$2H_2O_2 \longrightarrow 2H_2O + O_2$$

Another example is *carbonic anhydrase* which catalyses the conversion :

$$CO_2 + H_2O \rightleftharpoons H_2CO_3$$

and another is *carboxylase*, which converts pyruvic acid into acetaldehyde and CO_2 :—



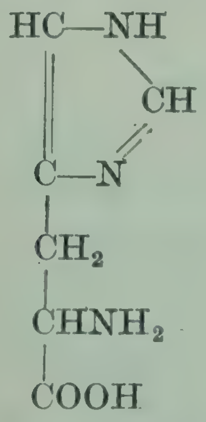
$$\begin{array}{l} CH_3 \\ | \\ CO \\ | \\ COOH \end{array} \rightleftharpoons \begin{array}{l} CH_3 \\ | \\ CHO \\ \\ + CO_2 \end{array}$$

This reaction is one stage in the formation of alcohol from glucose by yeast ; pyruvic acid is formed at one stage, and is then acted upon by carboxylase, of the yeast, with its co-enzyme, forming acetaldehyde and CO_2. The acetaldehyde is then further reduced to alcohol by other enzymes.

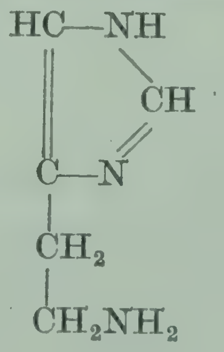
Many amino-acids when subjected to the action of bacteria lose a molecule of carbon dioxide and are converted into a corresponding amine. There is a large number of enzymes capable of decarboxylating amino-acids in this way : they are called the *amino-acid decarboxylases*, and each one is specific for a particular amino-acid.

For instance lysine is converted into pentamethylene diamine or cadaverine ;

and Histidine



becomes Histamine



In the same way ornithine is converted into tetra-methylene diamine or putrescine. Other examples of this process of decarboxylation are :

β-phenylethylamine $C_6H_5.CH_2.CH_2.NH_2$, from phenylalanine.
Para-hydroxyphenylethylamine $HO.C_6H_4.CH_2.CH_2.NH_2$, from tyrosine.

It is worthy of note that all the changes which we have so far been considering involve but little expenditure of energy.

II. **Transferring Enzymes.** These enzymes catalyse reactions i which a group is detached from one molecule, called the *donator* molecule, an transferred to another molecule, called the *acceptor* molecule, according to t general reaction :—

$$RA + R' \rightleftharpoons R + R'A$$

This is a large and important group, and includes enzymes concerned wit biological oxidations and reductions.

(1) OXIDISING AND REDUCING ENZYMES. Oxidation and reduction ar strictly speaking, the result of a transfer of electrons, oxidation being the los of an electron or of electrons, and reduction the gain. Most frequently oxidatio consists chemically in either a gain of oxygen, *e.g.*,

$$RCHO \longrightarrow RCOOH$$

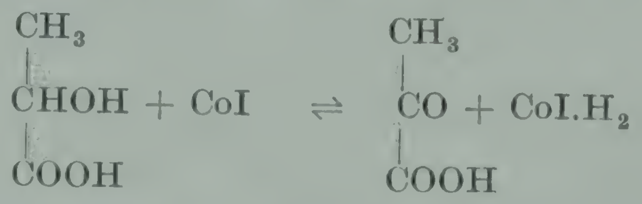
or loss of hydrogen atoms, *e.g.*,

$$RCH_2OH \longrightarrow RCHO$$

by the molecule under consideration, but whichever process happens, it i important to remember that two molecules are involved in the process, on being oxidised and the other reduced ; *oxidation of any substance is alway accompanied by reduction of some other substance.* We may conveniently regar oxidation as being most often a transference of H- atoms from the substanc oxidised to the substance reduced, and less often as a transference of oxyge in the opposite direction.

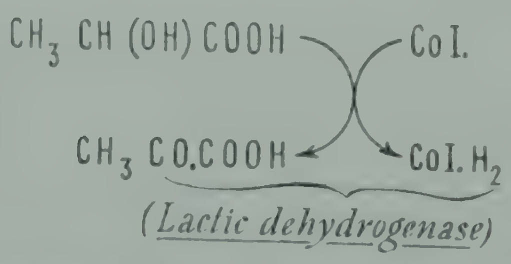
The oxidising and reducing enzymes thus are enzymes which transfer the group 2H : the substance losing the 2H is thereby oxidised and is called the *hydrogen donator*, while the substance gaining the 2H is simultaneously reduced, and is called the *hydrogen acceptor*.

In these oxidation-reduction reactions, various *co-enzymes* often play an important part by acting alternatively as hydrogen acceptors or donators. For example, the enzyme lactic dehydrogenase removes 2H from lactic acid (the donor) and so converts it into pyruvic acid, and simultaneously reduces Co-enzyme I (the acceptor) by transferring the 2H to it :—



$$\begin{matrix} CH_3 \\ | \\ CHOH \\ | \\ COOH \end{matrix} + CoI \rightleftharpoons \begin{matrix} CH_3 \\ | \\ CO \\ | \\ COOH \end{matrix} + CoI.H_2$$

This reaction can conveniently be shown by a scheme of the type introduced by Baldwin :—

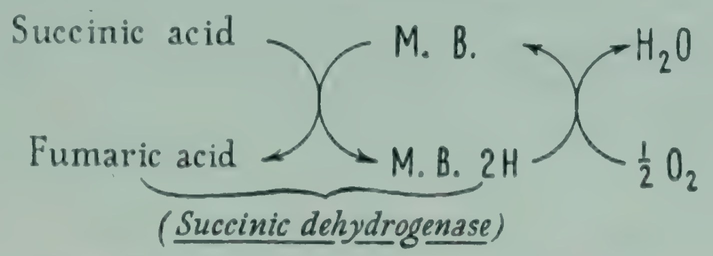


As we shall see later, the reduced CoI can subsequently be reoxidised by other reactions, and so can oxidise another molecule of lactic acid, and so on.

In some instances the 2H is ultimately transferred to atmospheric oxygen, which is reduced to H_2O or H_2O_2. Such oxidations by free oxygen are usually the result of a chain of reactions in which a series of different enzymes and co-enzymes are concerned, but are clearly of great interest since they provide a clue to the way in which oxygen is used by living cells to effect oxidations. As a simple illustration of the kind of thing that happens we may choose the action of *succinic dehydrogenase*. This enzyme can transfer hydrogen to methylene blue, which acts in place of a normal tissue H-acceptor. If washed minced muscle be placed in a dilute solution of methylene blue, a little succinic acid added to it, and the mixture placed out of contact with oxygen, and kept warm, the methylene blue is quickly reduced to a colourless compound, and an equivalent amount of succinic acid is oxidised to fumaric acid. The reaction is one of hydrogen transfer, the succinic acid losing two atoms :

$$C_4H_6O_4 \rightarrow C_4H_4O_4 + 2H,$$

and the 2H is taken up by the methylene blue. On now shaking the mixture with air, oxygen is taken up, and the colour is restored, owing to the reformation of methylene blue. In presence of oxygen, therefore, the oxidation will go on continuously to completion, as in the scheme :—

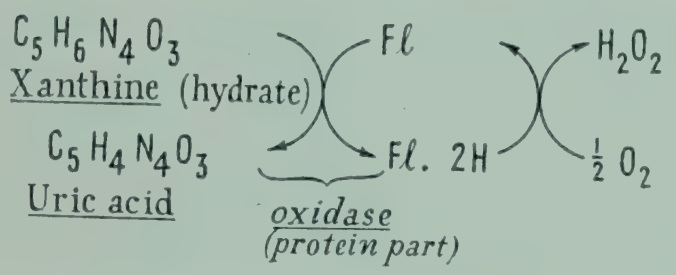


The direction of the arrows shows how the methylene blue is alternatively reduced and oxidised.

Some enzymes seem at first sight to be able to bring about a direct oxidation by free oxygen, with formation of hydrogen peroxide or water ; such enzymes are called *oxidases*. Thus the enzyme *xanthine oxidase* converts xanthine into uric acid :—

$$\underset{\textit{Xanthine}\text{ (hydrate)}}{C_5H_5N_4O_2OH} + O_2 = \underset{\textit{Uric acid}}{C_5H_4N_4O_3} + H_2O_2$$

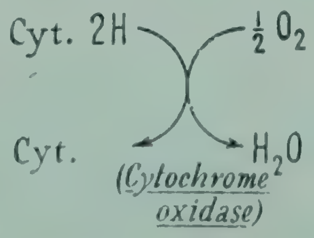
with formation of hydrogen peroxide. But the apparently direct oxidation is in reality a stagewise change. The xanthine oxidase is a conjugated protein, consisting of a protein part, the "real" oxidase enzyme, and a prosthetic group, flavine adenine dinucleotide (Fl) which is really a reversible hydrogen acceptor co-enzyme permanently attached to the protein. When reduced it can be reoxidised by free oxygen. Hence the whole reaction is as in the scheme :—



Any hydrogen peroxide formed in such reactions in the tissues is at once removed by the enzyme *catalase*, by which it is broken down to water and oxygen.

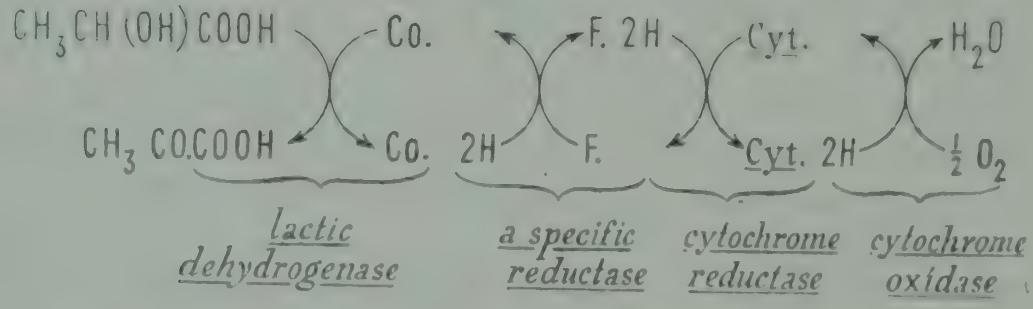
Aerobic Oxidases. There are, however, some enzymes which seem able to use free oxygen directly as a H- acceptor, the H- donator being thereby oxidised. One of the most important of these enzymes is called *cytochrome oxidase* : its H- donator being reduced cytochrome -*c*.

The cytochromes, of which there are several, *a*, *b*, *c*, etc., are conjugated proteins containing an iron-porphyrin group, which are present in all living cells capable of using oxygen. The iron can exist in the ferri- or ferro- form according as the state of the cytochrome is oxidised or reduced. Now, cytochrome oxidase in presence of oxygen *oxidises* reduced cytochrome -*c* to the oxidised form and reduces the oxygen to water :—



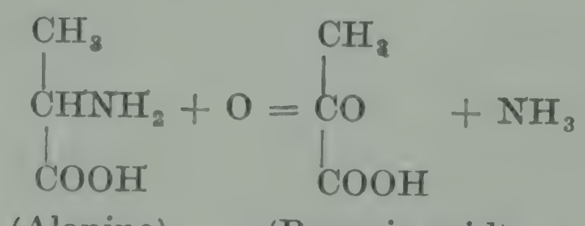
This action is prevented by the presence of traces of HCN, which paralyses the enzyme : it is probably on this account that cyanides suppress the oxidative processes of the tissues and are poisonous.

This oxidation of cytochrome -*c* by its oxidase is, however, the termina reaction in an oxidative chain: the cytochrome has previously been reduced by acting as H- acceptor for a dehydrogenase, and this dehydrogenase contain flavinadenine mono-nucleotide as its prosthetic group. It is called *cytochrom reductase*; its action is inhibited by narcotics like urethane or alcohol. Thi enzyme *reduces* cytochrome -*c* and oxidises reduced CoII, but there are probably other cytochrome reductases that can reduce cytochrome -*c* and oxidis reduced CoI. If so, we can expect that the complete series of reactions that lead to oxidation with ultimate oxygen absorption to be somewhat as follows (writing Co for co-enzyme I (or II), F for the flavine nucleotide and *Cyt.* for cytochrome), and taking as an example the oxidation of lactic acid :—



Deamination. This process involves the splitting off from an amino-acid of an NH_2 group as ammonia. Many tissues of the body appear to have this power: if, for instance, to slices of surviving liver or kidney, an amino-acid be added, ammonia is set free in proportion to the amount of amino-acid present.

Although the simplest mode of deamination of an amino-acid would apparently be the hydrolytic one, with formation of ammonia and a hydroxy acid, work by Neubauer and by Krebs showed that deamination is accompanied in the first place by oxidation, so that the first intermediate product formed is an α-ketonic acid.

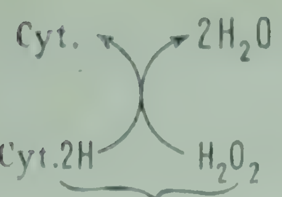


$$\begin{array}{l}CH_3\\ |\\ CHNH_2\\ |\\ COOH\end{array} + O = \begin{array}{l}CH_3\\ |\\ CO\\ |\\ COOH\end{array} + NH_3$$

(Alanine) (Pyruvic acid)

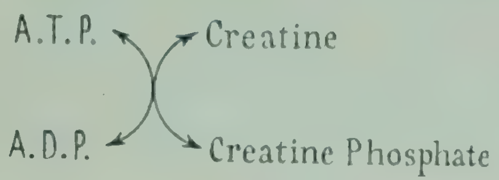
Little is known of the enzymes which effect this change, but one of them at least, viz, *l*-glutamic dehydrogenase functions with co-enzymes I or II, and possibly the others are similar though less specific as regards their substrates.

Peroxidases. It has long been known that hydrogen peroxide is able to effect oxidative changes similar to those observed in the animal body. Thus Dakin showed that the series of fatty acids, under the action of hydrogen peroxide, undergoes progressive oxidation in the β position, so that the carbon atoms are removed from the long chain of fatty acids two at a time. The action of hydrogen peroxide is much quickened by the presence of a trace of iron in the ferrous condition (Fenton's reaction): the iron thus acts as a catalyser. As we have seen above, hydrogen peroxide is sometimes formed as a result of the action of some of the oxidases. This is removed usually by the enzyme *catalase*, but it was at one time supposed that important oxidative changes were brought about by the activation of the peroxide by an enzyme called *peroxidase*. Such enzymes do exist, but are more readily demonstrable in plant than in animal tissues. They are detected by the fact that they oxidise certain substances to form coloured products. Thus guaiacum resin or guaiaconic acid is turned blue in presence of a peroxide and a peroxidase; if the enzyme preparation also generates H_2O_2 by the action of other enzymes, then it turns guaiacum blue without addition of a peroxide. The only important animal peroxidase appears to be *cytochrome peroxidase*, which oxidises reduced cytochrome -*c* by a reaction alternative to that by cytochrome oxidase.



(*cytochrome peroxidase*)

(2) Other Transferring Enzymes. These enzymes catalyse the transfer of various other groups from a donator to an acceptor molecule. The most important transferences of groups are those of the phosphoric acid group, by *Transphosphatases*, of the amino group by *Transaminases*, of the methyl group by *Transmethylases*, etc. For instance, one of the phosphokinases, transfers a phosphoric group, with energy-rich bond intact, from adenosine triphosphate to creatine :—



III. **Isomerases.** These enzymes cause their substrates to change into isomeric forms. For instance *oxoisomerase* catalyses the change of glucose 6-phosphate into fructose 6-phosphate, by molecular rearrangement. The *Mutases* are isomerases which cause more extensive internal rearrangements.

Oxidation–reduction Potentials. Although for most purposes it is sufficient to consider the phenomena of oxidation and reduction as simple chemical reactions, it is often valuable to regard them from the physico-chemical standpoint, as questions of transfer of electrons. In this sense oxidation is regarded as the loss of an electron, or of electrons, from an atom, and reduction as a gain of electrons. Thus when ferrous iron is oxidised to ferric iron an electron or charge of negative electricity is lost, so that the ferric iron atom gains a positive charge. This is expressed by the electro-chemical equation :—

$$\mathrm{Fe}\ {+}{+} \rightleftarrows \mathrm{Fe}\ {+}{+}{+} + e,$$

the quantum *e* for 1 gramme-atom being 1 Faraday, or 96,500 coulombs of negative electricity. It will be seen that this conception is really more accurate than one involving a transfer of either hydrogen or oxygen, since it covers all cases, *e.g.* the oxidation of ferrous chloride to ferric chloride, as above. Oxidation is always accompanied by reduction in some other substance, which thereby gains the electron lost by the oxidised substance. In cases where there is merely a transfer of electrons in this manner there is of course no energy change, but often there is liberation of some of the energy as heat or in some other form.

In order for oxidation to occur, there must be a readiness for the electron to escape, and the greater its escaping tendency, or *fugacity*, the more readily will oxidation take place. This tendency can be measured for any dissolved substance by the determination of the *oxidation-reduction potential*, which may be explained as follows : Suppose that into a readily oxidisable solution, *e.g.* $FeCl_2$, we dip a clean gold surface, then the Fe electrons, by their tendency to escape, will give to the electrode a negative charge, which will be greater the more the electron-fugacity of the substance. We thus have a half-cell, which may be combined with another half-cell, *e.g.* a hydrogen electrode, very much as described on p. 65, to form a cell the potential of which can be measured by some method which will not draw much current, *e.g.* an electrometer. The negativity of the gold electrode, as thus measured, is a measure of the ease of oxidisability of the substance into which it is dipped, or alternatively, of the reducing power of that substance towards other substances. Conversely, the less negative (or more positive) the electrode the greater the reducibility (or oxidising power) of the substance.

It is a convention to express the results in terms of what is called E_h, which is the reading, in volts, of the oxidation-reduction cell when set up with a normal hydrogen electrode, *i.e.* N.HCl. It follows from what has been said above that a solution of a substance capable of *reversible* oxidation and reduction will oxidise substances whose solutions have a more negative E_h (*i.e.* it will take up electrons from them), and reduce substances which have a more positive E_h than its own (*i.e.* it will give up electrons to them). Thus the E_h of the Ox/Red. flavine enzyme is $-$ 0·063 volts and that of Ox/Red. coenzyme I is $-$ 0·29, *i.e.* the flavin system can oxidise the $CoIH_2$. By determination of the E_h of a given oxidation-reduction system also, we can calculate the *free energy* of the change. For instance, it can be shown that for the reaction :—

$$\text{lactate} \rightleftharpoons \text{pyruvate} + 2H^+ + 2e$$
$$\text{the } \triangle F = -\ 8{\cdot}304 \text{ Cal.}$$

If we take a mixture of such a substance in the oxidised and reduced forms, it wil have a more negative E_h the more of the reduced form it contains, and *vice versa.* Many dyes are capable of oxidation and reduction, and since the reduced forms are often colourless, such dyes, when added to mixtures of other substances, become oxidised or reduced according to the oxidising or reducing potentials of the whole system in which they are present. We can use these dyes to assess the oxidation-reduction potentials in a manner somewhat analogous to the use of coloured buffer-dyes for the assessment of the hydrogen ion concentration of a mixture.

It has long been known that dyes such as methylene blue can often be reduced by most tissues; others, such as indophenol blue,* are reduced by some tissues but not by others, such as heart or brain: alizarin blue has so high a reduction potential that it could only be reduced by a few organs, *e.g.* lung, liver. Further, we know that such reversibly oxidisable substances, by being alternately reduced and oxidised, can act as hydrogen or oxygen carriers, and thus act with oxidation or reduction catalysts. Many naturally occurring substances, both in plants and animals, have this property, *e.g.* glutathione, ascorbic acid, various flavins, etc. Such substances, loosely linked to protein, form the oxidising enyzmes, and "when a group of these enzymes and their oxidisable substances act together . . . the oxidation reactions proceed, as a rule, in a series, the system of more negative potential being oxidised by the reduction of the system of more positive potential, and so on, in a series of graded steps up to the reduction of molecular oxygen. So, like locks in a canal, these reversible systems release gradually the oxidation energy" (Barron).

TISSUES SUBSERVING MOVEMENT AND CONDUCTION—MUSCLE AND NERVE

HISTORICAL NOTE

Anatomical dissection informed the ancients of the approximate uses of the various muscles, and the injuries which men sustained in the pursuit of war and assassination doubtless revealed to them the essential part played by the nervous system in the performance of voluntary movements. Galen (a.d. 130–200) recognised the involuntary muscles, realised the essential action of antagonistic muscles and of muscular tone, and showed by experiment that section or ligation of a motor nerve resulted in paralysis of its muscle. According to his speculations, which were an extension of those made some 500 years earlier by Erasistratus of the Alexandrian school, the working of the muscles was attributed to the passage into them from the nerves, of a pneuma, or spirit, the so-called psychic or animal spirit, which was engendered by the central nervous system. Although the succeeding fourteen centuries saw, towards its latter end, an extension of anatomical knowledge, there seems to have been little departure, and indeed little chance for a departure, from the Galenical outlook upon function. Even after the introduction of the microscope by Galileo in 1609, it was over half a century before the muscle fibre was described in some detail by Stensen (1664) and, more fully, by Leeuwenhoek (1715). It was not until, in the 17th century, the science of Physics, and later, that of Chemistry, began to take shape, that an outlook on biological science comparable with that which obtains to-day, became possible. Hence, with slight variations, the Galenical view, that in contraction the muscle became *distended* with the animal spirits, runs as a thread through the writings of 1500 years. Descartes (1662), Mayow (1674), and Borelli (1680) all subscribed to it in one form or another. Stensen showed that after ligation of its artery a muscle lost its power of contracting. Mayow's view was that the animal spirits consisted of " nitro-aerial spirit " (oxygen), and that, in the muscle, these meet with " salino-sulphureous particles " (combustible material), carried thither by the blood, with the result that there is an " effervescence " in the muscle causing it to swell up. Hence, in exercise, there is deeper breathing, to supply more " nitro-ærial spirit " : hence also, ligation of the nerve, by obstructing the flow of " nitro-aerial spirit," or of the artery, by obstructing the supply of salino-sulphureous particles, deprived the muscle of the power to act. The proof that, in fact, the volume of the muscle is not appreciably changed on contraction was furnished by Jan Swammerdam towards the end of that century, but was not published till 1738. He was the first to use the frog muscle-nerve preparation. Francis Glisson, about 1677 had also shown, by the use of a simple plethysmograph, that a limb shows no increase in volume, but rather a decrease, when its muscles contract : he also introduced the idea of excitability, or, as he called it, " irritability " though it was not adopted generally for nearly a century.

Until about 1664, or even later, doubt existed as to which part of a muscle was responsible for its contraction, a prevalent view being that it was the connective tissue part : simultaneously in 1664, William Croone and Stensen decided in favour of the fleshy part as the active tissue.

Early in the 18th century, the first text-book of physiology, Boerhaave's *Institutiones medicæ* (1708), marked the commencement of formal treatment of the subject, and later Albrecht von Haller's *Elementa physiologiæ corporis humani* (1757–65) collected together all the contemporary knowledge. It contained the results of the author's own work on muscle and nerve, and on the irritability of tissues. He studied the effects of various stimuli on the muscles and nerves of live and of recently killed animals, and concluded that the animal spirits of the older writers was, in fact, a fluid " unlike everything else," and was passed along the nerves, which were tubular in structure. The term " excitability " was substituted for irritability by John Brown in 1780.

In 1743 the mathematician Hausen, with knowledge of the electrical machine, put forward the suggestion that nervous action was electrical in nature, but Haller, the then dominant physiologist, rejected this view on the grounds that ligation of the nerve, though incapable of stopping the passage of an electric current, suspended the propagation of the nervous action.

The invention of the Leyden jar about the middle of the 18th century soon led to the discovery that electricity supplied an admirable stimulus for the excitable tissues, and towards the close of the century, in 1786, Galvani (publ. anonymously in 1794) made th original observations from which sprang the knowledge of animal electricity, and adum brated the hypothesis of the essentially electrical nature of the conducted process in nerve a view which the introduction of the telegraph in 1835 further encouraged.

During the 19th century, events and discoveries followed at an accelerating pace, t culminate in an avalanche of fact and theory in the present century. The period of mos fruitful harvest was on the virgin soil between 1835 and about 1880, and a mere catalogu of salient events must suffice here.

The study of the heat production of contracting muscle by means of thermo-electri couples or thermopiles was due to Bequerel and Breschet (1835), Helmholtz (1864 Heidenhain (1864), and Fick (1882), the last two considering the phenomena from th thermodynamical standpoint. The researches of A. V. Hill for decades from 1910 adde largely to knowledge in this field.

Animal electricity became the subject of more exact study after the invention b Nobili, in 1827, of the astatic couple, and Matteucci and Du Bois Reymond made mos of the pioneer discoveries in this field between 1840 and 1843.

The main laws of the excitation of nerve by the constant current had been sketche out by about 1848. The way for further investigations on the nerve impulse was opene by the introduction into physiology of the induction coil by Du Bois Reymond in 1849 and the time relations of muscular contraction were first worked out by Helmholtz in 1850. Du Bois Reymond about 1849 accepted the electrical changes in nerve as a sig of the transit of the conducted disturbance, and in 1859 he added improvements to the non-polarisable electrodes introduced in 1854 by Regnauld.

Views concerning the chemical events associated with muscular contraction developed much later. The increase of oxygen utilisation during muscular exercise observed in 1789 by Lavoisier and Seguin, were more exactly confirmed by Regnault and Reiset in 1849. The formation of lactic acid in contraction, discovered by Berzelius in 1841, was stressed by Hermann in 1867. It was Hermann also who, with Pflüger, postulated the existence in muscle of a labile component, "*inogen*," the breakdown of which provided the energy for contraction. Glycogen was discovered by Claude Bernard in 1857, Creatine by Chevreuil in 1835, and Creatine phosphate by the Eggletons and independently by Fiske and Subarrow in 1928. The construction of plausible chemical hypotheses regarding muscular contraction began with the work of Fletcher and Hopkins in 1907, and is still in progress. The discovery in 1928 of adenosine triphosphate in muscle, by Lohmann, has turned out to be one of the most important discoveries in biological chemistry. Its properties strangely recall those of Hermann's inogen.

The study of the molecular structure of muscle protein by X-ray spectra by Meyer and Astbury, from 1929 onwards, opened up a new line of enquiry into the mechanism of muscular contraction.

An idea of the rapid development of the subject in the mid-19th century is given by considering the views on the velocity of the nervous impulse. In 1844 the great Johannes Müller stated that it must be similar to the velocity of light, and could probably never be measured: reflexes, similarly, were regarded as instantaneous. But in 1850 Helmholtz, by a procedure closely resembling that now carried out in student exercises, measured the velocity of the transmission in frog's nerve, and he also measured a reflex time in 1854.

The electrotonic currents of nerve were demonstrated by Du Bois Reymond in 1843, and the whole subject of electrotonus was extensively studied by Pflüger, whose book on the subject appeared in 1859. The "core model" illustrating its phenomena (Matteucci, 1863) was developed by Hermann (1873), and was a source of much controversy.

The action of curare was studied by Claude Bernard in 1857; by its use he showed that muscle was independently excitable, and that a chemical substance could be used as an implement of physiological research and analysis.

The regeneration of divided nerves was first observed by Cruickshank in 1776: the process of degeneration was studied by Waller in 1850, and shown to be of use for tracing the cells of origin of the divided nerves.

The relative unfatigability of nerve was first properly demonstrated by Bernstein in 1877. Various attempts were made to show that nerves generated heat when impulses passed along them, but the most accomplished experimenters of the 19th century, Helmholtz (1848) and Heidenhain (1868), failed, where others claimed to have succeeded. It was not until 1931 that a heat production was demonstrated in nerve fibres.

The all-or-none character of nerve-fibre transmission was first recognised about 1909 by the work of Keith Lucas.

In the last two or three decades, refinements of physical and chemical methods have permitted the investigation in detail of many aspects of the physiology of muscle and nerve that were previously not amenable to such precise examination. Among these advances in technique are the employment (about 1921) of radio amplification together with the use of the cathode ray oscillograph, and the adaptation of many micro-chemical methods. The idea of the humoral transmitters grew out of Otto Loewi's demonstration in 1921 that acetyl-choline was formed in the heart on vagus stimulation.

CHAPTER X

VOLUNTARY STRIATED MUSCLE

MOVEMENT and conductivity are of the very essence of life phenomena. The potentiality or property of exhibiting movement, macroscopic or microscopic, is probably inherent in every living cell; so also is the potentiality or property of conducting a state of change (often excitatory) from one part of the cell to another. In all the higher animals the power of movement is a condition for survival, and they accordingly possess tissues in which the power of movement is especially well developed. These are the muscular tissues. Further, speedy correlation between the various parts of the body is effected by tissues of highly developed conductivity for states of excitation. These are the nervous tissues.

In the higher animals we may distinguish three varieties of muscle. In all three varieties, movements are effected as a result of a shortening, or *contraction*, of a fibre or cell, usually of elongated form. All movements that require to be sharply carried out are effected by means of striated muscular tissue and, as these movements are often under the control of the will, the muscles are generally spoken of as *voluntary*. Whether controlled by the will or not, however, they are normally always caused to contract as the result of excitation received by way of a nerve, *i.e.* they are *nerve-operated*. If its nerves are severed, the muscle is useless and soon degenerates. Plain or *involuntary* muscles form sheets or closed tubes surrounding the viscera, the blood vessels, etc. By their slow prolonged contractions they serve to maintain and regulate the flow of the contents of these organs. Intermediate in properties as well as in structure between these two classes is the *heart or cardiac muscle*.

Plain and cardiac muscle can and do normally contract independently of nerves, though nerves can alter these contractions, *i.e.* they are *nerve-regulated* but not nerve-operated.

The properties of contractile tissues have been most fully investigated in the voluntary muscles, particularly those of the frog. The selection of cold-blooded animals is guided by the fact that it is possible to isolate the muscle from the rest of the body and to keep it alive long enough to study its reactions during a considerable time. We shall therefore deal at length with the properties of skeletal muscle, pointing out incidentally in what respects heart muscle and involuntary muscle differ from it.

Much of our knowledge on the subject of muscle has been derived from the study of the isolated gastrocnemius and sartorius muscles of the frog. The gastrocnemius, with the attached sciatic nerve, can conveniently be removed from the body, and is called a *nerve-muscle preparation*. On account of a penniform arrangement of the muscular fibres, while the actual shortening of the gastrocnemius is but small, its strength of contraction is considerable.

The sartorius muscle is of especial value on account of the fact that its fibres are parallel. When a greater mass of approximately parallel fibres is necessary, recourse may be had to the gracilis and semimembranosus muscles together.

Other muscles in the frog used for particular purposes are the mylohyoid and the dorsocutaneous muscles. The mylohyoid muscle, which lies on the central surface of the tongue, has the advantage that its fibres lie in close contact with a lymph space occupying the centre of the tongue. If any drug be injected into this lymph space it acts with extreme rapidity on the muscle fibres, so that this preparation is useful for the study of the action of different substances on muscle fibres.

Experiments on isolated muscle fibres have often been carried out. They are valued in fundamental observations because the results obtained are supposed to be unequivocal.

Present-day investigations employ, to an increasing extent, mammalian, or human, muscle as their material.

STRUCTURE OF STRIATED MUSCLE

The striated muscles form up to 50 per cent. by weight of the body. Eac muscle is embedded in a layer of connective tissue and is made up of a aggregation of muscular fibres 10 to 100μ in diameter, which are united int bundles by means of connective tissue. The individual fibres vary much i length and may exceed 10 cm., though often each fibre is shorter than th bundle of which it forms a part; most of them taper towards one or both end At each end of the muscle the fibres are firmly united by their blunt ends t the tendon of the muscles which are attached to bones. The fine taperin ends of the fibres end in the connective tissue between the fibres. Runnin in the connective tissue framework of the muscle we find a number of bloo vessels, capillaries and nerves.

The living muscle fibre exhibits a series of alternate light and dark band arranged at right angles to its long axis and enclosed in a structureless laye the sarcoplasmatic membrane. The whole fibre is encased in a tough sheath the sarcolemma (Fig. 32). Lying under the sarcolemma are a number of oval nuclei embedded in granular protoplasm. Each fibre may be artificially split into a bundle of parallel fibrils, which are embedded in an interstitial material called sarcoplasm. Each fibril consists of a column of compartments (after the fashion of a minute stick of bamboo), 2 to 3μ in length and each called a *sarcomere*. Each sarcomere is more transparent at the two ends than in the middle, thus giving rise to the appearance of light and dark striæ. In a fibre, corresponding structures in adjacent fibrils are side by side, thus giving rise to the cross striation. In the middle of the light band is a line or row of dots (often appearing double) called Krause's membrane or the Z line: this is the boundary of the sarcomere.

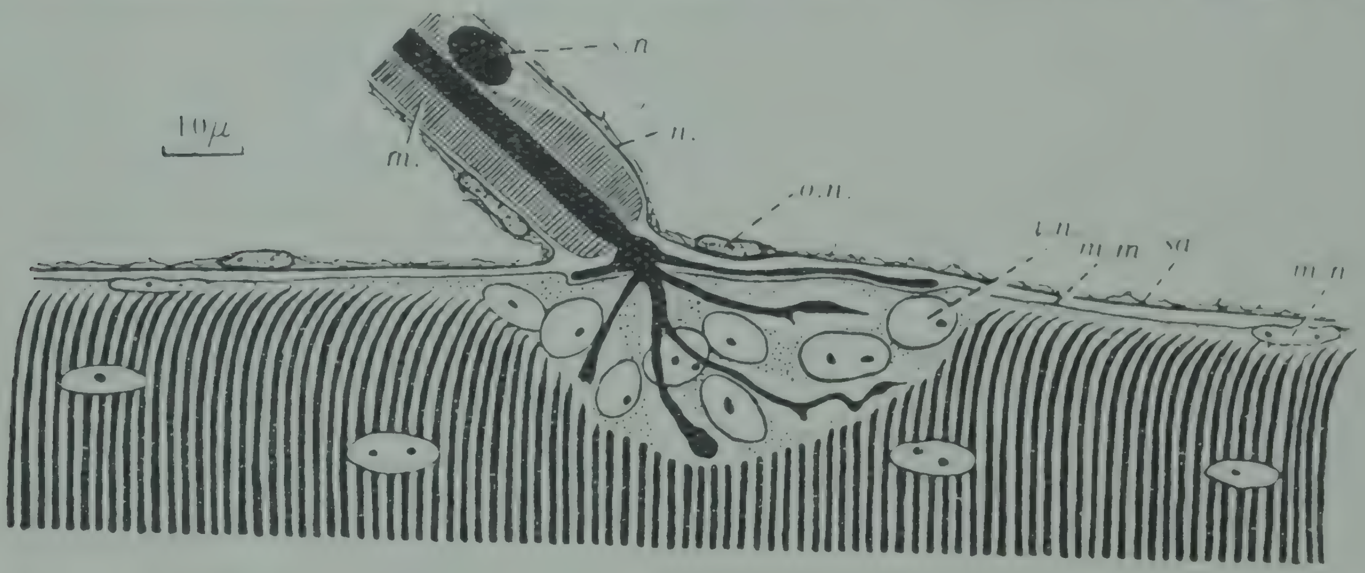

FIG. 32. Semi-diagrammatic view of part of a striated muscle fibre and of its motor end-plate. *m.* myelin sheath; *s.n.* Schwann nucleus; *n.* neurilemma; *o.n.* outer end-plate nucleus; *i.n.* inner end-plate nucleus; *m.m.* muscle (sarcoplasmatic) membrane; *s.a.* sarcolemma; *m.n.* muscle (sub-sarcolemmal) nucleus. (GUTMANN and YOUNG, *J. Anat.*, 1944, **78,** 15.)

The development of this regular cross and longitudinal striation is closely connected with the evolution and specialisation of the muscular function, *i.e.* contraction. In the developing muscle of the embryo or the adult muscles of many invertebrates, this differentiation affects only part of the cell, so that, while one part presents the ordinary granular appearance, the other half is finely and longitudinally striated, due to the development of special contractile fibrillæ. In the striated muscle of vertebrates, and still more in the wonderful wing-muscles of insects which can perform three hundred presumably tetanic contractions in a second, the longitudinal is associated with and subordinated to a transverse striation, due to the regular segmentation of the contractile fibrillæ. The great divergence in the aspect of muscular fibres from different parts of the animal kingdom is largely conditioned by the varying relations, spatial and quantitative, of the sarcoplasm to the fibrils. Thus in the higher vertebrates, two types of voluntary muscular fibre are distinguished, according to the amount of sarcoplasm they contain: one (red fibres) rich in sarcoplasm, more granular in cross section and generally containing a red pigment, myoglobin; the other (pale fibres) poor in sarcoplasm, clear in cross section and containing no myoglobin.

The red fibres are found chiefly in those muscles which have to carry out long continued and powerful contractions. The myoglobin assists in this by acting as a local oxygen store.

In some animals, such as the rabbit, we find muscles consisting almost entirely of one or other of these varieties ; but in most animals the two varieties occur together in one muscle, so that what we have to say about the properties of voluntary muscle really has reference to a muscle containing both red and white fibres. Generally, however, pale muscle predominates in the quick-acting flexor muscles, and red in the tonically acting extensors.

The appearances which are revealed within the fibril by the microscope have been variously interpreted by the eye of faith, or of doubt. The current opinion accepts, at least, the physical reality of the sarcomere and of the striations, though even the permanence of the latter has been questioned.

We will accept the view that the essential contractile element is the chain of sarcomeres forming the muscle fibril (Fig. 33). Each myofibril * is divided by Krause's membrane, often called the Z-disc (the lines in the middle of each light stripe) into sarcomeres. The Z-disc runs right across the fibre from fibril to fibril. Each sarcomere contains a darker substance (A or Q-disc) divided near the centre into two parts by Hensen's (M or Q*h*) disc. At each end of the sarcomere the contents (I or J-disc) are clear and hyaline. Most histologists agree in assigning to the Q-disc of the sarcomere a denser structure than to the two ends. In the resting fibre of the frog the Q stripe occupies 63 per cent. of the height of the sarcomere and the J stripe 37 per cent. When stretched, the Q stripe extends about twice as much as the J stripe.

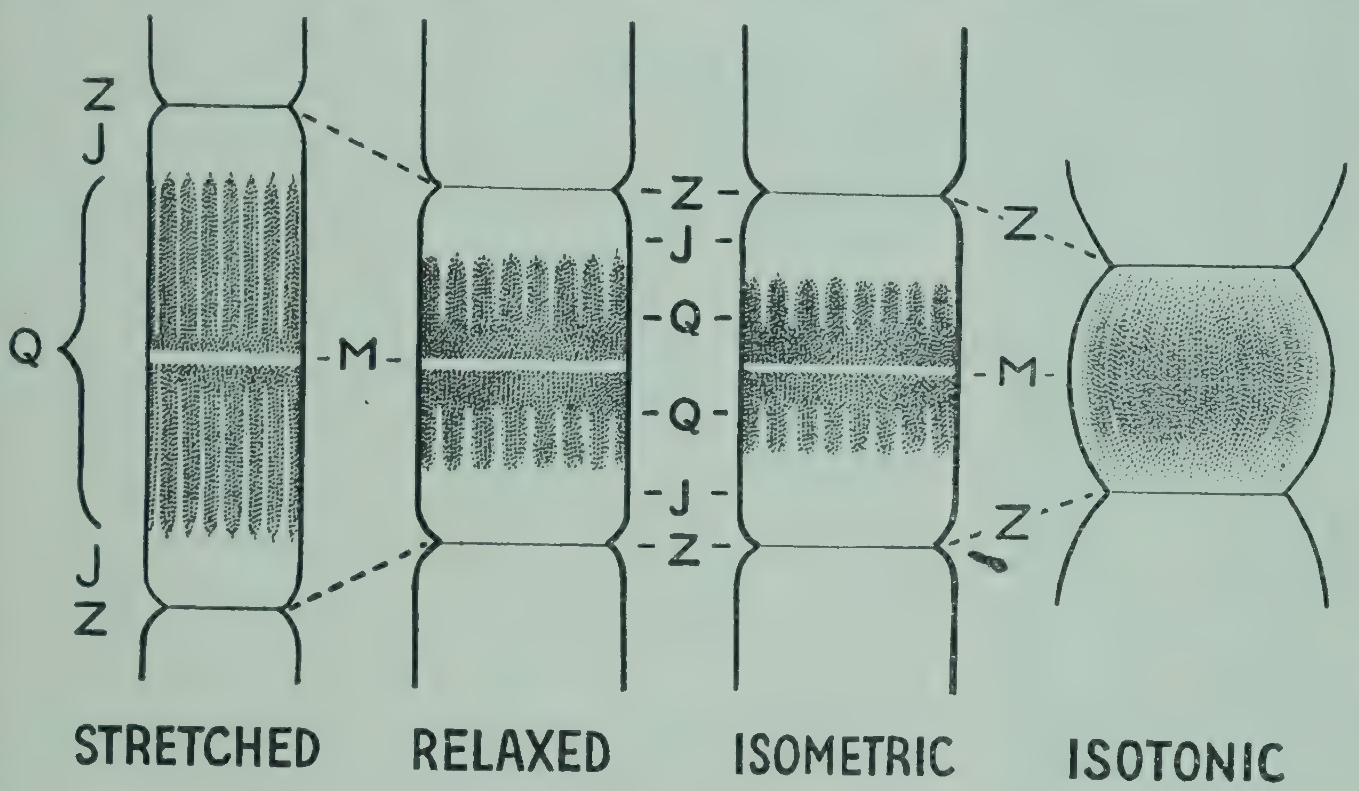

Fig. 33. Diagram of Sarcomeres in various states.

On isometric contraction the sarcomere remains unaltered in length and volume, but there is a shrinkage by 18 per cent. of the dark (Q) stripe and an expansion by 28 per cent. of the light (J) stripe.† Tiegs ‡ considers that the membrane of Krause does not form simple transverse partitions across the fibril, but runs in a spiral form along its whole length as a continuous structure, between the turns of which the sarcomeres are placed (Fig. 34).

When a muscle fibre is examined under the microscope by polarised light, it is seen to be made up of alternate bands of singly and doubly refracting material. The doubly refracting (*anisotropic*) substance which appears bright when viewed with crossed Nicol prisms, corresponds to the dark (or Q) band, and the Z-disc ; the singly refracting (*isotropic*), which now looks dark, to the light (or J) band. Actually the J band is also slightly anisotropic.

Double refraction is due to a substance possessing a regular molecular organisation which is not perfectly symmetrical in all directions. Thus, most crystals show it, but not those which belong to the cubical system, *e.g.*, NaCl. A muscle fibre can be shown by the electron microscope § to be made up of elongated filaments (aggregated molecules) of myosin, each of them birefringent, arranged parallel to one another in the fibril, and running through both light and dark bands in continuity. The transverse bands of cross striation are also visible in these fibrils. It has been found that while solutions of myosin are flowing, or are being stirred, which would orient the elongated molecules parallel to one another, the property of double refraction appears.* This would explain the str birefringence of the Q-discs, but not the much slighter birefringence of the J: it is tr however, that the myosin molecules are more regularly arranged in the Q-discs. It h been stated that the adenosine derivations and lipoids are concentrated in the J ban but most of the cations in the Q band; perhaps these modify the optical properti Glycogen is chiefly found in the sarcoplasm.

When a muscle fibre contracts, there is an appare reversal of the situations of the light and dark stripes, owi to the fact that the interstitial sarcoplasm is squeezed o from between the bulging sarcomeres, and accumulates each side of the membranes of Krause. The accumulation sarcoplasm in this situation makes the previously light str appear dark, and the dark striæ by contrast lighter than the were before. That there is no true reversal of the striæ shown by examining the muscle by polarised light, the tw substances, isotropic and anisotropic, retaining their relativ positions, though the double refraction is reduced. The tim course of the change in the double refraction has bee found † to follow a curve very similar to that for tensio development.

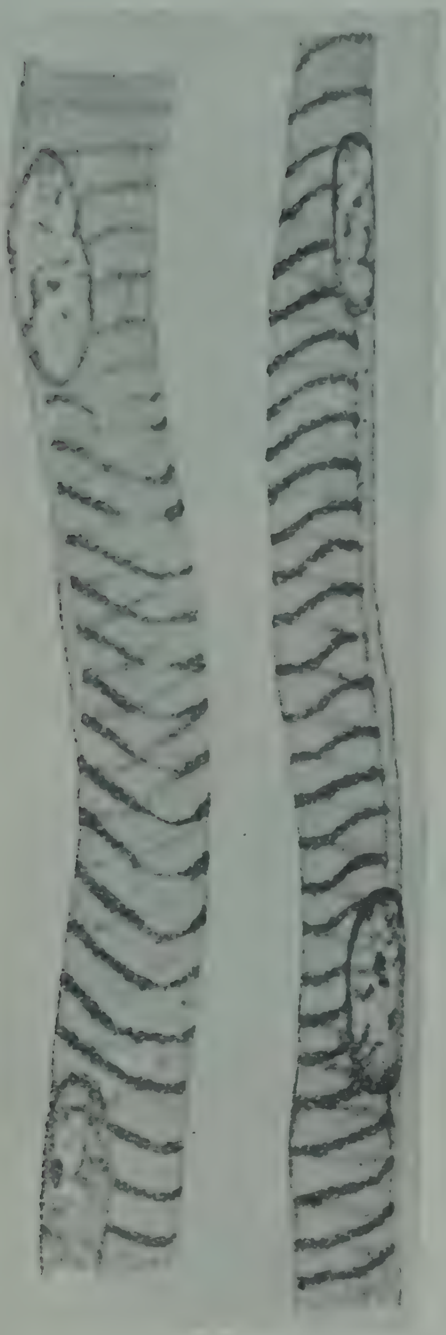

FIG. 34. Two thin muscle fibres of superior oblique muscle of rabbit. The left-hand one shows a double and the right-hand one a single spiral arrangement of striation. (TIEGS. *Proc. Roy. Soc.*, 1934, **116B.**)

Nerve Supply. Every skeletal muscle is connected with the central nervous system by a so-calle motor nerve. The fibres of this are by no mean all motor in function; some, often as many as two fifths of the whole, conveying impressions from th muscle to a centre, some are sympathetic fibres o unknown function, but the remainder are motor fibre conveying nerve impulses from a nerve centre to th muscle. These last—the motor nerve fibres, divide into numerous (sometimes as many as 150) branche when near to the muscle, and each branch terminate in a muscle fibre by means of a special end organ—th motor end plate. Here, the neurilemma of the nerve fibre becomes continuous with the sarcolemma, the medullary sheath ends suddenly, while the axis cylinder ramifies in a plate of nucleated protoplasm, called the *motor end plate*, the protoplasm of which i continuous with a thin sub-sarcolemmal layer of sarcoplasm (Fig. 32). Beneath this layer of sarcoplasm lies the striated contractile substance of the muscle. The ultimate ramifications of the axis cylinder end freely upon the surface of the end-plate protoplasm, but are precluded from physical continuity with this by retaining, and being enclosed by, the thin axolemma of the nerve fibre. This membrane, and the superficial sarcoplastic material, are of considerable theoretical importance in the study of neuromuscular transmission. Each muscle fibre has one end plate. It has been claimed that the end plates are capable of amœboid movements, that when muscles have been exercised they are demonstrably expanded over a larger area,‡ and that the bulk of the sole plate is increased when the muscle is paralysed by curare and diminished when exhausted by strychnine.§

After section of a motor nerve the muscle fibre shrinks and loses its contractility, but the end plates remain intact for many months, and if the nerve regenerates, regain their nerve fibres and may resume function a few days after re-innervation.||

EXCITATION OF MUSCLE AND OTHER TISSUES

In order to avoid subsequent repetitions, we shall now consider the excitation of muscle, and at the same time give a general account of the excitability of other tissues, such as nerve, since many phenomena of excitation are common to all tissues.

A skeletal muscle may be caused to contract in various ways. Normally it contracts only in response to impulses starting in the central nervous system and transmitted down the nerves. But contraction may be artificially excited in various ways in a muscle *in situ* or freshly removed from the body. The agency which is applied to the muscle to evoke a response is called a *stimulus*. Most of the fundamental work on striated muscle has been done with the muscles of cold-blooded animals, mainly the frog, dissected out of the body, often with a length of the motor nerve attached. In such a nerve-muscle preparation we can cause contraction by various forms of stimuli—mechanical, thermal, or electrical—applied to the muscle or to the nerve (direct and indirect stimulation). Thus the muscle responds with a twitch if we pass an induction shock through it or its nerve, or pinch either with a pair of forceps. Or we may cause contraction by the application of strong glycerol or salt solution to the nerve.

When the stimulus is powerful enough to elicit a response it is called an *adequate stimulus* : if not strong enough it is inadequate, but may nevertheless produce certain concealed effects.

Independent Excitability. These experiments do not prove conclusively that muscle itself is excitable. It might be urged that, when we stimulated the muscle, we really only excited the ramifications of the nerve in the muscle, and that these in their turn excited the muscle to contract. This is indeed usually the case,* because nerve fibres are excited by smaller stimuli than are muscle fibres. But that muscle fibres are capable of independent excitability is shown in the classical experiment by Claude Bernard.†

The brain of a frog is destroyed, and the sciatic nerves on each side exposed. A ligature is then passed round the right thigh underneath the nerve, and tied tightly so as effectually to close all the blood vessels supplying the limbs, without interfering with the blood supply, to the nerve. A little curare solution is then injected into the dorsal lymph sac. After a quarter of an hour it is found that the strongest stimuli may be applied to the left sciatic nerve without causing any contraction of the muscles it supplies. On the right side, stimulation of the nerve is as efficacious as before. Both gastrocnemii respond readily to direct stimulation, showing that the muscles are not affected by the drug. Since both sciatic nerves have been exposed to the influence of the curare, the difference on the two sides cannot be due to any effect on them of the curare. We have also excluded the muscles themselves. So we must conclude that the curare paralyses the muscles by preventing the excitatory process from passing over from the nerve to the muscle, and that muscle can be excited by direct stimulation.

Direct proof of independent excitability of muscle is provided by the fact that individual muscle fibres may be seen under the microscope to contract when stimulated by microelectrodes at points remote from end plates.‡

ELECTRICAL EXCITATION

It is characteristic of excitability in general that a stimulus of very small energy content may evoke a response in which very much larger amounts of energy are released.

‡ Gelfan. *Amer. J. Physiol.*, 1930, **93**, 1.

Of all the different stimuli capable of exciting muscular contraction, th electrical is the most satisfactory, because the phenomenon of excitation is itse of an electrical nature. It is easy to graduate accurately the intensity an duration of the stimulus, and the stimulus may be applied many times to an point on the muscle or nerve without injury. The four commonest forms c electrical stimuli employed are (1) the make and break of a constant current such as that from an accumulator, (2) the inducted currents of high intensit and short duration obtained from an induction coil, (3) condenser discharge (4) alternating current.* As the student will become familiar with thes in his practical work, no description of the common forms of apparatus neede for producing these stimuli will be necessary here.†

Resistance and Impedance. When a constant current is passed through a tissue, the *resistance*, in accordance with Ohm's law, is,

$$R = E/C,$$

where E is the e.m.f. and C the current intensity. Owing to polarization (p. 116) the current strength rapidly falls off to a low value, because the permeability of the membranes in the tissue to the ions is restricted.

If an alternating current is used less resistance is offered because of the absence of polarisation. The resistance to an alternating current is called *impedance*. With an alternating current $I = I_0 \sin \omega t$, where $\omega = 2\pi \times \nu$ (ν = frequency and I_0 = amplitude) the impedance Z includes resistance R and capacitance C. If resistance and capacitance are in parallel, then ‡

$$Z = \sqrt{\frac{R^2 + \omega^2C^2R^4}{(1 + \omega^2C^2R^2)^2}}$$

Galvanic Stimulation. If a weak *constant current* be passed through a muscle or any part of its nerve, at the make of the current the muscle gives a single sharp contraction—a *muscle twitch*, in which, according to the current strength, and other conditions, few or many of its muscle fibres may be involved. During the passage of the current no effect is apparently produced, though on careful observation we may with strong currents see that there is a state of continued contracture limited to the immediate neighbourhood of the cathode, which lasts as long as the current is passing through the muscle, and is not propagated to the rest of the muscle. If the current be now broken, the muscle may remain quiescent, but if the current was above a certain strength, the muscle responds to the break of the current with another single twitch. With a current of moderate strength we may get a contraction both at make and break of the current, *the make stimulus being more effective than the break stimulus.*

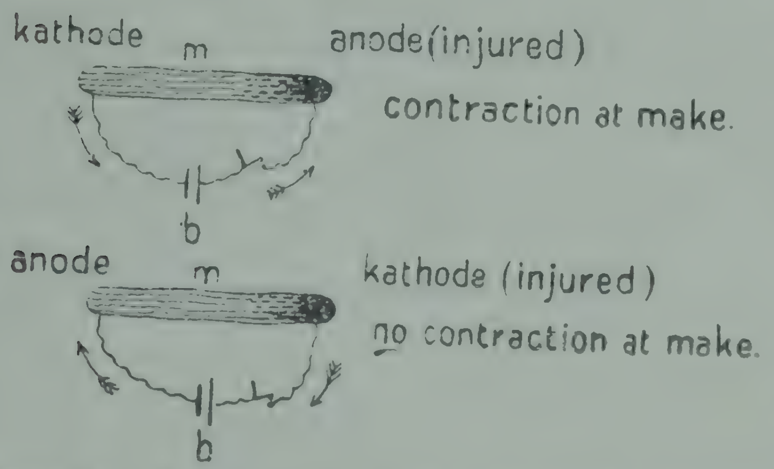

Fig. 35. Diagram to show the Effect of Local Injury on the Excitability of a Muscle. *b*, battery; *m*, muscle. The arrows indicate the direction of the current.

Besides this difference in intensity at make and break of the constant current, there is a difference in the point from which excitation starts. *A make contraction starts from the cathode, a break contraction from the anode.* This is called *polar stimulation* and is well shown by the following experiment.

If a muscle be killed at any spot, its excitability at this spot will be destroyed. Hence if we stimulate a muscle at the dead spot, no contraction will ensue. This fact may be used to demonstrate the facts of polar excitation. A muscle with parallel fibres such as the sartorius, is killed at one end, and a constant current passed, first from the dead to the uninjured end, and then in

the reverse direction (Fig. 35). It is found in the former case, when the anode is on the dead part (which is therefore inexcitable), that break of the current is ineffective, and in the latter, when the cathode is on the dead surface, that the make stimulus is ineffective, showing that the part excited corresponds to the cathode at make and to the anode at break.

As will be seen later, the *duration* of the flow of current also affects the result when short periods of flow are concerned. With a current of very short duration no excitation is produced at break. Every induction shock is such a current of very short duration produced in the secondary coil by make or break of the primary circuit, and can be therefore regarded as a make stimulus, and when such a shock is led through a muscle the contraction in each case will start at the cathode, *i.e.* the point at which the induction shock leaves the muscle.

The general laws for stimulation of nerve fibres are similar to those for stimulation of muscle fibres directly.

Faradic Stimulation. Using the *induced current* as a stimulus, it is found that the contraction on break of the primary current is often stronger than that on make. It must not be imagined, however, that there is any contradiction between this and the fact that the make of a constant current is a stronger stimulus than the break. It is due to the fact that the break-induced current is, for physical reasons, a stronger one than the make current. Both are currents of very short duration, so short that only the rising phase of each is effective. It has been shown that, when we use currents of such short duration, the fall is ineffective ; so in both cases, whether we make or break the current in the primary circuit, we are dealing with a *make* stimulus in the muscle.

In using either of these modes of stimulation we find that there is a certain intensity which the stimulating current must possess in order that any effect shall be produced. Any strength of stimulus below this is known as a *subliminal* stimulus. A *liminal* stimulus (sometimes known as *minimal* or *threshold* stimulus) is the weakest stimulus that will produce any result, *i.e.* in muscle a contraction. With galvanic excitation, this is also called the *rheobasic strength.* A *maximal* stimulus is one that produces the strongest contraction of which a muscle is capable as a result of a single stimulus. A *submaximal* stimulus is any strength of stimulus between these two extremes.

Time Factor in Excitability. Examination of the properties of different living tissues demonstrates that their excitabilities vary widely. Some tissues require on galvanic stimulation a much stronger current than others, or, on faradic stimulation, a closer coupling of the secondary to the primary coil. Again, some respond to galvanic but not to faradic excitation, or *vice versa.* It is clear that comparison of excitabilities in different tissues is unsatisfactory, if at all possible, on such indications as these. In view of the fact that there is no fundamental qualitative difference between galvanic and faradic currents, such a statement as " excitable to faradic, inexcitable to galvanic electricity," is meaningless.

Dealing with galvanic stimulation as more readily analysable than faradic, it is found that the following must be taken into account in studying excitability :—

(*a*) *The current density* or strength of current (c) or else the *voltage* (V)—to which (c) is proportional—required to stimulate.

(*b*) *The duration of flow* of the current. It has been found that a current that will just excite when of a particular duration, fails to do so when its duration is reduced below a certain level ; also, for a given current, further continuation of the current, beyond a particular duration, differing for each tissue, produces no further effect.

An elementary illustration, given by Lapicque, will serve to show the importance of the time factor in excitation. A liquid potentiometer is used consisting of a long narrow trough filled with zinc sulphate solution. Into it dip two plates of amalgamated zinc A and B (Fig. 36), placed about one metre apart and connected with the source of current ; two other similar plates also dip into the gutter; O is stationary and near to A, while C can be dipped in and out of the solution, thus making and breaking contact. The electrodes EE are placed in contact with a strip of plain muscle (frog's stomach). The strength of current flowing through the tissue is proportional to the distance of C from O. If C be plunged into the groove at intervals of a few seconds, farther and farther from O at each immersion, a point, the *threshold* will be reached, at which each prolonged immersion is followed by contraction of the plain muscle. The distance OC at which this occurs (say 10 cm.) is noted. Now C is withdrawn and dipped as quickly as possible in and out of the groove at the same point, giving stimuli lasting only about one-tenth of a second; no contraction will result. If the distance OC is made greater, however (say 70 cm.), so as to increase the potential tapped off, even this brief duration will stimulate.

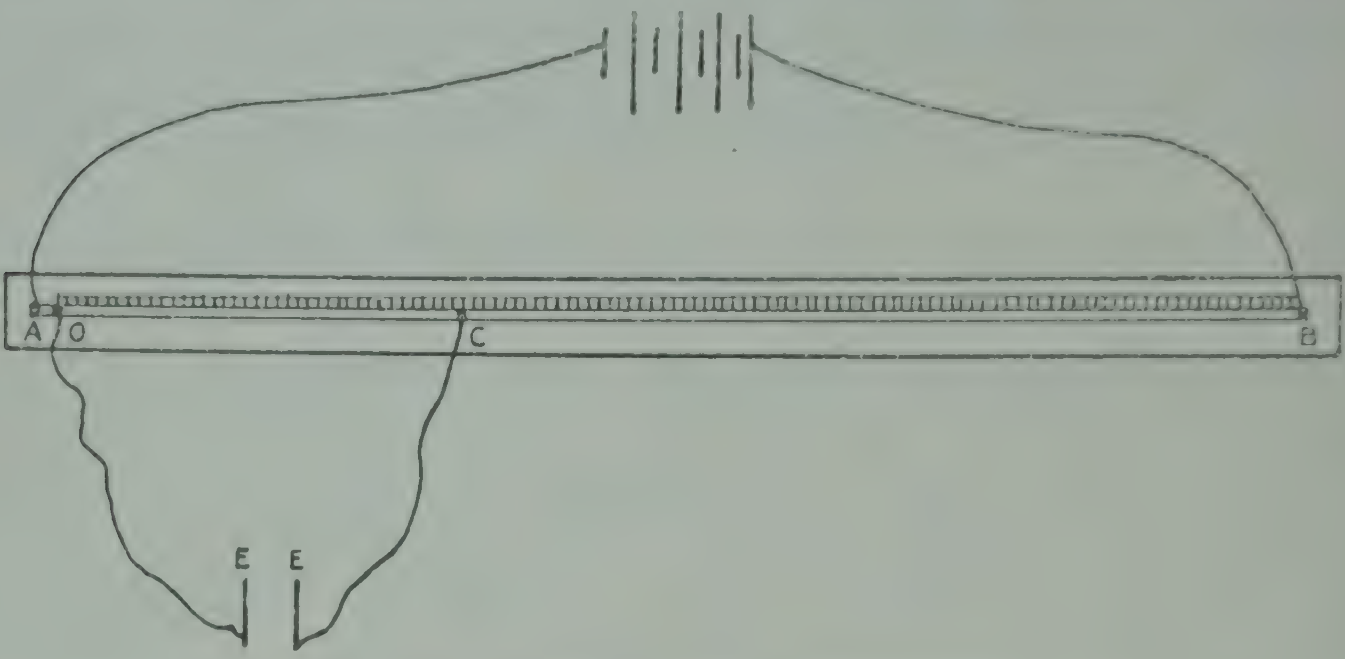

FIG. 36. Simple Liquid Potentiometer.

(*c*) The *rate of change* of the current strength. In (*a*) and (*b*) it has been assumed that the current was established and stopped instantaneously ("rectilinear" or "square" waves) as in Fig. 37 (A), whereas under certain circumstances a current might fluctuate by a slope, *e.g.* as shown in Fig. 37 (B), and these fluctuations would need to be taken into account. If, instead of plain muscle, the nerve of a frog's sciatic-gastrocnemius preparation be placed in the electrodes EE, and the cursor C of Fig. 36 be *quickly* moved along the groove, say, from O to 20 cm., so as to cause a rapidly increasing current to flow through the nerve, the latter will be stimulated as shown by contraction of the muscle. Now return the cursor to O and move it away *very slowly*; it will be found that although it be moved far beyond the previous distance (say to 50 cm.), no contraction will follow—the slow slope of current-increase is ineffective, whereas the steep gradient stimulated the nerve.

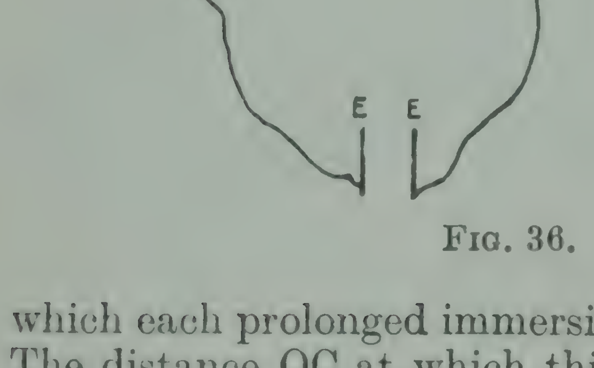

FIG. 37.

Du Bois Reymond expressed this fact by stating that excitation depends on the rate of variation of current density from moment to moment; the more rapid the change the greater the excitatory effect.

This statement is now known to be only partially true. We should now regard it as more correct to say that the current excites during the first moments of its passage, whether variable or constant, but that a certain duration of flow is essential.

To demonstrate the importance of duration in the stimulation of such highly excitable tissues as nerve or striated muscle we require much more refined apparatus than that described above for use with the relatively inexcitable plain muscle. If we can get currents of sufficiently short duration, we can demonstrate that with *any* tissue a liminal current which will excite at a longer duration fails to do so when it is abbreviated beyond a certain limiting value. This limit for the frog's stomach is of the order of tenths of a second, while for the sciatic nerve it is of the order of thousandths of a second.

These simple considerations serve to illustrate the importance of the time factor in excitation, and to show that "slow" and "rapid" are purely relative terms when different tissues are under consideration.

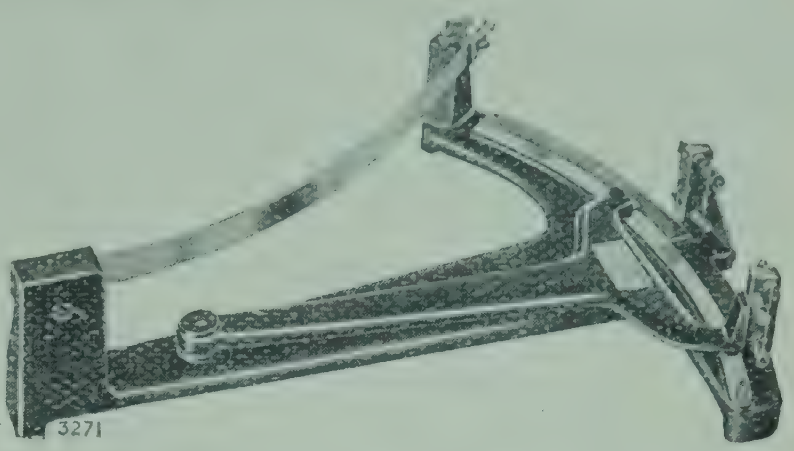

FIG. 38. Keith Lucas's Spring Rheotome.

Currents of sufficiently short duration can be obtained by the use of a mechanical device or rheotome, such as Lucas's pendulum or spring (Fig. 38), by which two keys are opened at known intervals. The first key is a short circuiting key, the opening of which starts the current, and the second one is in series, and its opening stops the current.

Another method is by the use of condenser discharges. The time taken for a condenser to discharge can be calculated if its capacity and the resistance of the circuit are known, the time being proportional to the product RC. The current strength is, of course, not constant during the discharge, but it is much easier to obtain currents of very short duration by the adjustment of condenser capacities than by any of the rheotomes for use with constant currents, and the drawbacks attendant on the use of discharges of rapidly declining strength have been overcome, since it has been shown that a discharge from a condenser charged to a given voltage is equivalent to a rectilinear constant current of duration = 0·37 RC seconds, at the same voltage (R = resistance of circuit in ohms ; C = capacity of condenser in farads).

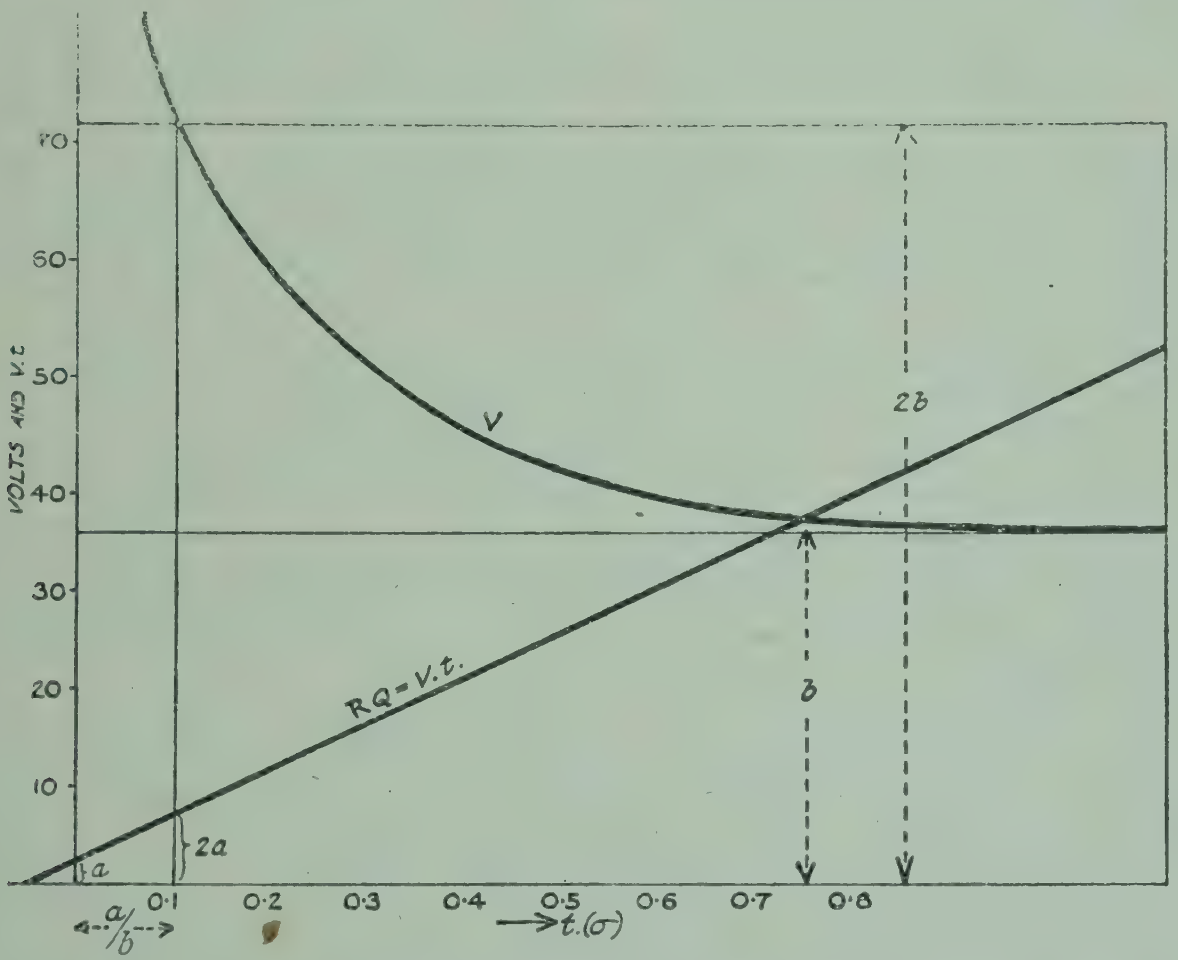

FIG. 39. To illustrate Weiss's Laws and their Relation to Chronaxie. V = curve of voltages. RQ = curve of quantities. $a = 3{\cdot}5$. $b = 36$ volts. $\frac{b}{a} = \bar{c}\ 0{\cdot}1$ msec. = chronaxie. Abscissæ = time in 0·1 msec. (σ). Ordinates figured = volts. Ordinates for RQ = V*t* are on same scale. (Modified from BOURGUIGNON. *La Chronaxie.*)

When the smallest voltages which will excite a tissue are plotted against the durations of the current, controlled in either of these ways, a curve of the rectangular hyperbola type (Fig. 39) is obtained, one of the asymptotes of which is a line at the level of the threshold voltage (*b*) for currents of infinite duration. Thus in Fig. 39, a voltage lower than *b* (= 36 v.)

will not stimulate that particular tissue under the given conditions of experiment ; a curren of 40 v. will stimulate if it lasts for not less than 0·55 msec., one of 50 v. if it lasts for a least 0·35 msec., etc.

For a different tissue, and with other conditions of experiment, quite different voltage and times would probably be obtained, but the form of the curve would always be the same, though the scales would differ. Such curves are called *strength-duration curves*. An important condition in the preparation of these is that all the conditions of experiment, except strength and duration of the exciting current, must remain the same throughout any given curve.

If the quantities of electricity (proportional to Vt) are plotted against times, a straight line is obtained.

These relations for constant currents are expressed by Weiss's laws :—

(1) For intensity,

$$= \frac{V}{R} = \frac{a}{i} + b.$$

(2) For quantity,

$$Q = it = a + bt,$$

where a and b are two constants.

a is the quantity of electricity where the graph cuts the ordinate.

b is the threshold strength at infinitely long duration. Almost identical relations are obtained by the use of condensers (Hoorweg's laws).

In a strength-duration curve, current strengths are plotted against the *excitation-times*, *i.e.* against the shortest times in which each strength can excite. Evidently, if other things were equal, the more excitable a tissue the shorter the time needed to rouse it to respond.

Lapicque calls the liminal value for indefinite duration (galvanic threshold) the *rheobase*, and estimates the excitability of a tissue by what he has called the *chronaxie*. This is one specially defined excitation-time.

The chronaxie may be defined as the shortest duration of a current of twice the rheobasic strength which will stimulate. Thus in Fig. 39, when the voltage is raised to 2b, the shortest duration which will excite is 0·1 msec., and this duration is the chronaxie. A less excitable tissue has a longer, and a more excitable one a shorter chronaxie.

In practice, in order to determine the chronaxie, all that is necessary is to find the galvanic threshold or rheobase, using an ordinary key, then double the voltage so employed, and finally, using either condensers or a suitable rheotome, find the shortest duration of this which will excite.

Provided the conditions of experiment are constant, the chronaxie of a tissue is a definite measure of its excitability, since in this time a current of twice the rheobasic strength is able to produce those physico-chemical alterations which determine excitation, and the more excitable the tissue is, the more quickly will that current produce those changes. It can be shown that what happens in an excitable tissue in, say, 0·3 msec., may require, say, eight seconds for a very inexcitable one.

Whether it is feasible to obtain constant conditions from one experiment to another, or even throughout a single experiment, is, however, a matter of opinion, which has been contested with some heat. Variation in the size or nature of the stimulating electrodes is especially liable to produce widely different results.*

The following table shows some approximate chronaxies for excitable tissues of very varying types :—

Tissue.	Chronaxie msec.	Approximate Duration of Contraction of Muscles.
		Seconds.
Frog's sciatic and gastrocnemius (esculenta) .	0·3	0·1
,, ,, ,, (temporaria)	0·7	0·1
Toad's sciatic gastrocnemius . . .	1·3	0·16
Frog's ventricle	3·5	1·0–2·0
Tortoise heart (testudo græca) . . .	8·2	2–3
Claw muscle of crab	30	5
Frog stomach	30–100	15–20
Pigment cells, skin of frog	1,000–15,000	—

It is evident from consideration of the figures for different chronaxies that there is a relation between chronaxie and speed of action of tissue. The more excitable tissue has, as a rule, a shorter chronaxie, shorter period of action, shorter refractory period, and a quicker rate of propagation than a less excitable one.

It is because of its very short duration (0·1 msec.) that the induced current is unable to effect the excitation of sluggish tissues such as some forms of plain muscle. When the duration is made extremely short, even very high voltages fail to excite any tissues. Hence high frequency alternating currents of enormous voltage can be passed through the body without any physiological effect other than that due to the heating effects, as in the practice of diathermy.

---

* For a criticism of the experimental facts regarding chronaxie, see RUSHTON. *Journ. Physiol.*, 1932, **74**, 424 ; **75**, 445.

According to Lapicque, the same chronaxie is found for a muscle stimulated directly or *via* its nerve. The classical view, which has been upheld by Rushton, was that the muscle is much less excitable than its motor nerve, and that when the " muscle " is stimulated it is really the nerves within it which are excited and these then stimulate the muscle fibres. In support of this opinion he adduces the α and γ curves of the nerve-muscle complex which were discovered by Keith Lucas. This observer found that the strength-duration curve of a muscle (with its contained nerve branches) was composite, as shown for curve B (Fig. 40), and supposed this to be due to the presence of a more excitable (or γ) tissue, which was probably nerve, and of a less excitable one (α), probably muscle. Lapicque, however, obtained a uniform curve resembling C, of properties akin to Lucas's α-curve. Rushton showed that in a parallel-fibred muscle either α- or γ-, or composite curves could be obtained, according to the angle at which the stimulating current passed relatively to the direction of the muscle and nerve fibres. This is because muscle and nerve fibres are most excitable when stimulated by currents parallel to their fibres, and least excitable to currents running at 90° to their fibre direction (more precisely the rheobase varies inversely as the cosine of the angle between current direction and fibre direction). Whether a given current tends to excite the muscle fibres or the intra-muscular nerve fibres will therefore depend not only on its strength and duration, but also on its relation to the direction of the muscle and nerve fibres. In many muscles a majority of the small nerves run roughly at right angles to the muscle fibres (Fig. 41). Hence, if as in Fig. 40 C, we stimulate with a current parallel to the muscle fibres we get the muscle or α curve, if at 90° the γ or nerve-excitation curve (Fig. 40 A), and if at 45° a composite curve (B).

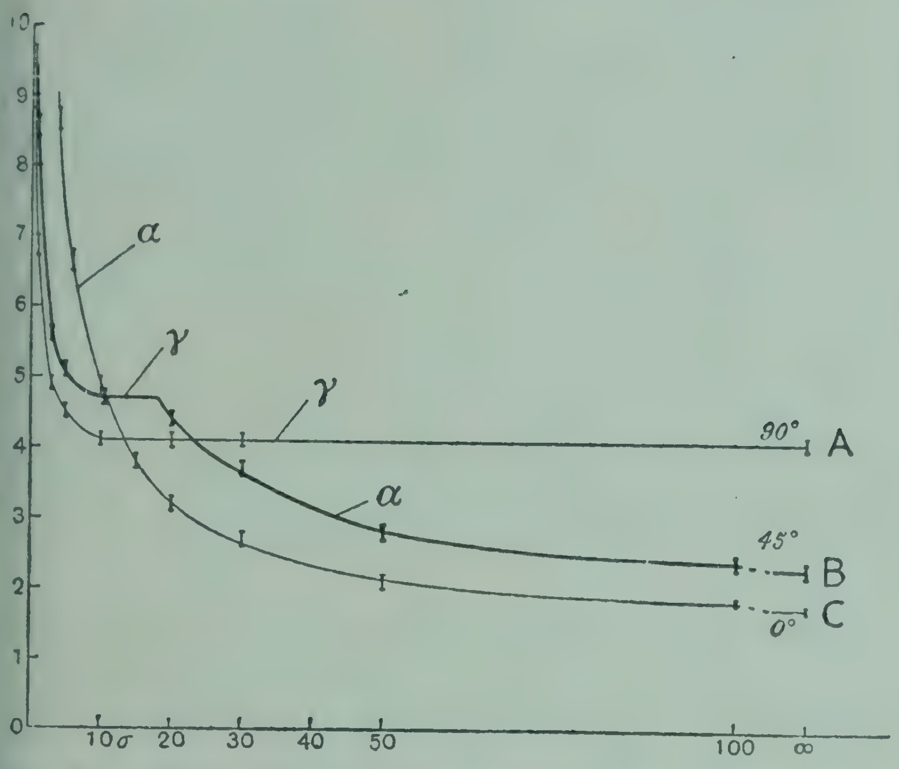

FIG. 40. Strength-duration curves from sterno-cutaneous muscle of frog stimulated at 90°, 45° and 0° to direction of muscle fibres. (RUSHTON, *J. Physiol.*, 1930, **70**, 334.)

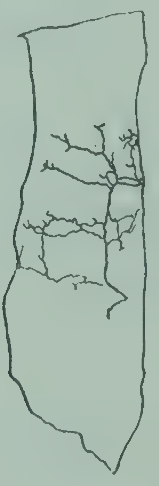

FIG. 41. Sterno-cutaneous muscle of frog showing direction of nerve fibres. (RUSHTON, *J. Physiol.*, 1932, **75**, 174.)

If the intra-muscular nerves are dissected away, or if curare is given, the curve becomes a smooth α-curve, characteristic of muscle, under all circumstances.

Lapicque's explanation is entirely different. He believed that unless the nerve and muscle have *approximately* the same chronaxie the excitatory state will not be transmitted (law of isochronism): this failure occurs when the chronaxie of one tissue is more than twice that of the other. Curare, he claimed, increases the chronaxie of muscle but not that of nerve; strychnine on the other hand reduces that of nerve but leaves the muscle unaltered: in both cases conductivity from nerve to muscle fails. He claimed that the conditions of Rushton's experiments are not such as would be expected to give true chronaxies.

LATENT ADDITION. Closely associated with the excitability of the tissues are the phenomena of latent addition of excitation, or " *summation of stimuli* " and of " *refractory period.*" If two *subliminal* stimuli are sent in within a sufficiently short interval of time, heir effect is summated so that two stimuli, each of which would be ineffective, may ogether produce an excitation. For summation of two stimuli to take place, the second timulus must occur at a time before the condition excited by the first stimulus has died way. The maximum time interval at which summation can take place will therefore vary rom tissue to tissue, and will bear a relation to the chronaxie. This is evident if we compare the maximum summation intervals for different tissues with their chronaxies. Thus for frog's nerve, with a chronaxie of 0·3 msec., the summation interval is 0·5 msec., while for frog's heart, with a chronaxie of about 3·5 msec., the maximal summation interval is 8·0 msec.

ELECTRICAL CHANGES IN MUSCLE

The fact that electrical currents can be obtained from living tissues was proved by Galvani * by his demonstration of " contraction without metals," as described below. It is easy with present-day apparatus to show that all living tissues when active exhibit differences of electrical potential, and these phenomena are of considerable practical and theoretical importance. Much of the description given here for muscle applies equally well to other tissues.

Polarisation. If a current from a battery be passed between two plates of platinum immersed in acidulated water or salt solution, *electrolysis* of the water takes place, bubbles of oxygen appearing on the anode, and bubbles of hydrogen on the cathode. If now we remove the battery, and connect the two electrodes by wires with a galvanometer, a current passes through the galvanometer and water in the reverse direction to the previous battery current. This current is called the polarisation current. The vessel in which the electrodes are immersed has in fact become a storage cell, the platinum covered with oxygen bubbles being the positive pole, and that covered with hydrogen bubbles the negative pole. Similar polarisation takes place when we pass currents through the tissues of the body by means of metallic electrodes.

We have already learnt in Chapter VIII that the electrical phenomena of living tissues are due to the existence of polarised membranes at the surfaces of the cells ; *i.e.* of membranes having a positive charge on one surface, usually the outer one, and a negative charge on the other surface. It is therefore essential in studying such phenomena to avoid other forms of polarisation, which would mask or modify them.

Hence, before we can pass currents into, or lead off currents from, living tissues, it is necessary to have some form of electrodes in which this polarisation will not occur. With one exception, polarisation always results when a current passes from an ordinary metallic conductor to a saline solution, but not when it passes from one saline solution to another. This exception is when the metal dips into a solution of its own ions, and this fact is taken advantage of in the construction of *non-polarisable electrodes.* In these a metal dips into a solution of its salt ; any tendency for polarisation is at once counteracted at the cathode by deposition of the metal on to the electrode from the solution, or at the anode by solution of the metal of the electrode to neutralise the negative charges carried thence by anions (Fig. 42). Some types of these electrodes are shown diagrammatically in Fig. 43.

In such electrodes the conduction of the current through the nerve or muscle to the metallic part of the circuit may be presented as shown in Fig. 42.

If a muscle such as the sartorius be removed from the body, and two non-polarisable electrodes connected with a delicate galvanometer be applied to two points of its surface, there will be a deflection of the galvanometer, showing the presence of a current which flows in the external circuit from uninjured to injured surfaces. This current of resting muscle is due to the leading off from the cell interiors at the injured places and the cell surfaces at uninjured ones, as explained in Chapter VIII. Hermann described the currents of rest thus : " In partially injured muscles every point of the injured part is negative towards the points of the uninjured surface." These phenomena are explained in Chapter VIII, Figs. 27—30. When the injured fibres are quite dead, this current of rest or " demarcation current " disappears. The potential is due to the electrical charge on the two sides of the plasma membrane, negative inside and positive outside. If the sartorius of the frog be cut out and immersed for

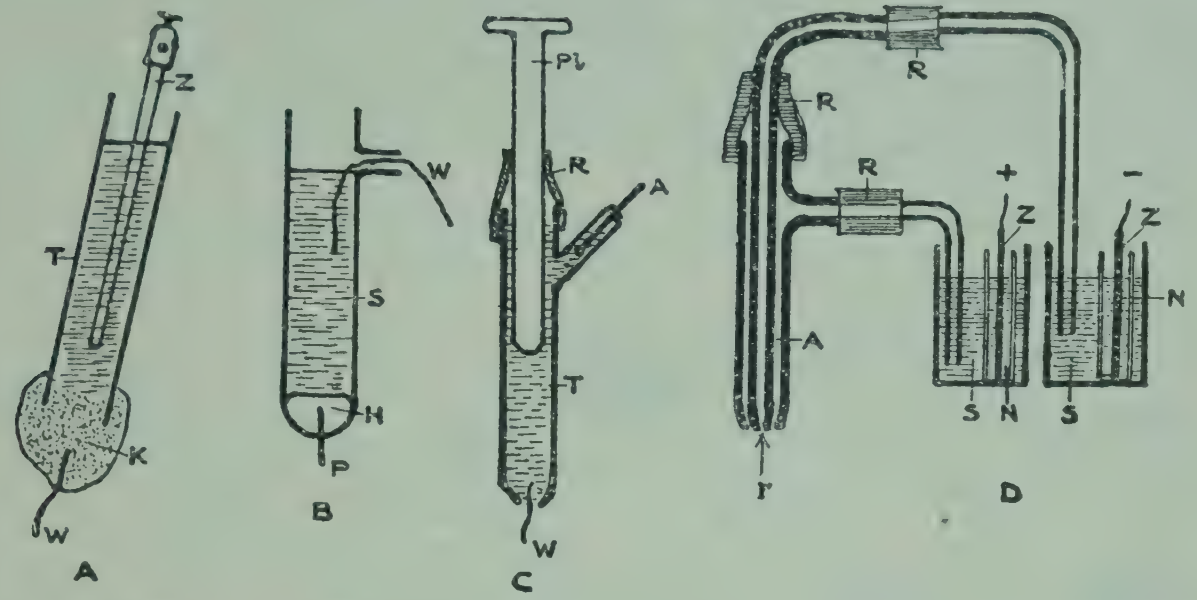

FIG. 43. Types of Non-polarisable Electrodes.

(A) Noyons' type of non-polarisable electrode. Z = amalgamated zinc rod imbedded in 10 per cent. gelatine containing $ZnSO_4$ and contained in the glass tube, T. K = plug of kaolin made with isotonic NaCl solution. W = thread wick soaked in isotonic NaCl leading to tissue.

(B) Ostwald type of N.P.E. P = platinum wire making contact with mercury H. S = isotonic NaCl solution containing solid calomel. W = saline wick lead to tissue.

(C) Lapicque's AgCl electrode. A = silver electrode coated with AgCl. Pl = plunger fitting rubber sleeve R, for filling electrode with NaCl solution. W = saline wick lead.

(D) Pratt's pore electrode. r = the fine pore which is the stimulating point. The tube is filled with saline solution and connected with the saline solution in the vessel S, in which is a porous N.P.E. cell filled with $ZnSO_4$ solution and having a Zn rod immersed in it. The outer tube, A, is the other electrode and is similarly connected with the other N.P.E. cell. R = rubber connections.

twenty-four hours in Ringer's solution, all the injured fibres die, and the uninjured fibre surfaces are then found to be equipotential.

If one end of the muscle be now injured by cutting or burning, a galvanometer will show the presence of a potential between injured and uninjured tissue. The existence of this current may be demonstrated as in Galvani's classical experiment, without using a galvanometer. If the nerve of a sensitive muscle-nerve preparation *a* (Fig. 44) be allowed to fall on an excised muscle *b*, so that one point of the nerve is in contact with the cut end and one with the surface of the second muscle *b*, the muscle *a* will contract each time the nerve touches *b* so as to complete the circuit. If the nerve of *b* is tetanised, *a* as well as *b* enters into a tetanic contraction, for reasons that will be clear later.

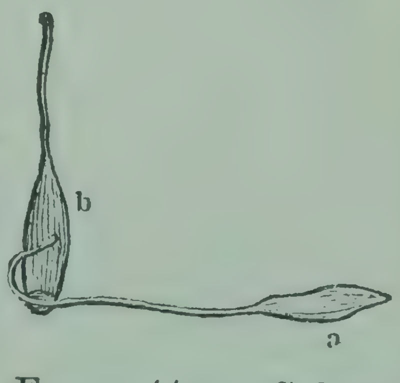

FIG. 44. Galvani's "Contraction without metals."

Although resting uninjured muscle shows no current, a definite electrical change occurs in it when it contracts. As we saw in Chapter VIII these changes are due to depolarisation (or even reversed polarisation) of the membranes at the active places. To show this change, we may lead off two points, one on a cut end and one on the surface of the muscle of a muscle-nerve preparation, to a galvanometer. We shall first obtain a deflection of the mirror due to the "*current of rest*," the cut surface being negative to the resting uninjured surface. If now the nerve be stimulated in any way, so as to throw the muscle into a tetanus, the galvanometer mirror swings back towards the zero, showing that the current which was present before is diminished, *i.e.* the uninjured surface on excitation also becomes negative, so that little or no current now flows from it to the injured part. When the excitation of the nerve is discontinued, the galvanometer indicates once more the original current of rest. This diminution of the current of rest during activity used to be spoken of as the "negative variation." It is now usually termed an "action potential."

In order to obtain a graphic record showing the time-relations of the electrical changes accompanying a single muscle twitch, it is necessary to employ some instrument which can react much more rapidly than the ordinary galvanometer. For this purpose we may employ either the capillary electrometer, the string galvanometer or a suitable oscillograph.

The Capillary Electrometer consists of a glass tube drawn out to a fine capillary, and filled with mercury. The point dips into dilute sulphuric acid. The meniscus of the mercury in the capillary is observed under the microscope. If now the capillary and acid be connected with two points, any difference in the potential of these two points causes a movement of the meniscus in the direction in which the current is flowing, and the extent of the excursion varies with the difference of potential. It is little used to-day.

FIG. 45. Diagram of arrangement of cathode ray oscillograph with photographic apparatus, for electrocardiography. For other purposes a similar arrangement can be used, lead-off being to any two of the "patient electrodes" shown in the figure. (HARRIS.)

In the *String Galvanometer of Einthoven* a very delicate thread, of silvered quartz or of platinum, is stretched between the poles of a strong magnet, which are pierced by holes so that the thread may be illumined by an electric light from one side, and from the other a magnified image of the thread may be thrown upon a screen. Whenever a current passes through the thread it moves laterally, and the lateral movement may be photographed on a moving photographic plate. It will detect very small currents and will respond reasonably accurately to very rapid changes in potential. The records of rapid fluctuations are more nearly correct than those obtained by the capillary electrometer, but such errors as are present are less amenable to correction.

All modern workers prefer to use the more delicate and more rapidly moving *oscillograph*, such as the *cathode ray oscillograph*, the potentials being amplified by valves, and the movements of the beam being photographed (Fig. 45). This instrument is an electrometer (measurer of difference of potential), and not a galvanometer (current measurer) so that no current passes the surface. Hence the use of non-polarisable electrodes is not essential.

Diphasic and Monophasic Potential Waves. If an uninjured regular muscle (Fig. 46) such as the sartorius be kept in moist air and stimulated with a single induction shock at one end, *x*, or indirectly, and two points, *a* and *b*, be led off to a suitable instrument, *e.g.* a string galvanometer, each stimulus applied at *x* gives rise to a *diphasic* electrical variation. When the muscle is stimulated at *x*, a contraction wave commences which travels down the muscle through *a* to *b*. The electrical investigation of the muscle shows that excitation of *x* arouses an electrical change which also passes down the muscle at the same rate as the mechanical change, which it slightly precedes. On leading off from *a* and *b* there is a latent period between the stimulus and the first change, representing the time taken for the change to travel from *x* to *a*. When the change reaches *a*, this becomes the seat of a depolarisation, the membranes previously positive becoming discharged. Hence the current would pass in the outer circuit from *b*, which is still positive, to *a*. We may say therefore that *a* is negative to *b*. A fraction of a second later the excitatory change has passed on to *b* and has died away at *a*. Now *b* is negative to *a*, and the current therefore passes in the opposite direction. Between *a* and *b*, therefore, there is a diphasic current, the first phase representing negativity of *a* to *b*, and the second phase negativity of *b* to *a*. *A diphasic change is thus also a sign of a propagated change.* Every excitation of a normal muscle gives rise to a diphasic variation of such a direction that the point stimulated first becomes negative to all other points of the muscle, and this "negativity," to use a loose but convenient expression, passes as a wave down the muscle, preceding the wave of contraction and travelling at the same rate (Fig. 47).

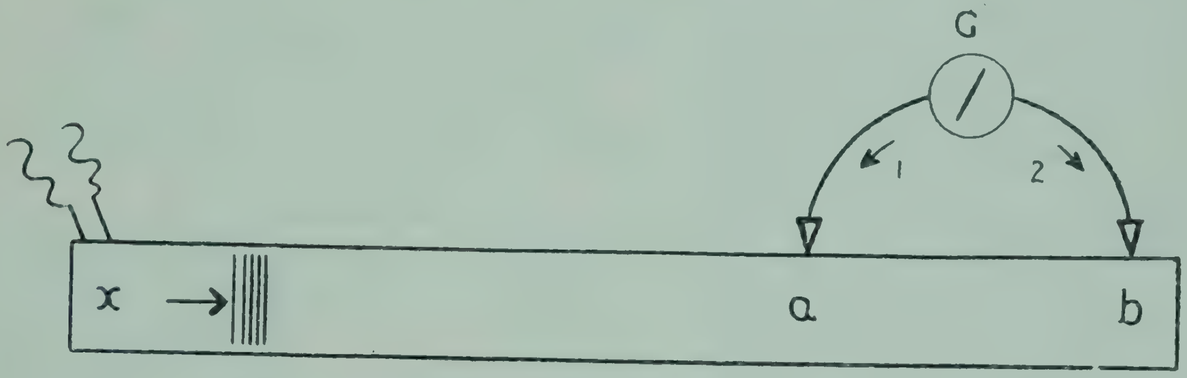

FIG. 46. Diagram showing Diphasic Variation of uninjured Muscle.

If one leading-off point be injured, *e.g.* at *b*, that point becomes permanently negative, and excitation fails at that point. A single stimulus applied at *x* will in this case give only a *monophasic* variation, or *spike*, in which *a* is relatively negative, *i.e.* less positive than previously, compared with *b*.

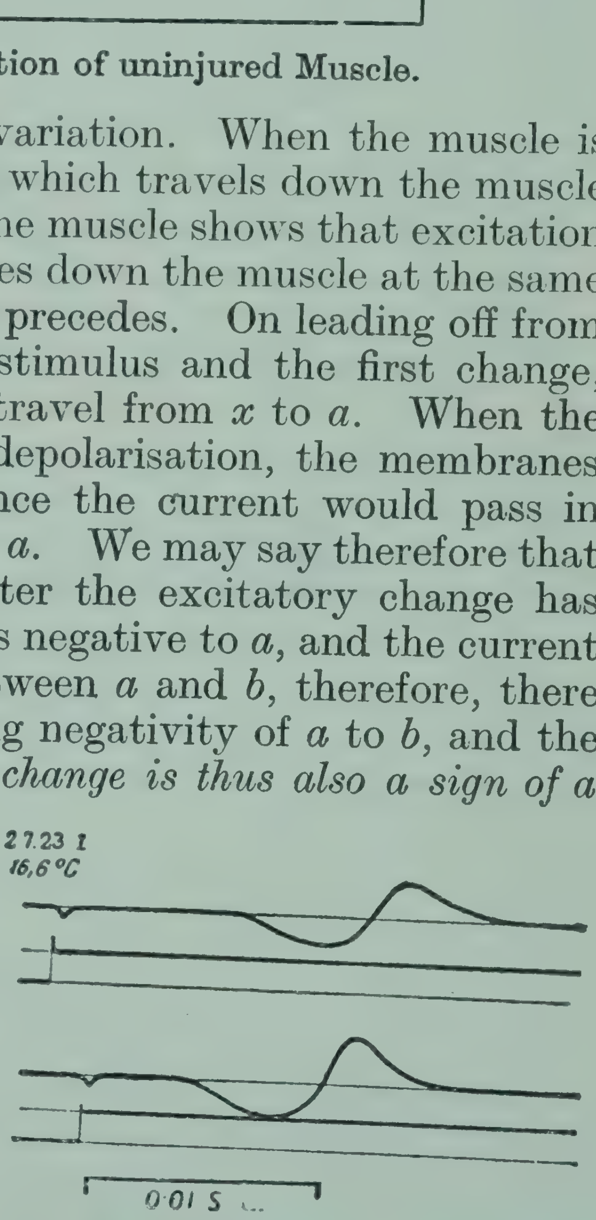

FIG. 47. Diphasic action potentials in gastrocnemius muscle of frog, recorded by an oscillograph. Below each tracing is the signal line showing stimulation of the sciatic nerve. The upper tracing shows stimulation of central end of the nerve, the lower one of the peripheral end. The time-line below indicates 0·01 sec. (ROSENBERG. *Pfluger's Arch.*, 1929, **223**, 120.)

When we study the time relation of the electrical variation ensuing on a single stimulus, we find that the electrical change under the electrodes begins at the moment that the stimulus is applied. It takes for frog muscle about 0·0025 second to attain its culminating point. At this point the mechanical change or contraction of the muscle begins. These time relations vary with the temperature of the muscle. We have already seen that the effect of lowering the temperature is to increase the latent period of the contraction. In the same way it slows the rise of the electrical change and the rate of propagation of the wave of electrical change. We are therefore justified in regarding the electrical change as an index to the ionic changes evoked in the muscle as the direct result of the stimulus. The material change in form of each contracting unit is secondary to these changes. As the result of stimulation, depolarisation is aroused at the point of excitation, and travels thence along the muscle fibre at a rate of about 3 metres per second, *i.e.* the same rate as that of the following wave of mechanical change and, like this, varying with the temperature.

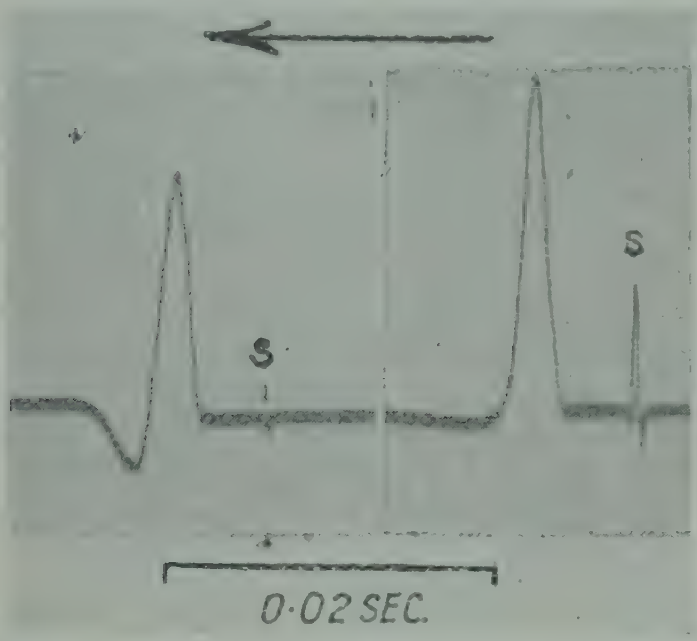

FIG. 48. Diphasic (left) and monophasic (right) action potentials in non-medullated nerve of Maia, recorded by cathode ray oscillograph. Point of stimulation shown by S. Read from right to left. Time indication = 0·02 sec. (Tracing by Dr. J. Yule Bogue.)

Under no conditions, however, may an excitatory condition be propagated without the presence of a contraction, though often this may be so small as to be difficult of detection. When a muscle is so treated as to diminish its mechanical response, *e.g.* by soaking in water, the electrical response is also reduced, and the two finally vanish together when the muscle passes into " water rigor."

The phenomena of diphasic and monophasic action potentials are shown with even greater clarity in nerve than in muscle. If two uninjured points on a nerve trunk are led off to an oscillograph, a diphasic potential wave can be recorded at the passage of each excitation applied to the nerve, and indicates the transmission along the nerve of a nerve impulse. If one of the points led off has been injured, *e.g.* by burning with a hot wire, then each nerve impulse passing the other, uninjured, point occasions a monophasic action potential (Fig. 48).

Somewhat similar tracings can be obtained from almost any tissue when excited.

For further details of nerve action potentials, see Chapter XII.

THE MECHANICAL CHANGES THAT A MUSCLE UNDERGOES WHEN IT CONTRACTS

By " contraction," in the physiological sense, we mean the state, resulting from an adequate stimulus, which would, if unopposed, lead to shortening of the muscle. If the state is opposed there may be no shortening, but even lengthening of the muscle.

If a skeletal muscle be stimulated by a single induction shock either directly or by the intermediation of its nerve, it responds by a single short, sharp contraction, followed immediately by a relaxation. The amount of shortening in contraction obviously depends on the length of the fibres, which can usually shorten by, at most, about half their resting length ; so the sartorius, with long fibres, shortens by about 50 per cent., but rectus femoris, with short fibres, only by 23 per cent. It is equally obvious that the force exerted by a muscle depends on the number of fibres present in a cross section, and on their direction with reference to the tendon or bone to be moved. In volume the muscle undergoes a very slight, and for most purposes negligible, shrinkage,* but each muscle fibre, and the whole muscle, becomes shorter and thicker.

Isotonic Contraction. If a weight be hung on to the tendon of the muscle, the muscle during contraction may raise the weight and thus perform mechanical work. Under these conditions the muscle supports the weight all the time, and on contraction lifts it. Such a contraction is called *isotonic.* To determine the time relations of the contraction it is necessary to employ the graphic method.

In order to record the shortening of the frog's gastrocnemius, the muscle is excised together with a portion of the femur to which it is attached, and often with the whole length of the sciatic nerve. The femur is clamped firmly, and the tendo Achillis attached by a thread to a light lever, free to move round an axis at one end. The point of this lever is armed with a writing point, which just touches the blackened surface of a piece of glazed paper stretched round a cylinder (drum) which can be made to rotate at a constant speed.

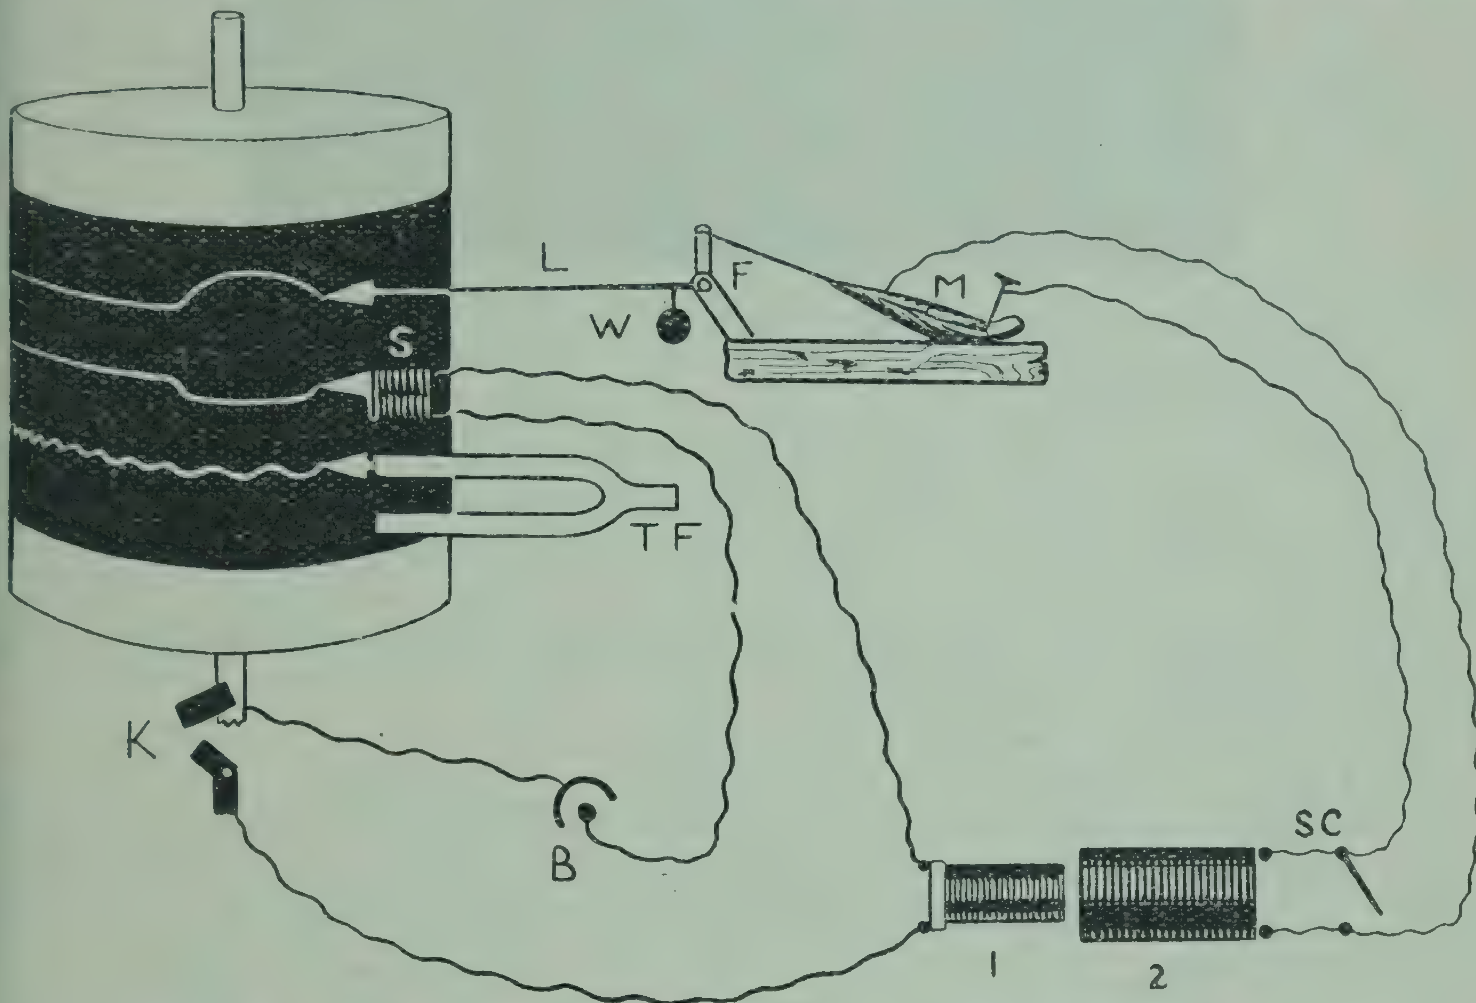

FIG. 49. Diagram of Apparatus for recording simple Muscle Twitch.

If the drum is moving, the point draws a horizontal white line or abscissa on the smoked paper.

If a single induction shock be sent through the muscle, M (Fig. 49), or nerve, the lever, L, turning on the fulcrum, F, and carrying the weight, W, is jerked up, falling again almost directly, and a curve is drawn like that shown in Fig. 50.

In all such graphic records we should have also—

(1) *A time record.* This is furnished by means of a tuning fork, T.F., vibrating at a suitable rate, *e.g.* 100 times per sec.

(2) *A record of the exact point at which the nerve or muscle is stimulated.* This may be obtained by means of an electro-magnetic signal, S, interposed in the circuit, and arranged to write on the revolving drum.

In Fig. 50 the upper line is the curve drawn by the lever as the muscle contracts; the small upright line *a* shows the point at which the muscle was stimulated; and the lower line is the tracing of the chronograph, every vibration representing $\frac{1}{100}$ of a second.

The graphic record may, in consequence of instrumental inertia, be a very inaccurate reproduction of the true events occurring in the muscle itself. When the muscle begins to contract, it imparts a very rapid movement to the lever which therefore tends to overshoot the mark and deform the curve. This source of error may be reduced by making the lever as light as possible, and hanging the extending weight in close proximity to the fulcrum of the lever, as shown in Fig. 49. Since the energy of a moving mass is proportional to the square of the velocity ($= \frac{1}{2} mv^2$) and the tension due to the weight as well as the velocity imparted to the weight on contraction is directly proportional to the distance of the weight from the fulcrum, it follows that it is better to load the muscle with 40 grammes 1 millimetre from the axis than with 1 gramme 40 millimetres from the axis, though the tensio put on the muscle will be the same in both cases.

---

* MEYERHOF and MÖHLE. *Bioch. Ztschr.*, 1933, **260**, 544, 469; **261**, 252.

In the first case the energy of the moving mass will be proportional to $\frac{40 \times (1)}{2} = 20$ and in the second to $\frac{1 \times (40)^2}{2} = 800$, and it is this energy which determines the overshootin of the lever and the deformation of the curve.

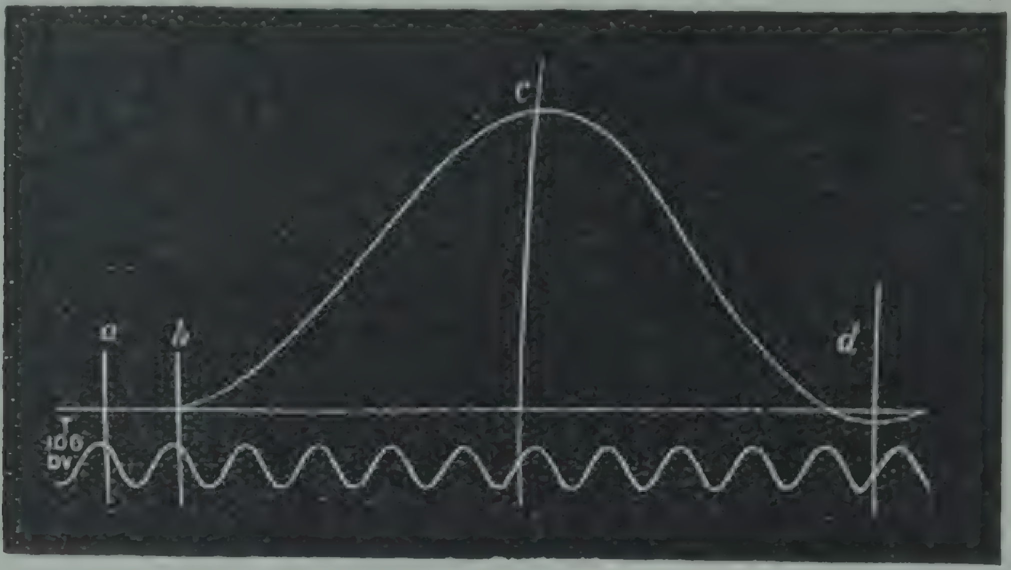

FIG. 50. Curve of simple Muscle Twitch. *a*, point of stimulation ; *ab*, latent period ; *bc*, period of contraction ; *cd*, period of relaxation. Time = $\frac{1}{100}$ sec. (After STIRLING.)

In the method just described, the lever follows the muscle in its movement, the tension on the muscle remains nearly the same throughout, and hence the term *isotonic*. An isotonic contraction or twitch, such as that in Fig. 50, produced by a single stimulus, consists of three evident phases :

(1) A phase during which no apparent change takes place in the muscle. This is called the *latent period.*

(2) A phase of shortening or *contraction.*

(3) A phase of *relaxation* or return to the original length.

The small curve seen after the main curve is due to elastic vibrations of the lever. The latent period for the frog gastrocnemius as usually recorded at 18° C. occupies about 10 msec., the phase of shortening 40 msec. and the relaxation 50 msec.

Thus a single muscle twitch in a frog is completed in about $\frac{1}{10}$ second. It must be remembered, however, that this figure is only approximate, and varies with the temperature of the muscle and its condition, being much longer in a fatigued muscle. It depends also on the animal from which the muscle is taken, and on the particular muscle. In mammals it is not necessarily shorter than in the frog. Thus in the cat, the period of actual *contraction* is, soleus 100 msec., gastrocnemius 40 msec., internal rectus of eye 8 msec. In the tortoise a single twitch may last from half a second to five seconds, according to temperature. In the wing muscle of a wasp the duration of a single contraction may be only 5 msec.

In the living body the latent period is considerably increased by reason of the inertia of the parts moved. But it is of considerable theoretical interest. When measured as above, there is also instrumental inertia, so that the true latent period must always be shorter than is apparent from a curve obtained by the foregoing method. The viscosity and extensibility of the muscle must also prolong this apparent latent period, since the first effect of contraction of any part of the muscle will be to stretch the adjacent part, and only later to move the tendon to which the lever is attached. If we have a weight suspended by a piece of elastic, it will not follow a pull exactly, but will lag behind, the first part of the pull being occupied with stretching the india-rubber, and only when this is stretched to a certain degree will the weight begin to rise.

It is possible to obviate instrumental inertia by employing photographic methods for the record. Such experiments were carried out long ago by Burdon-Sanderson. But more recent observations have brought fresh facts of interest to theory regarding the latent period.

According to Einthoven[*] and also Roos[†] the interval between the moment of stimulation and the onset of mechanical changes is less than 0·4 msec., if inertia is eliminated

[*] EINTHOVEN, Harvey Lectures, 1924–1925, p. 111.

[†] ROOS. *J. Physiol.*, 1932, **74**, 17.

as much as possible, but most observers find it to lie between 3 and 20 msec., according to emperature, in frog sartorius muscle.

If very accurate records are made of isometric contractions, the first mechanical change n frog sartorius at 0° C. is a *relaxation* * about 7·5 msec. after the stimulus : it is only about $\frac{1}{1000}$th as great as the subsequent increase of tension, which begins (at 0° C.) between 11 and 20 msec. from the stimulus (Fig. 51) ; the degree of initial relaxation is so slight as to have been missed previously.

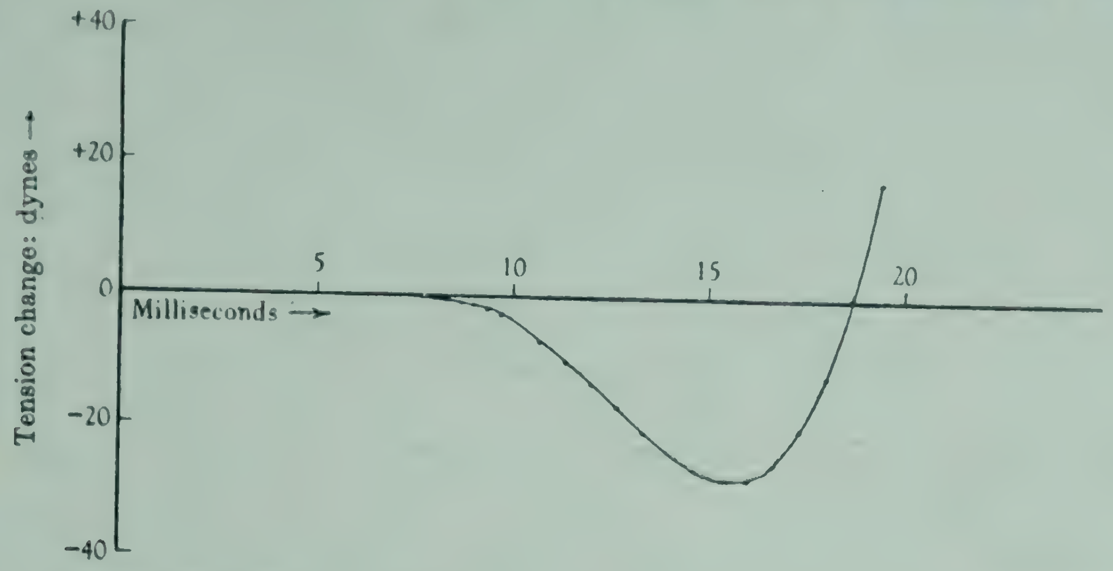

Fig. 51. Change of tension vertically against time after shock horizontally in isometric contraction of a frog sartorius at 0° C. The small initial relaxation is shown, and commencement of the tension increase. (Abbott and Ritchie, *Proc. Phys. Soc.: J. Phys.*, 1947, **107,** 5.)

The relaxation after contraction is helped by a moderate load, and in a normal condition is complete. It is probably not active but is a passive effect of extension. This may be shown by allowing a muscle to contract while floating on mercury when the subsequent lengthening on relaxation is incomplete.

Isometric Contraction. It is sometimes useful to be able to record the development of tension in the active muscle when a change in length is prevented y fixing its ends immovably. For this purpose the muscle is allowed to pull gainst a strong spring, the movements of which are magnified. Thus the hortening of the muscle is almost entirely prevented, but the increase in its

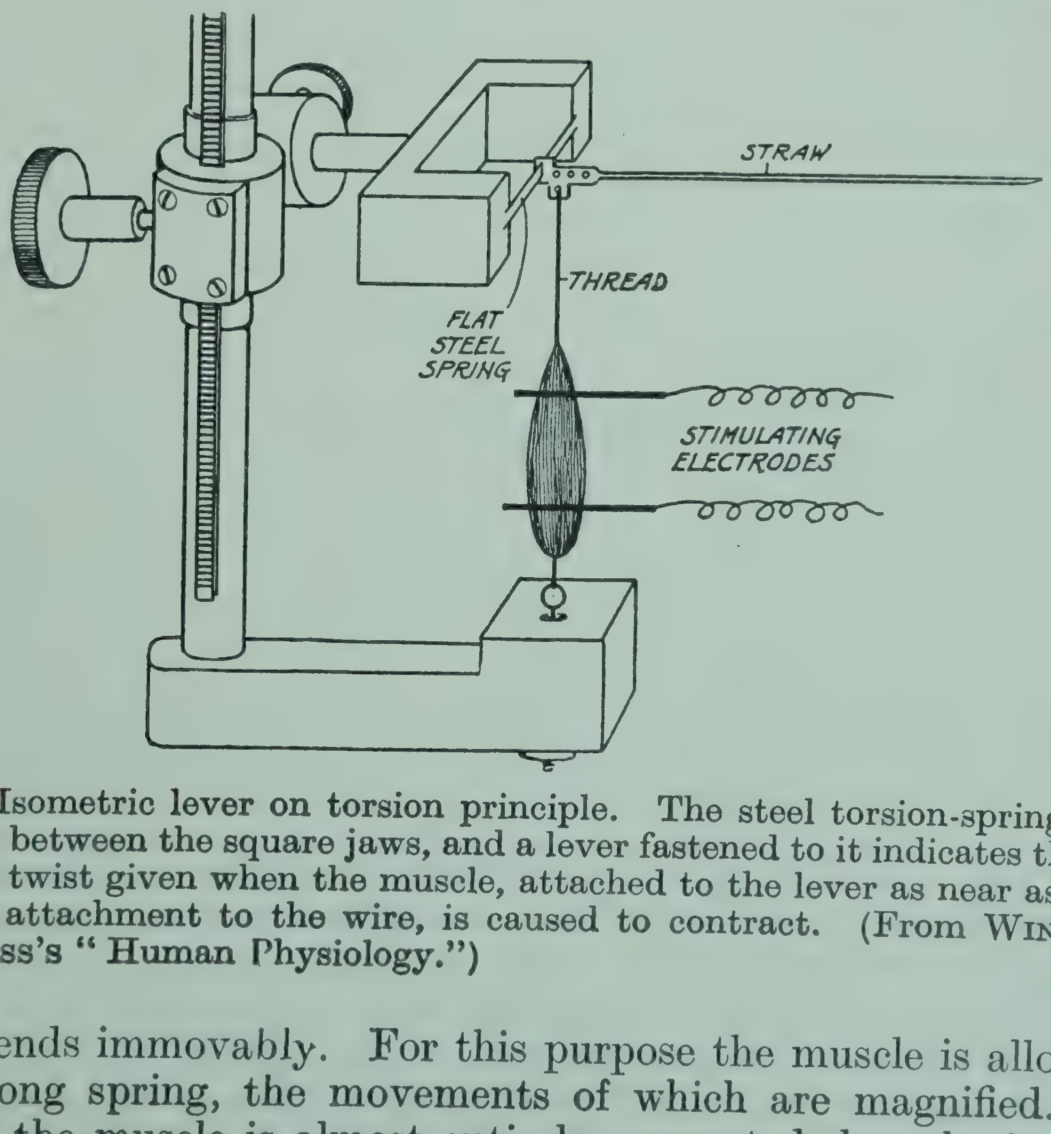

Fig. 52. Isometric lever on torsion principle. The steel torsion-spring is fixed firmly between the square jaws, and a lever fastened to it indicates the extent of the twist given when the muscle, attached to the lever as near as possible to its attachment to the wire, is caused to contract. (From Winton and Bayliss's "Human Physiology.")

---

* Sandow. *J. Cell. and Comp. Phys.*, 1941, **24,** 221.

tension causes a minute but proportionate movement of the spring, which is suitably recorded. Since in this case the length of the muscle remains approximately constant throughout, it is known as the *isometric* method. The great magnification necessary in this method necessitates the use of instruments having low inertias and very high natural vibration frequencies (about 1,000–2,000 per second), as otherwise the record is deformed by the vibrations of the spring. The simplest arrangements are on the torsion-wire principle, one type of which is shown in Fig. 52. A piezoelectric device is probably more precise.

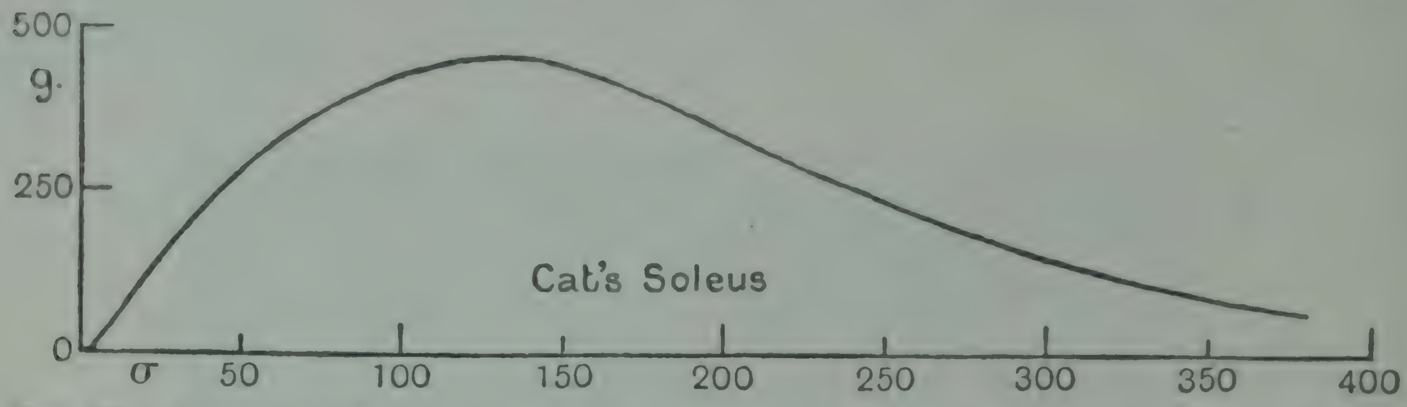

Fig. 53. Isometric Contraction of Cat's Soleus Muscle. Abscissæ = time in msec. Ordinates = grammes tension. (Cooper and Eccles, *Journ. Physiol.*)

The *isometric twitch* shows that tension change with time has a form roughly similar to that of the isotonic contraction relating length change with time, but differing from it in detail. The rise of tension commences very abruptly about 1 msec. after the beginning of the electrical response (mammal), the curve showing at first an upward concavity, soon followed by an upward convexity. After reaching the summit, there is an upwardly concave passive relaxation (Fig. 53). The duration of the contraction process is given by the interval between the onset of electrical response and the summit of tension production.

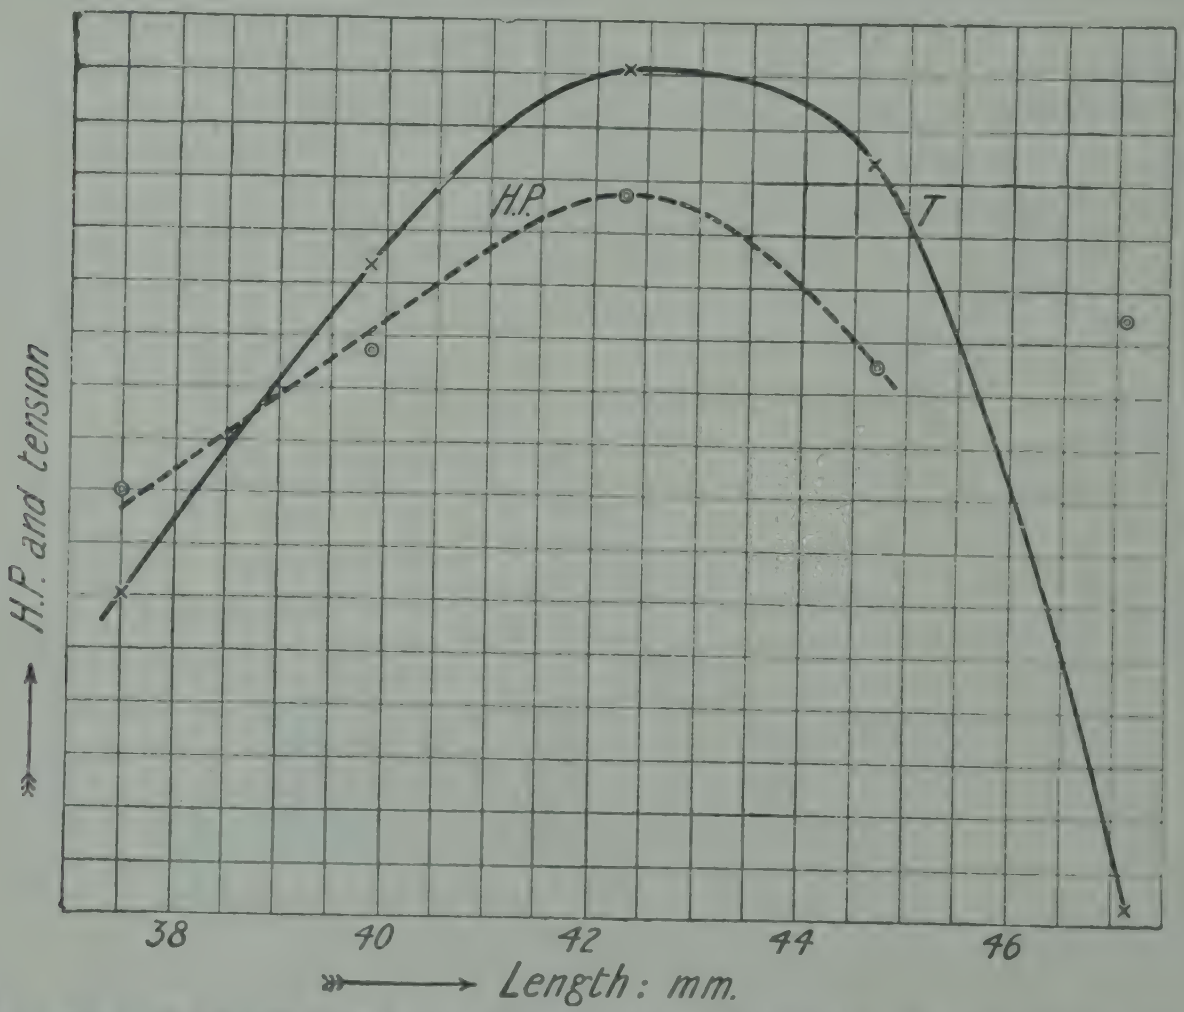

Fig. 54. Relations of heat and tension production on isometric contraction to initial length of muscle. (After Evans and Hill. *Journ. Physiol.*, **49**, 10.)

Very considerable tensions are produced in isometric contractions; several hundred grammes with a small frog's gastrocnemius. The maximum is reached sooner, but the duration of the contraction process is definitely *longer* in an sometric twitch than in an isotonic contraction ; the duration is also increased y increasing the "initial" tension on the muscle, *i.e.* by stretching the muscle efore its stimulation. Isometric contractions have been recorded in single ibres.*

The isometric contraction is a practical convenience, but is theoretically a pure abstraction, because, in order to record the tension changes, *some* shortening, though slight, must occur : also, even if approximation of the extremities of the muscle is quite prevented, internal shortenings occur during the contractile stress, and these changes introduce complications into the theoretical study of the energetics of contraction.

Effect of Initial Length of Fibre. The tension developed in a muscle contracting isometrically in response either to a single stimulus or to a short tetanus is not constant but is found to vary with the initial length of the muscle (Fig. 54). As the length of the resting muscle is increased by extending it, up to a length somewhat greater than that which it possesses in its normal extension in the body, the tension developed on contraction also increases.† Single fibres also show this property.‡

In the body the bony levers are so arranged that the muscles at their greatest length work at a maximum mechanical disadvantage which lessens continuously as the muscles shorten and approximate their points of attachment. The load on a muscle is thus diminished continuously as the muscle contracts.

MECHANICAL PROPERTIES OF MUSCLE

The operation of the musculature in bringing about skeletal movements is a question of the direct application of elementary anatomy and mechanics : with such knowledge the bodily movements are easily explained. But the causation of muscular contraction is a primary physiological problem.

So far as we know, the only function subserved by muscle is the mechanical one of contracting and so causing movement. It is therefore important to have as clear an understanding as possible of the differences in the physical properties of muscle in the resting and contracted states, and of the energy changes involved in contraction and relaxation. Yet despite much work on the subject these properties are so far by no means adequately studied, or even properly defined. This is largely because the properties of a muscle, considered as a whole, are the resultant of the properties of its different structural components, *e.g.* contractile substance proper, sarcolemma, connective tissue sheaths, etc. ; the separate properties of which must differ considerably.

Tension-length Relationship. When a resting muscle is stretched, the relation between tension and length is not in agreement with Hooke's law, which says that strain (= elongation) is proportional to the stress (= tension) producing it. Instead, we find that the successive lengthenings produced by successive equal increments of tension become less and less, so that, over a large range the tension is an exponential, instead of a linear, function of the stretch. The explanation of the departure from Hooke's law is probably to be found in the compound make-up of a muscle ; the isolated fibre, however, shows similar properties, but it has been claimed that the sarcolemma alone also does, so that the properties of the actual contractile material in this respect are unknown.

The tension-length diagram of a tetanically contracted muscle is altogether different (Fig. 55). At lengths between 60 per cent. and 100 per cent. of the normal extended length of the muscle the relation is roughly linear, as Hooke's law would lead us to expect, but at lengths over 100 per cent. the tension *falls off* with increasing length, though up to 160 per cent. this is reversible : above 160 per cent. the stretching is not fully reversible. At lengths *below* about 60 per cent. of the normal extended length the shortening is also partly irreversible, the fibres then being said to be in the delta state. These relationships mean that, as already explained, at the lengths at which muscles normally function in the body, the greater the initial length of the muscle, the greater th tension produced when the muscle contracts isometrically.

Energy Disposal in Shortening. When a muscle shortens the tension set up is utilised either to lift a load or accelerate a mass, to act on its own elasticity, or to overcome its own viscous resistance. Much work on these properties has led to conflicting results and it is now clear that the problem cannot be reduced to these simple terms. The difficulties are due to the complex structure of muscle and to the fact that the muscle fibres do not instantly develop the full amount of energy, and then utilise this tension to do work, etc., but *develop the energy of contraction as shortening proceeds*, and at a rate which depends on the speed and extent of shortening. If the muscle is allowed to shorten, more energy is set free than if the contraction is isometric (the Fenn effect) : if it lengthens on " contraction " (as when there is too heavy a load) then the energy supply is reduced. Consequently, any attempts to compare the viscous and elastic properties of resting with those of contracting muscle are defeated, because the properties of the contracting tissue are altered by the methods used to test those properties. In fact, the muscle is living, and therefore has the property of adjusting itself to altered conditions. This shows itself as a " stiffness " of the contracting muscle, which has sometimes been regarded as due to an alteration in its visco-elastic properties.

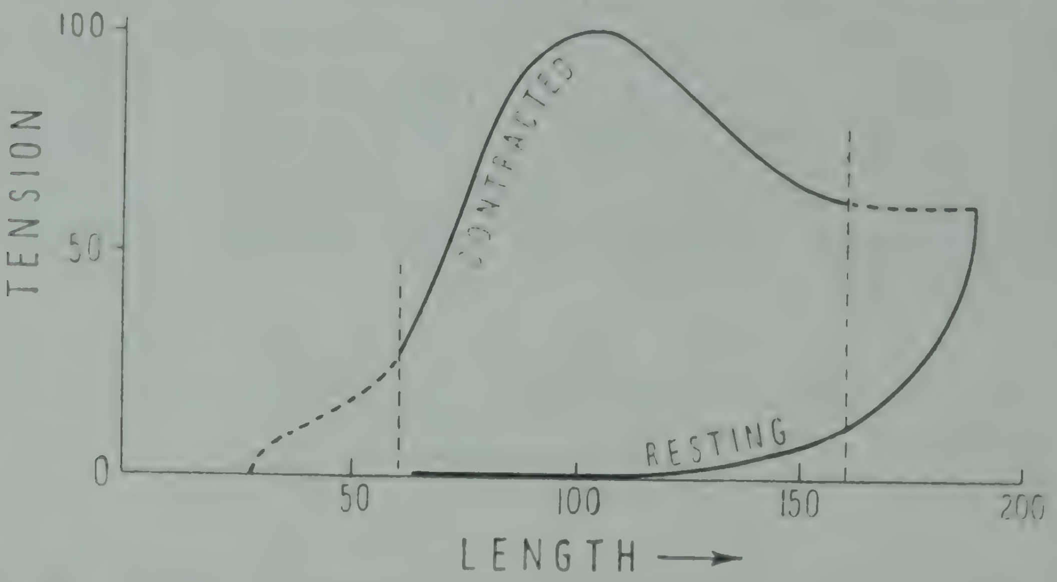

Fig. 55. Relation between tension and length in resting and fully contracted muscle.

It is for these reasons that muscle shows a decrease of force with increase in speed of shortening, and a decrease in speed of shortening with increase of load.

Effect of Temperature. When a muscle is moderately warmed, the chemical processes involved in the phase of shortening as well as those responsible for relaxation are hurried up, while the "viscosity" is diminished. The latent period therefore becomes shorter and the muscle curve steeper and shorter.

It is very often observed that in an isotonic twitch the height of the curve of contraction of the warmed muscle is greater than that obtained at ordinary temperatures. This apparent increase in height is really instrumental in origin, the quicker moving muscle jerking the lever beyond the real extent of the contraction.

When isometric contractions are recorded, it is found, at any rate in the frog, (1) that the tension developed in a single twitch diminishes slightly as the temperature is raised from 0° C. to 25° C. ; (2) that the tension developed in a tetanus lasting a sufficient time to attain its maximum is increased with rise of temperature, but not to a very marked extent ; (3) that the durations of the latent period and contractile process are greatly reduced, and the duration of relaxation somewhat reduced by rise of temperature.

If a muscle be heated gradually (without stimulation) up to about 45° C., it begins to contract slowly at about 34° C., and this contraction reaches its maximum at 45° C., at which point the muscle has entered into pronounced *rigor mortis.* This form is often called heat rigor.

Cold has the reverse effect. All the processes of muscular activity are slowed, so that the latent period and the contraction period are prolonged. It is therefore often convenient for analysis of the progress of events in contraction to use frog muscle at 0° C. Slight cooling also lowers the *threshold of excitability* of muscle, so that any form of stimulus is more effective at 5° C. than at 25° C. If a muscle be cooled for a short time to a little below zero, it loses its irritability, which returns if the muscle be gradually warmed again. Prolonged exposure to severe cold irrevocably destroys its irritability, and warming the muscle will now simply being about *rigor mortis*.

PROPAGATION OF CONTRACTION. The whole muscle does not, as a rule, contract simultaneously. When excited from its nerve the contraction begins at the end plates and spreads in both directions through the muscle. The rate of propagation of the contraction wave can be measured only by employing a curarised muscle, so as to avoid the wide spreading of the excitatory change by means of the intra-muscular nerve twigs. For this purpose a curarised sartorius muscle is stimulated at one end, and the electrical variation in the muscle recorded by two pairs of electrodes, one (*a*) placed near the exciting electrodes and the second (*b*) at the other end of the muscle. The difference between the times of commencement of the electrical variations at the two places gives the time taken by the contraction wave in travelling from *a* to *b*.

By measurements carried out in this way it is found that the rate of propagation of the contraction in frog's muscle is 3 to 4 metres per second ; in the muscle of warm-blooded animals it may amount to 6 to 12 metres. The *length of the wave* is obtained by multiplying the rate of transmission by the duration of the wave at any one point. It varies in frog's muscle between 150 and 360 millimetres. Thus the muscle fibres are much too short to accommodate the whole length of the wave, and the contraction of the whole muscle must be made up of the summated effects of the contraction wave as it passes from point to point.

The Effect of Strength of Stimulus. The "All-or-None" Rule. If a series of single break induction shocks be applied to a muscle at intervals of not less than five seconds, it will be found that when these are below a certain strength no effect at all is produced. The shocks are said to be *subliminal*. On gradually increasing the strength a point will be reached at which a small contraction will be observed (*liminal* or *threshold* stimulus). Further steady increase in the strength of stimulus will now result in a gradual increase in the power of the contractions (*submaximal stimuli*) until finally a maximum response is reached (*maximal stimulus*) ; further increase in the strength of stimuli (*supra-maximal stimuli*) cause no further increase in contraction, although the current actually used may be increased a hundred times. It might seem that this limited gradation of the muscular response according to strength of stimulus was due to a similar gradation in the response of each of the muscle fibres of which the muscle is composed. The fact is, however, that when a minimal or submaximal response is obtained, not all the fibres making up the muscle are contracting. A minimal contraction is, in fact, a contraction in which *a few* fibres of the whole muscle are stimulated. A maximal contraction is one in which *all* the fibres are stimulated. So far as concerns each individual muscle fibre every contraction is probably a maximal contraction, *i.e.* the rule of "all-or-none" which was first enunciated for heart muscle is probably true for skeletal muscle. The difference between skeletal and heart muscle lies in the fact that in the former the excitatory process does not spread from one fibre to its neighbours. If, for instance, we take a curarised sartorius and split its lower end as in Fig. 56, the stimulus applied to A causes a contraction only of the left side of the muscle, while a stimulus applied to B in the same way limited to the right side. If a piece of ventricular or auricular muscle of the frog or tortoise were treated in the same way, a stimulus applied at A would cause a contraction which would extend to B.

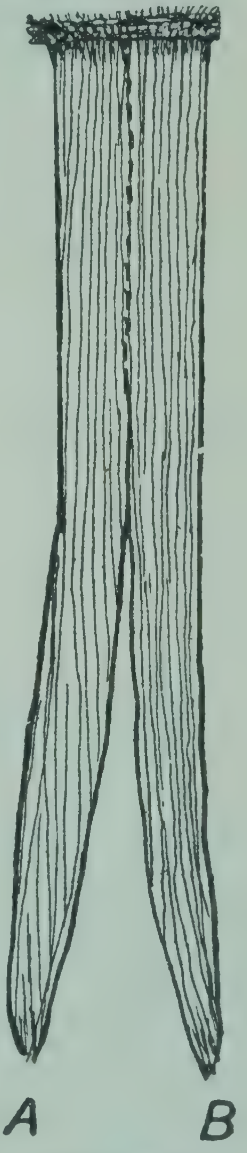

FIG. 56.

The "all-or-none" law does not mean that it is impossible to vary *by any means* the extent of the mechanical response of a fibre to stimulation, but only that such variations cannot be brought about by altering the strength of the stimulus.

The "all-or-none" character of muscular contraction was indicated by Gotch and Keith Lucas,* but the clearest demonstration of it is that given by the experiments of Pratt and Eisenberger.† These investigators were able, by the use of micro-electrodes, to apply stimuli to individual fibres, while observing these directly under the microscope, an also to take photomicrographic records of the extent of the contractions which resulted One of these records is shown in Fig. 57. It will be noticed that, as the strength of th stimulus is steadily increased, the response increases in a series of steps, each of whic was seen to correspond to the occurrence of contraction in a fresh fibre or fibres which had been unaffected by the weaker stimuli: each fibre which enters into contraction does so with maximal strength. A grading of muscular power is thus achieved by variation in the number of fibres or parts of fibres brought into play. Further investigation of the phenomenon by other workers suggests that this simple view may need to be qualified, since when very fine electrodes and weak stimuli are used, the response in their immediate neighbourhood, up to a point, is graded.* This is apparently due to the fact that weak and very localised stimulation of a single fibre causes a localised contraction which does not propagate and occupy the whole fibre.† But beyond a certain point of intensity, propagation succeeds, and then the whole fibre springs into activity, and this is all-or-none.

THE REPETITION OF STIMULI

Summation of Contractions and Tetanus. The response of a single muscle fibre to a single shock, whether measured by the isotonic or the isometric method, *i.e.* as shortening or as tension, is independent of the strength of stimulus and varies only with the length of the fibre. If, however, a second shock is sent in during the rise of the excitatory condition, a further evolution of energy is possible, and the effect is still further increased by putting a series of stimuli into the muscle, or its attached nerve, before the development of the contractile stress due to each previous stimulus has reached its maximum. If two shocks at intervals of, say, 20 msec. be sent into a cat gastrocnemius muscle, the response will be greater than that produced by one shock (Fig. 58). The effects of the two stimuli are summated; the resulting contraction may be less than twice the size of the simple twitch, or it may be more.‡ Thus, in the ocular muscle of the cat, stimulated via its nerve, summation begins at about

0·5 msec. interval (the R.P.), and is maximal at 2·5 msec., and is then about 2–3 times the response due to a single stimulus.* With 5 (or more) msec. separation the two responses separate out. (This phenomenon of *summation of contractions* must be clearly distinguished from that of summation of stimuli referred to previously.)

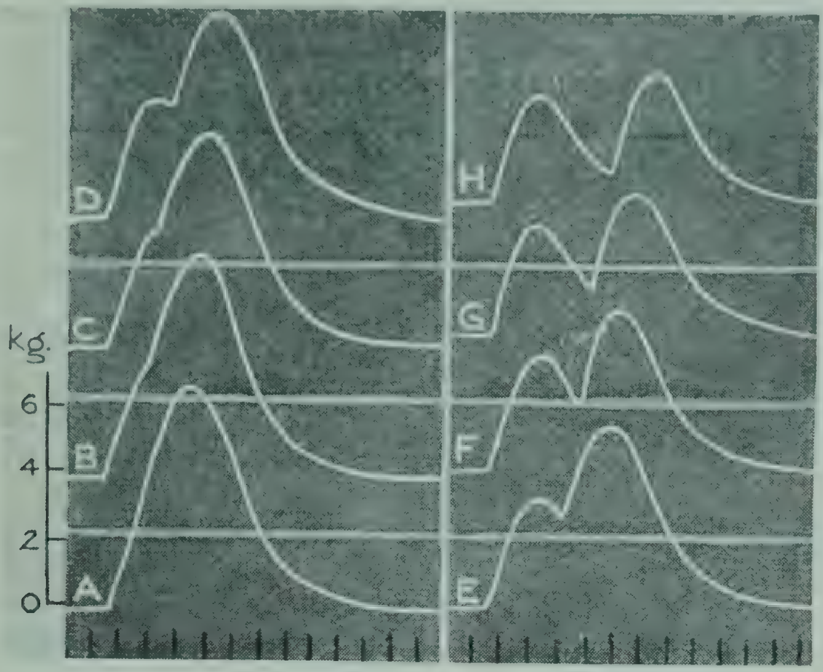

FIG. 58. Isometric Responses of Median Head of Gastrocnemius of Cat, *in situ*, to two maximal stimuli to peroneal nerve.

The intervals between the two shocks were lengthened in order from A (shortest interval) to H (longest interval). The times between the first and second shocks were, in msec.: A, 24; B, 32; C, 40; D, 48; E, 57; F, 69; G, 77; H, 88. Time intervals marked are 20 msec. (After COOPER and ECCLES, *Journ. Physiol.*, 1930, **69**, **377**.)

If a series of shocks be sent in, the excitatory condition is maintained, so that instead of a simple muscle twitch, rising to a maximum and then falling,

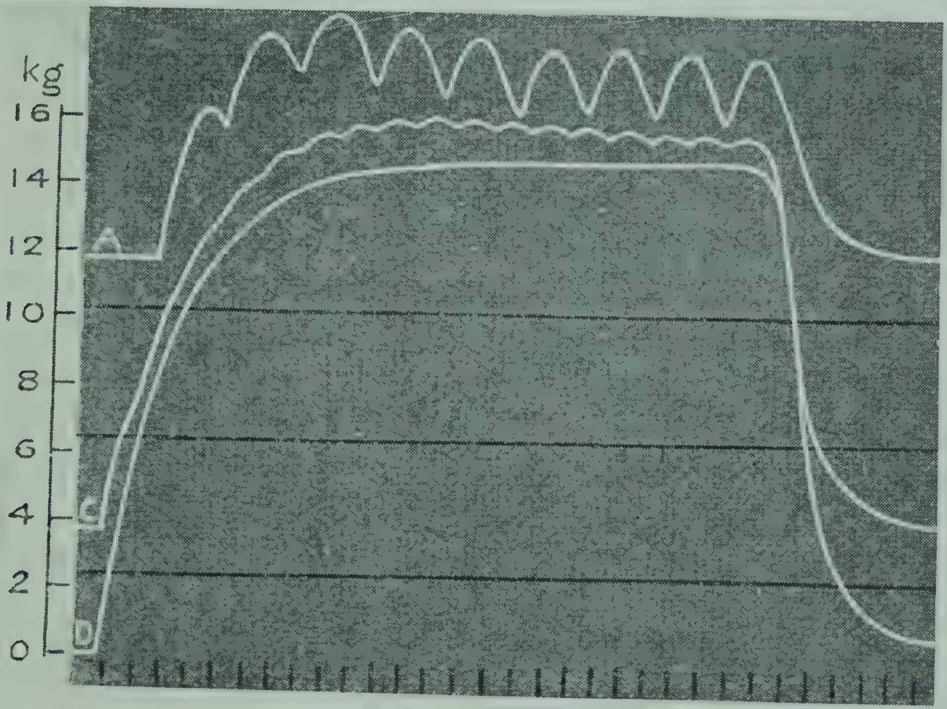

FIG. 59. Isometric Responses of Median Head of Cat's Gastrocnemius to rapidly interrupted Repetitive Stimulation of Popliteal Nerve. A at 19; C at 35; D at 115, shocks per second. (COOPER and ECCLES.)

he muscle lever rises to a given point (Figs. 59 and 60), which in the muscle ontracting isometrically may be four times that due to a single stimulus and hen remains at this height during the continuance of the repeated excitations. he state of apparently continuous contraction evoked in a muscle by repeated hocks is called a *tetanus* (Fig. 59, D). If the stimuli are not rapid enough to ive complete fusion, a partially maintained contraction, called incomplete tetanus, or *clonus*, results (Fig. 59, A, C). The rate necessary to give tetanu is higher the shorter the contraction time of the muscle, and therefore varie from muscle to muscle. If the muscle be allowed to contract isotonically the sustained shortening produced by a series of stimuli may, with a heav load, be three or four times as great as that produced by a single stimulus.

---

* BROWN and HARVEY. *J. Physiol.*, 1941, **99**, 379.

When, as under the conditions of ordinary life, the muscle contracts in response t impulses transmitted to it by its motor nerve, the conditions are not quite the same as whe the muscle is stimulated directly. Each motor nerve fibre supplies many muscle fibres often about 150.* The unit of response i therefore a nerve fibre with all the muscl fibres which it supplies; this is called a *moto unit.*

When a motor nerve is stimulated elec trically with a maximal shock, we may suppose that all its motor units are thrown into action. If a second shock follows quickly on the first, and both are maximal, we get summation, as explained above. The same phenomenon is seen when the stimuli are submaximal.

This type of summation may be called *wave-summation,* because it is due to the fusion of successive waves of contraction in the same fibres. This summation is not algebraical, *i.e.* the second contraction does not exactly double the shortening brought about by the first, nor does it double the duration; the effect of the second stimulus is greater the earlier it falls during the first response.

When the nerve is stimulated with a strong shock, it causes a larger contraction than if excited by a weak stimulus. This is an example of another type of summation called "*multi-fibre*" or *quantal* summation, which is due to an increase in the number of motor units responding, each fibre giving an all-or-none contraction. Thus in submaximal responses, as the strength of stimulation is increased, more and more fibres respond (synchronously). Or, again, when a mixed muscle containing fibres of different contraction durations (*e.g.* red and white fibres) is stimulated a summated contraction combining the features of both will result. Quantal summation is algebraical in character.

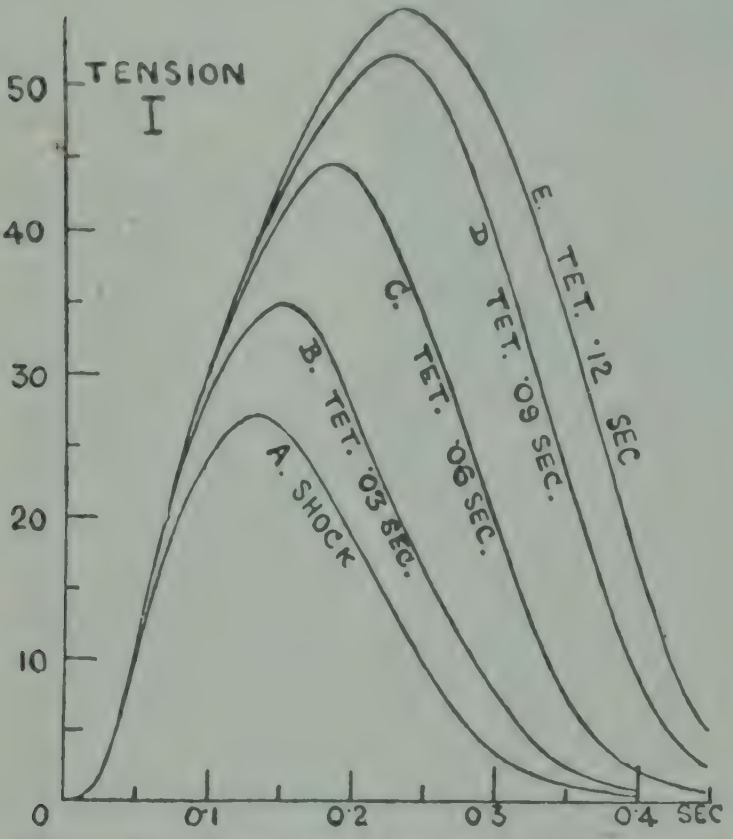

FIG. 60 Isometric Contraction Tetani showing continued rise of tension with prolongation of the excitation.

REFRACTORY PERIOD. If the interval between two stimuli sent into a curarised muscle be successively shortened in a series of observations, we finally arrive at a point at which summation of contraction is no longer apparent, *i.e.* the effect of the two stimuli is no greater than the effect of a single stimulus. This means that for a *very* short period of time after stimulation a muscle is inexcitable to a second stimulus. The period during which it is inexcitable is known as the refractory period and amounts in frog's skeletal muscle to about 5 msec. It is shorter in mammalian muscle (less than 2 msec.), and in all types is greatly increased by reduction of temperature.† The same phenomenon is a common property of excitable tissues generally.

RELATION BETWEEN MECHANICAL AND ELECTRICAL RESPONSE

We have seen on p. 119 that excitation of muscle leads to the developmen of an action potential, the appearance of which may be accepted as an indicatio that an adequate stimulus has been applied. When the time relations of th stimulus, the action potential and the mechanical response are compared it i seen that the action potential commences almost precisely when the stimulu is applied, but that it is practically over before the mechanical response begins

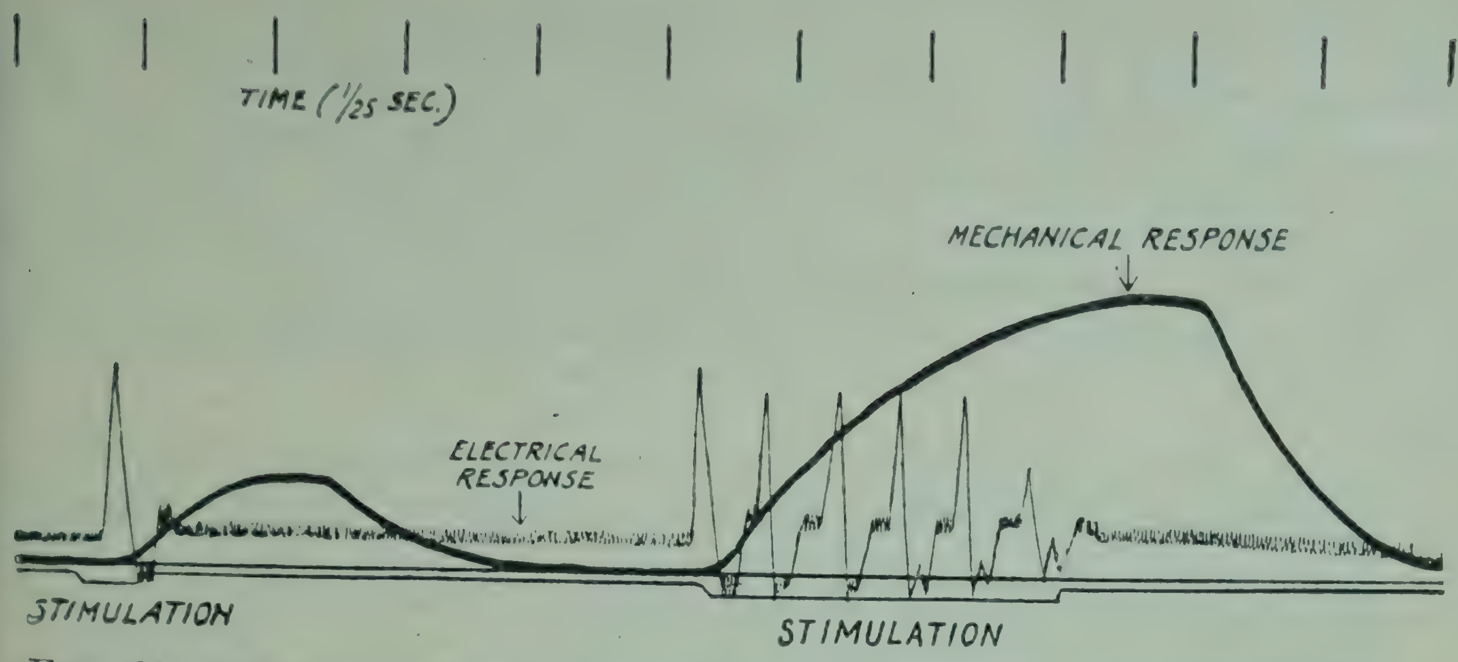

FIG. 61. Relation between Mechanical and Electrical Responses of frog's gastrocnemius *in vivo*, to (1) a single shock, (2) a rapid succession of six shocks. (After FULTON.)

It is further seen that when stimuli are repeated at short intervals, so as to result in a smooth tetanus summation, the action potentials do not so fuse, but each one separately appears after each stimulus (Fig. 61).

THE TONUS OF MUSCLE

The muscles in the normal body differ from excised muscles in being frequently in a condition of slight tension, which is called tone or tonus. This is due to reflex activity, since it is lost if the spinal cord is destroyed or if the motor nerves to the muscles are severed: the denervated muscle is toneless and inert.

If the tendon of a muscle *in situ* be cut and pulled, so as to stretch the muscle, the muscle pulls back against the extending force, *i.e.* its state of tonus, or tonic contraction is increased. When there is no pull upon its tendon there is little tonus, but as soon as the tendon is pulled upon the tone augments and increases with increase of the tension. This is called the "*stretch-reflex*" and is more fully dealt with under the central nervous system. If the motor nerve is cut the tonus is abolished, so it is obviously a state transmitted to the muscle through its motor nerve. But it can be shown that the slight constant contraction of tonus is not due to a slight continued shortening of all the muscle-fibres, but rather to their working, a few motor units at a time, in relays. These contractions, and the action potentials that precede them, can be recorded in single motor units if sufficiently precise methods are used (Fig. 62). It is then seen that at the commencement of the stretch-reflex the tone is stepped up by wave-summation, resulting from double discharges, but is then maintained by rhythmic single discharges, producing slight contractions. For this reason, tonus is not followed by fatigue and may be, and is, kept up steadily for hours on end if the conditions are appropriate.

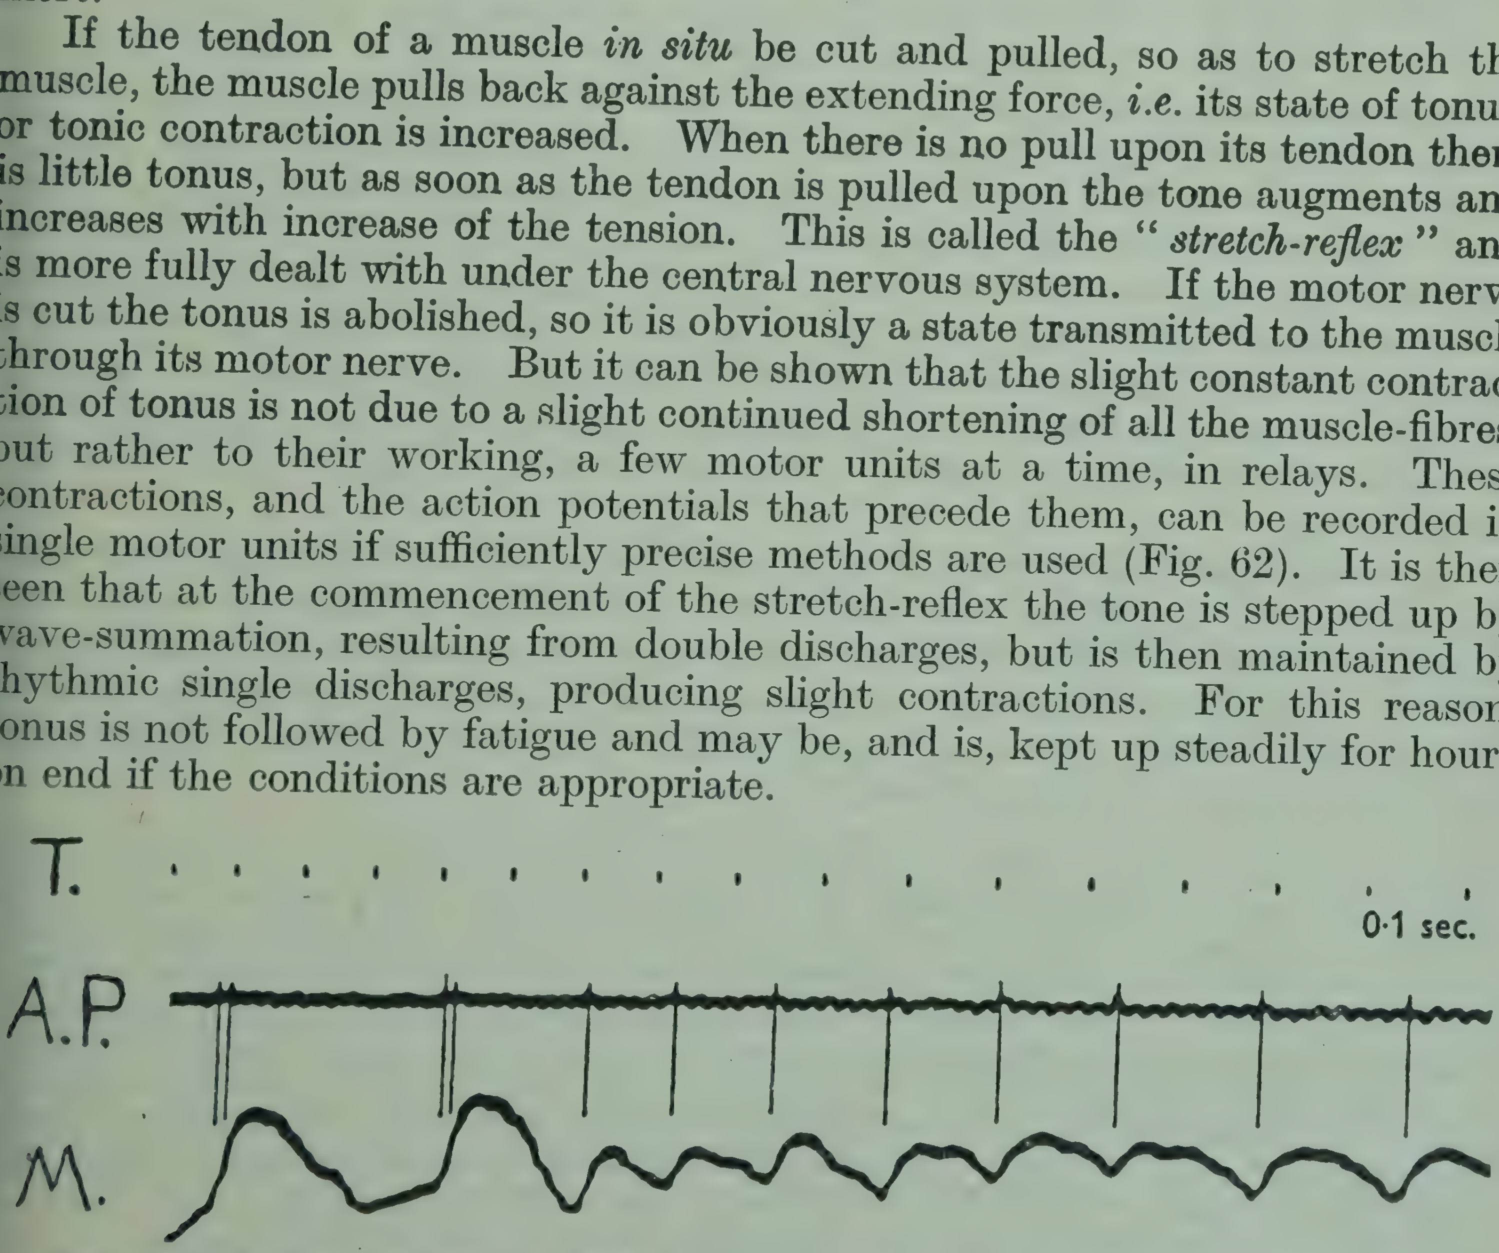

FIG. 62. Action potentials (A.P.) and movements (M.) in single motor unit of *crureus* muscle of decerebrate cat during a stretch-reflex. (GORDON and HOLBOURN. *Proc. Physiol. Soc.*, 1948, **107**, 18.P.)

Muscle tonus is also lost if the afferent nerves from the muscle and its tendon are divided, even though the motor nerves remain intact. It follows from this that the reflex involved in the tonus arises in the muscle itself. The muscle is supplied with afferent end-organs in the muscle spindles, and the nerve endings in the tendons, and when the muscle is pulled upon these originate a stream of nervous messages which passes to the spinal cord and there initiates the discharge along the motor nerves to which the tonus is due ; the stronger the pull upon the muscle the more frequent the nerve impulses which are sent from it.

Tonus is of great importance in all our muscular responses ; our posture is largely maintained by its action, and all our voluntary movements take place on a background of general tonus. In diseased conditions, where it is lost, the clumsy movements bear witness to the disability occasioned by its absence.

VOLUNTARY CONTRACTION

Under normal circumstances the contraction of skeletal muscles is brought about either reflexly, or in response to some stimulus descending from the cerebral cortex, the so-called "voluntary contraction." These contractions may have a duration of almost any extent from about 0·1 sec., but nearly all voluntary contractions last considerably longer than that.

Since we know no certain means of extending contractions to any given length except by means of summation, it is natural that physiologists have regarded voluntary contractions as similar to the artificial tetanus produced by a summation of effect, either as wave summation or as quantal summation. In the belief that the response of each muscle fibre is invariably all or none in character, it must be supposed that the delicate gradation shown in the power of voluntary contractions is due to the participation of a variable number of motor units, the maximal force being exerted if and when all the fibres contract. Smoothness of contraction could be ensured by either mode of summation. Thus by a wave summation the same set of fibres would remain in a state of tetanic contraction throughout, whereas in quantal summation different sets of fibres would work "in shifts," each fibre giving a short tetanus or even a single twitch.

It was formerly supposed, in the belief that the response was synchronous in all fibres, that definite information as to the nature of voluntary contraction would be obtainable by a study of the electrical variations or of the mechanical records ; but the accumulated evidence of quantal summation of asynchronous contractions renders such investigations of doubtful value unless single fibres, or at most only a few fibres, could be studied.

The impulse, which normally travels down the motor nerve from the anterior cornual cell to the muscle, is discontinuous. Gasser and Newcomer [*] investigated the electrical changes accompanying contraction of the diaphragm, and also those in the phrenic nerve. They found that each contraction of the muscle is accompanied by the discharge, in both nerve and muscle, of about seventy separate electrical waves per second. Adrian and Cooper [†] have shown that interrupted stimuli at up to 230 per second can be transmitted through the spinal cord and give rise to an identical rhythm in the muscles responding reflexly to the stimulation. This evidence is in favour of the view that the stimuli causing voluntary contraction and, one must add, the tonic contractions of all skeletal muscles, are discontinuous in nature and often analogous to those which we may evoke artificially by rapid stimulation either of muscle or of its motor nerve.

[*] Gasser and Newcomer. *Amer. Journ. Physiol.*, 1921, **58**, 1.

[†] Adrian and Cooper. *Journ. Physiol.*, 1924, **59**, 61.

The problem was solved by the work of Adrian and Bronk,* by the use of electrodes so small as to pick up the electrical changes accompanying contraction in only a few fibres. The electrode was made in the form of a needle which could be stuck into the muscle of a human subject. The tracings showed the arrival of stimuli at only one or two motor units. It was found that on executing a weak contraction the muscle showed a series of regular electrical changes, each of which means the arrival, at one of the motor units, of a stimulus *via* the motor nerve fibre (Fig. 63, A). This stream of stimuli may be as slow as 6 per second, which would give little opportunity for wave summation, so we must suppose the summation in such weak stimuli to be quantal, and the smooth contraction of the whole muscle to be due to the fact that the various motor units involved are not contracting synchronously.

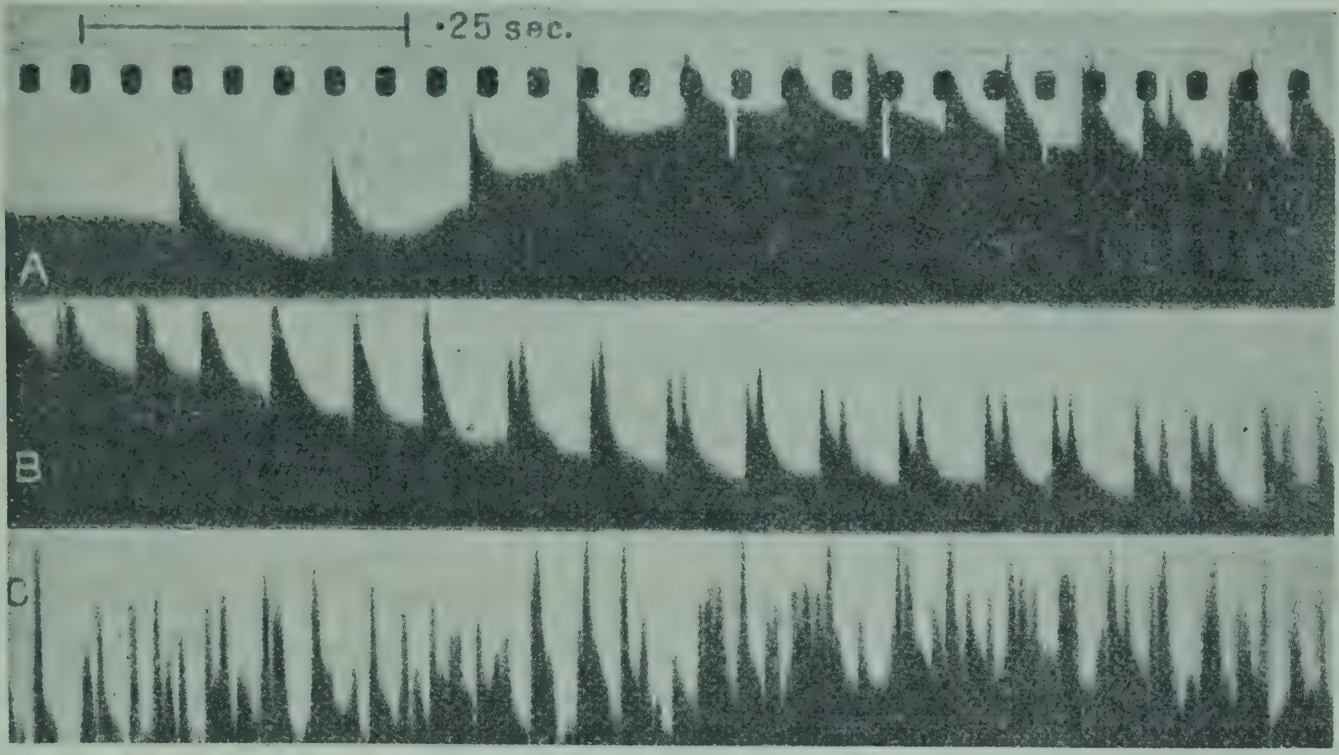

FIG. 63. Action currents in human triceps. A, weak contraction, continued at B, and showing there the entry of a new rhythm due to a fresh motor unit being excited at the same slow rate. C, powerful contraction, showing rapid rhythm of stimuli. (ADRIAN and BRONK.)

When the contraction is more powerful, fresh motor units are brought into play, and new rhythms are seen ; also the rate of stimulation is increased in each motor unit (Fig. 63, B, C), so that tetanic contractions occur. We may conclude, then, that both types of summation are concerned in voluntary contractions—in weak ones, quantal summation only, in strong ones both forms.

THE MECHANICAL ENERGY OF CONTRACTION

Whereas resting muscle is soft, flabby and presents little resistance to slight stretching, the contracted muscle is hard, rigid and resists extension. It might be thought, therefore, that the essential feature in muscular activity consisted in a change in its elastic qualities, and that contraction involved the setting up of tension which could be used for doing work or, as in the isometric twitch, degenerating into heat as the contractile state passed away. The potential energy of a muscle in a state of isometric contraction is given by the expression $Tl/8$, where l is the length of the individual fibres and T is the tension produced.† If a stimulated muscle were simply an elastic body like a spring under tension, the amount of work which it could do when allowed to shorten would be a constant amount and equal to the expression just mentioned. (We now know that owing to the " Fenn effect " it could be even greater.)

---

* ADRIAN and BRONK. *Journ. Physiol.*, 1929, **67**, 119.

† HILL. *Journ. Physiol.*, 1913, **46**, 435 ; DOI. *J. Physiol.*, 1920, **54**, 335.

It is found that under most circumstances the muscle cannot realise this maximum theoretical work, but tends more nearly to do so the slower the rate of shortening. The best method of testing the power of a muscle to do work is

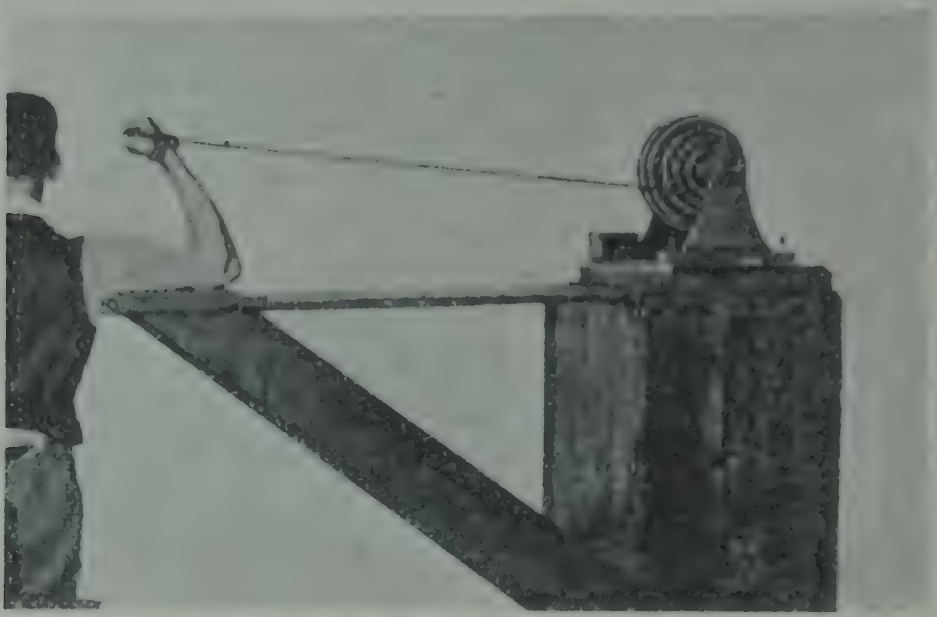

FIG. 64. Inertia flywheel for human muscle. The work done is calculated from the speed of rotation imparted to the flywheel, which weighs 35 kg., and, according to the pulley used, gives an effective mass of inertial resistance varying from 11·3 to 579 kg. (A. V. HILL. *J. Physiol.*, 1922, **56**, 19.)

to hinder its contraction by opposing it to the inertia of a mass, *e.g.* that of a heavy flywheel * (Fig. 64). If a spring under tension were made to pull against such an apparatus, the amount of work it would do would be independent of the mass moved. In muscle, however, it is found that the amount of work done against a large mass is greater than that done against a small one. The essential factor involved here is the speed with which a muscle is allowed to shorten: the greater the speed of shortening, the less, within limits, will be the work done.† This is because time is needed to liberate the energy required to move large loads. Conversely, a muscle can shorten the more quickly the smaller the

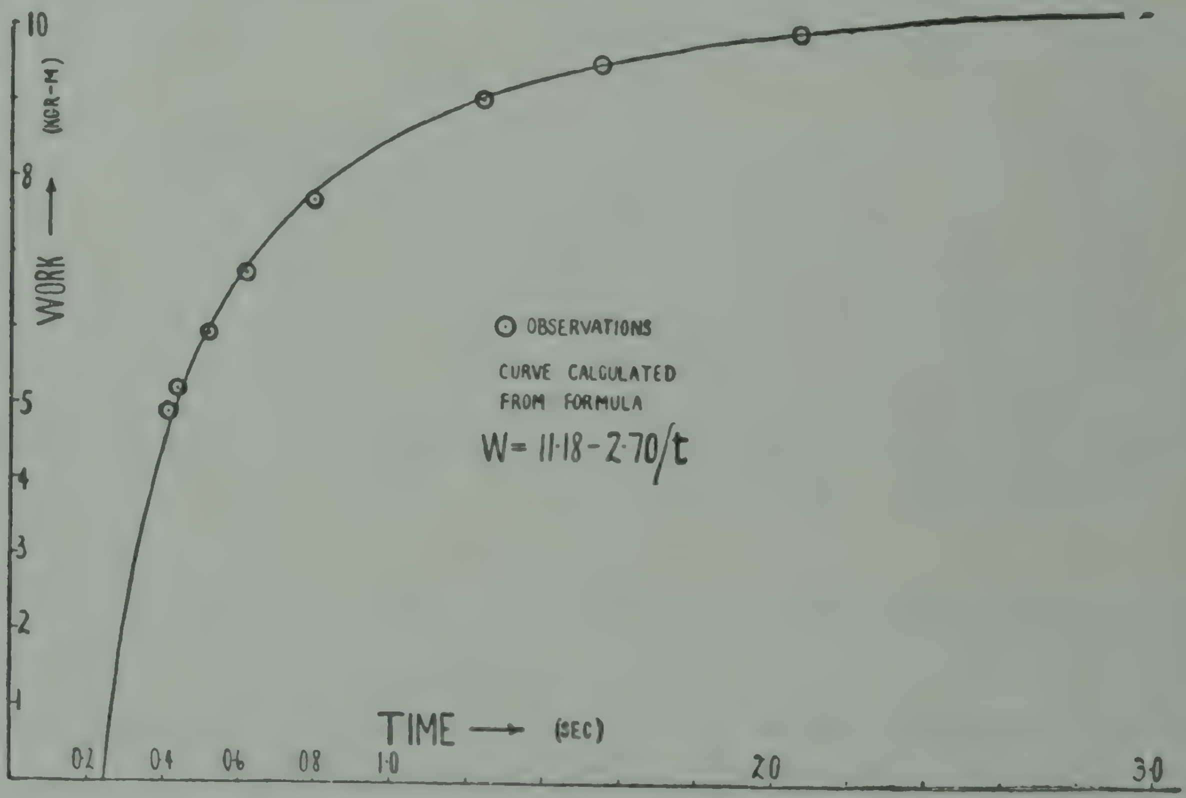

FIG. 65. Relation between maximum realisable work and duration of contraction for human arm muscles. Theoretical maximal work = 11·18 kg.-m. (A. V. HILL. *J. Physiol.*, 1922, **56**, 19.)

---

* HILL. *Journ. Physiol.*, 1922, **56**, 19.

† HILL. *Journ. Physiol.*, 1922, **56**, 19; *Proc. R.S.*, 1939, **127B**, **434**; LEVIN and WYMAN. *Proc. Roy. Soc.*, 1927, **101B**, 218.

force opposing it. Speed and force of contraction are related by the equation

$$(P + a)(V + b) = \text{constant},$$

where P = force, V = velocity, and a and b are constants; this holds for isolated frog muscle * and for human voluntary contractions.† In the case of human arm muscles the work does not approach its maximum value unless the contraction has been opposed by a mass large enough to make it occupy at least two seconds (Fig. 65). The frog's muscle is ten times quicker than that of man.

Optimal Rate of Contraction. We have seen above that the slower the speed of shortening of a muscle the greater is the amount of work done. It must be remembered however that energy is required in order to *maintain* the contracted condition in muscle.‡ There will thus be a point at which the extra energy required to maintain the contraction more than compensates for the gain in work done by increased duration of the contraction, so that for each group of muscles there will be an optimal rate at which the muscles will work with the greatest economy. We have seen that in the case of the human arm muscles the rate is ten times slower than in the isolated frog's muscle, and probably the rate will vary according to the mass of the limb involved and therefore, to a certain extent, to the size of the individual. It is a familiar experience that the effort of going upstairs becomes less as the rate is diminished, but not indefinitely, and that it may become more tiring if the rate is made too slow. The same thing applies to practically any form of exercise in which external work is being done.

FATIGUE

If a muscle be repeatedly stimulated, changes soon become apparent in the curve of contraction. The latent period is prolonged, as well as the length of the contractions; the absolute height and work done are diminished. At the same time the muscle does not return to its original length; the shortening which remains is spoken of as "*contraction remainder*." After an initial rise during the first few contractions, these diminish uniformly in height till they are no longer apparent, so that the muscle is now said to have lost its excitability. At the same time there is a great prolongation of the relaxation, so that after forty or fifty contractions several seconds may elapse before the lever returns to the base line (Fig. 66).

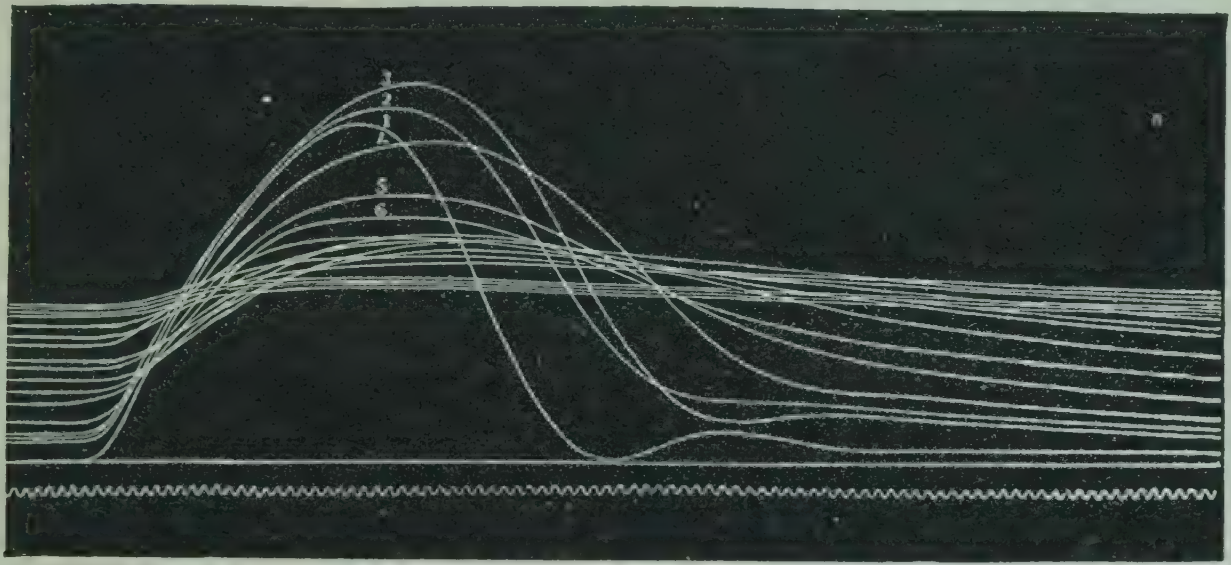

Fig. 66. Muscle Curves showing Fatigue in consequence of Repeated Stimulation. The first six contractions are numbered, and show the initial increase of the first three contractions. (Brodie.)

If left to itself, the muscle which has been exhausted by repeated stimulation will partially recover. The recovery is hastened by passing a stream of blood, or even of salt solution, through the blood vessels of the muscle. Still more important is a free supply of oxygen.

---

* A. V. Hill. *Proc. Roy. Soc.*, 1938, **126B**, 136.

† Wilkie. *J. Physiol.*, Proc., 1948, **108**, **7P**.

‡ Bronk. *Journ. Physiol.*, 1930, **69**, 306.

The phenomena of fatigue in isolated muscle depend on three factors :

(1) The consumption of the substances available for the supply of potential energy to the contractile material.

(2) The accumulation of products of the contractile process. Among these waste products is lactic acid. Fatigue may be artificially reduced by washing out the muscle with normal saline solution containing a small percentage of alkali. The beneficial effects of oxygen supply are also due in part to the removal of lactic acid and, in general, to re-establishment of the chemical *status quo.*

(3) Failure to re-establish the normal electrical polarisation of surface membranes.

In speaking of fatigue it is important to specify the tissue which is fatigued. If instead of being stimulated directly the muscle is repeatedly made to contract by stimulation of its motor nerve, fatigue sets in much sooner ; yet if the muscle be now excited directly it is seen not to be fatigued. This shows that either the nerve trunk or the motor end-plates are fatigued sooner than the muscle. Actually, the latter explanation is the correct one, since nerve trunks are practically unfatiguable.

Fatigue in the intact animal as a result of *voluntary* contractions is not strictly comparable with that of excised muscle stimulated either directly or indirectly. It may be studied in man by the use of instruments called ergographs, in which a finger, or one of the limbs, pulls up a weight or contracts against a spring, the degree of shortening or tension change being recorded. When after repeated contractions, fatigue has set in, the resulting tracing is very similar in appearance to that obtained from an isolated muscle stimulated electrically to the point of fatigue. But, in point of fact, in voluntary contraction the muscle is very far from being fatigued, as may be shown by applying electrical stimuli through the skin to it, or to its nerve, when powerful contractions result. What have been fatigued as the result of the voluntary efforts are the motor nerve cells responsible for the activation of the muscle.

We may conclude then, that the most readily fatiguable point is the motor nerve cell, next the conduction from nerve trunk to muscle, then the muscle, and last of all the nerve fibre.

CONTRACTURE

Skeletal muscle may, under certain conditions, enter into a state of prolonged reversible shortening which is distinct from tetanus, and which is called *contracture.* Thus, if a fresh frog's muscle be stimulated by repeated supramaximal opening induction shocks, the relaxation after the twitches is slow and incomplete ; it is due to a prolonged action of the stimulus.* It may in part be due to over-shortening, and passage of the fibres into the " delta state," which is only partly reversible. After many contractions also, a muscle shows another form of contracture, the " contraction remainder," due to delay in the relaxation process.

Contractures of various types can also be produced by thermal, mechanical or chemical stimuli of the most diverse description. Contractures differ from tetani and other forms of contraction in that the contractile process is not conducted through the tissue and no wave-like action potentials occur ; contractures of long duration may therefore be quite definitely localised in a muscle, the remainder of which is in a relaxed condition.

To what extent contractures may occur in the intact body is a matter of dispute ; many pathological shortenings of muscle which are seen clinically and which are sometimes called contractures, are often manifestations of tonic reflexes, fibrosis, and other phenomena not connected with real contractures. But a true prolonged contracture, called " idiomuscular contraction," is seen on mechanical stimulation of certain irritable muscles.

An interesting instance of contracture is seen in muscles after section and degeneration of their motor nerves. In such muscles, stimulation of the *vaso-dilator* nerve (or of the sensory nerve) to the muscle causes a prolonged contracture. This, which is sometimes called the Vulpian-Heidenhain-Sherrington phenomenon, is of great theoretical interest. It was discovered by Vulpian and Philippeaux in 1863 that, some days after section of the hypoglossal nerve (motor to the tongue), stimulation of the chorda tympani fibres in the lingual nerve (vaso-dilator to the tongue) caused contracture of the tongue muscles. In the normal state, stimulation of the chorda tympani produced no effect at all on the tongue muscles. It was shown by Sherrington * that the phenomenon is obtainable under comparable conditions from any muscle

---

* BREMER. *J. Physiol.*, 1932, **76**, 65.

The key to this apparent paradox is to be found in the theory that the action of vaso-dilator nerves is due, at least in part, to the liberation at their terminations in the tissues, of acetyl choline.† The muscle when deprived of its motor nerve supply is thrown into contracture by acetyl choline, as may easily be demonstrated, whereas the normally innervated muscle is less sensitive to its action. By injection of acetyl choline in large doses (*e.g.* 1–2μg.) direct into the arterial blood stream to a normal muscle, however, a quick contraction, followed by a slow contracture, results.‡ The effect of acetyl choline on the denervated muscle, in accordance with this hypothesis, is enhanced by eserine and abolished by atropine. What happens under the conditions of the experiment, therefore, is that when the vaso-dilator nerve is stimulated, acetyl choline is liberated in the region to which the nerve is distributed, *i.e.* in the muscle. This substance causes dilatation of the bloodvessels there, both in the normal muscle and in the denervated muscle. But in the denervated muscle the acetyl choline also produces the effect of contracture, which it does not do in the less sensitive normal muscle.

Rigor Mortis. All muscles after removal from the body, or if left in the body after general death, lose their excitability after a time, and this loss is succeeded by the phenomenon known as *rigor mortis*. The muscle, which was previously flaccid, shortens, though not very powerfully. Whereas the living muscle is translucent, supple and extensible, it becomes in the process of rigor opaque and much less extensible, the modulus of elasticity, measured along the fibres, increasing about tenfold.§ The rate of onset of rigor is greatly accelerated by treating the muscles with solutions of caffeine, arsenates or chloroform vapour, but is not much affected by temperature.§ When rigor has been established, the reaction of the muscle is *usually* found to have changed from a slightly alkaline (pH 7·3) to a distinctly acid one (pH 5·8), due to the presence of lactic acid. But acidification is not a necessary condition for rigor to occur. From this condition of rigor there is no recovery of contractility, though the muscle softens before putrefaction sets in. There can be no doubt that the change in consistence of the muscle, and probably also its shortening in rigor, are due to changes in the muscle proteins. Both conditions can be imitated by heating the muscle. After severe muscular fatigue, as in hunted animals, rigidity may come on almost immediately after death.

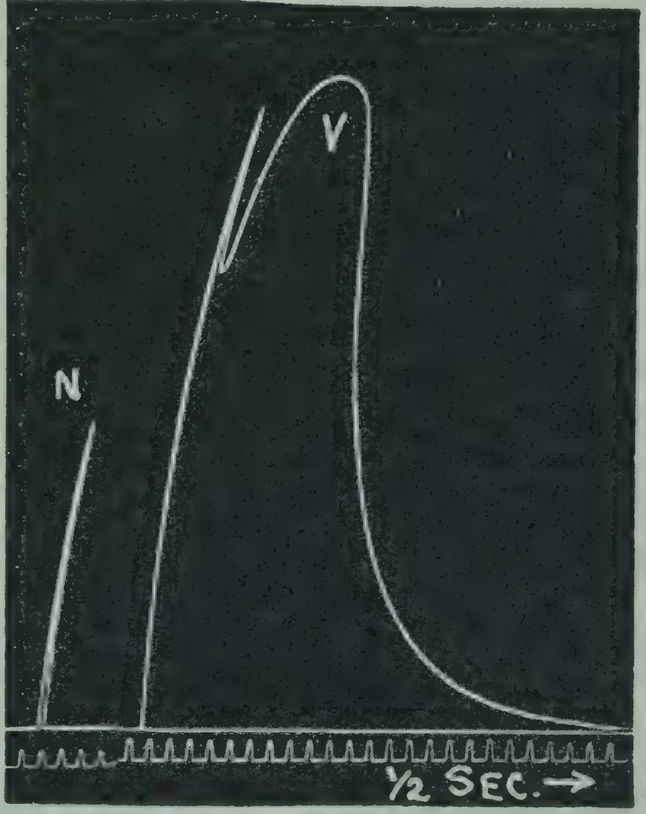

Fig. 67. Contractions of frog's sartorius. N, before, and V, twenty minutes after, soaking in Ringer's solution containing 1 : 100,000 veratrine. The records were taken on a slowly moving surface, as the time tracing shows.

THE ACTION OF CHEMICAL SUBSTANCES

Salts. The membrane of muscle fibres is permeable to the $K^{\cdot}$ ion, but impermeable to $Na^{\cdot}$ or larger cations ; it is also permeable to small anions, such as Cl', HCO_3', etc. The question of the distribution of ions inside and outside the fibre is too complex to discuss here.||

It has been supposed that potassium accumulates inside the fibres t replace sodium, which is actively expelled, and is not able to return. The action of sodium salts on muscle is of considerable interest. A 0·65 per cent NaCl solution has an excitatory effect upon the muscle, so that single induction shocks may cause contracture. The same excitatory effect is still better marked with solutions of sodium carbonate or oxalate which reduce the free $Ca^{\cdot\cdot}$ of the muscle. If a thin muscle, such as a frog's sartorius, be immersed in a solution containing 0·5 per cent. NaCl, 0·2 per cent. Na_2HPO_4, and 0·04 per cent. Na_2CO_3 (Biedermann's fluid), the muscle enters into a series of frequent contractions. This excitatory action of sodium salts is neutralised by the addition of traces of calcium salts.

Potassium salts if injected direct into the artery supplying a muscle, in doses of a few mg. cause a brief twitch.[*] Yet if a muscle is soaked in a solution of KCl, it quickly loses its excitability. If a muscle be transfused with suitable fluids containing small amounts of potassium salts, it shows all the signs of fatigue, which may be removed by washing out the potassium salts.

If a frog's muscle be isolated and kept moist for a few hours, it often shows a complete loss of excitability, but regains it after a short immersion in Ringer's fluid, and does not become non-irritable again during its survival. The loss of excitability is apparently due to the passage of potassium salts from the inside to the outside of the fibre.[†]

OTHER DRUGS. Of the drugs that have a direct action on muscle, the most remarkable is veratrine. If a muscle is soaked in a 1 : 100,000 solution of this alkaloid, a single stimulus results, not in a short twitch, but in a sustained "contracture," which may last for many seconds (Fig. 67). The effect appears to be due to an increase in the duration of the excitatory state or to scattered asynchronous tetani of single fibres.[‡] For some time after the "contracture" has died down the effect of stimulation is to give an ordinary twitch. Formaldehyde, barium salts, and many other substances produce similar contractures.[§]

Quinine increases the response to a single maximal stimulus, but also increases the refractory period, so that response to a tetanus is diminished. Eserine and veratrine do not produce their effects after quinine.[||]

Chloroform and caffeine cause the muscle to shorten and quickly to pass into *rigor mortis*. Barium salts have a similar though less marked effect.

CHEMICAL COMPOSITION OF SKELETAL MUSCLE

Muscle contains about 75 per cent. of water. The chief solid constituents are the proteins (20 per cent.) which form the bulk of the cellular structure of the tissue. Of the remaining solids, several constituents referred to later are of great importance, though only present in small amounts.

MUSCLE PROTEINS. The contents of the living fibres, once thought to be fluid, are now recognised to be in the state of a weak gel; this is shown by their behaviour when expressed by micro-dissection operations, and also by a consideration of certain physical properties of the muscle. By mincing the living muscle with ice and a little salt and subsequently filtering under pressure, a viscous fluid formerly called "muscle plasma" can be obtained. This is not, as once thought, the unaltered cell contents, but a partial solution of the gel in dilute salt solution. If the temperature of the extract rises, it clots to a firm gel, but the nature of the coagulation is unknown.

The older investigations of Halliburton and others have been extended,[¶] [**] and it appears that the living muscle contains five proteins, called respectively *myogen*, *myosin*, *globulin X*, *myoalbumin* and *stroma proteins*.

Myogen, a mixture of albumins, is obtained by dialysing the "plasma," which precipitates the myosin, and subsequently filtering. It is soluble in water and has an isoelectric point of pH 6·3. It is readily denatured at the isoelectric point. It represents about 20 per cent. of the total proteins. Part of it consists of enzymes.

Myosin, a globulin, is obtained by precipitation from a slightly alkaline (pH 7·2) saline extract by neutralisation and dilution. The precipitate is redissolved in dilute salt solution at pH 7·0.* Its solutions are extremely viscous and it readily forms a gel when the salt concentration is low. Its isoelectric point is dependent on the salt concentration, but is about pH 5·1. The globulin is insoluble in water, and, between pH 5 and 6, also insoluble in salt solutions. It is completely precipitated in 0·04 m. KCl at pH 7·0. About 40 per cent. of the total muscle protein is myosin, and this is largely present in the Q-discs. Here, owing to the rod-like nature of its molecules, it confers on the muscle its elasticity, its thermo-elastic properties and the known relationship between damped and undamped elasticity. According to Szent-Gyorgyi † myosin can be fractionated into two proteins, *myosin* and "*actin*," which combine to form a complex called "*actomyosin*." This has different properties from its components, and in particular can be caused, when in gel form, to "contract" when brought into contact with A.T.P. or K ions. The shortening is, however, accompanied by volume shrinkage or synæresis of the gel, and is not strictly comparable with the shortening of the contractile material in muscle.

Globulin X, only slightly soluble, is completely precipitated in 0·005 m. KCl at pH 7·0. It represents about 20 per cent. of total protein.

Stroma proteins are insoluble even in concentrated salt solutions, but it is uncertain how much, if any, of these represent constituents of the living fibre.

It is interesting to note that the amount of protein capable of extraction from muscle by means of salt solution is greater (90 per cent.) when the muscle is quite fresh. When rigor has set in only 30 per cent. of the total protein is thus extractable and ‡ it would seem that the processes of fatigue and rigor, like that of the coagulation of fresh extracts, is the result of a process of denaturation which takes place in the protein before or after death. The hydrogen ion concentration of fresh resting muscle is probably about pH 7·0 § so that the muscle proteins would be on the alkaline side of their isoelectric point, *i.e.* they would be present as salts of bases and be ionised as anions. Although coagulation can be produced in a fresh muscle by immersion in acid, it appears to be different from true rigor mortis, which, moreover, is not necessarily associated with an acidification of the muscle.

OTHER CONSTITUENTS OF MUSCLE. Of the remaining constituents of fresh resting muscle the most important are glycogen, lactic acid, and three types of phosphorus compounds, viz. creatine phosphate, hexose phosphates and the adenosine phosphates ; all of them appear to participate in the enzymic chemical changes which are associated with contraction.

Glycogen is present up to 0·5 to 1 per cent. ; embryonic muscle contains more.

Lactic acid ($CH_3.CHOH.COOH$) is the *l*-(+) isomer. It is only present in amounts of the order of 0·02 per cent. when muscle is fresh, well oxygenated and resting. When the muscle is injured, and under various other conditions, glycogen is rapidly converted into lactic acid.

The *hexose phosphates* are discussed on p. 34, and *creatine phosphate, adenosine diphosphate* (A.D.P.) and *adenosine triphosphate* (A.T.P.), on pp. 52 and 68.

Creatine phosphate is very readily broken down by acid, or by enzymes on injury of the muscle, into creatine and phosphoric acid. It has been synthesised.‖ In invertebrates it is replaced by arginine phosphoric acid, which has similar functions. Phosphocreatine is a stronger acid than phosphoric, and so is an important base-binder, the base being set free when it hydrolyses.

The phosphoric acid compounds are all important in connection with the chemical changes that occur in muscle in relation to contraction. Indeed, since phosphorylation plays a dominant *rôle* in many processes of intermediary metabolism, the general reaction

$$\text{A.T.P.} + H_2PO_3\text{-acceptor} \rightleftharpoons \text{A.D.P.} + H_2PO_3\text{-donator}$$

by which H_2PO_3 is moved into and out of molecules (by the action of appropriate enzymes), is of the greatest biochemical significance. Moreover, as already explained (p. 52) some of the phosphate groups carry a large amount of energy which can either be set free to do work, or transferred withou diminution to other compounds.

Porphyrin Derivatives. The red muscles contain an iron-holding pigment which closel resembles hæmoglobin; it has been isolated in crystalline form* and called *myoglobin*, o myo-hæmoglobin. It probably acts as a temporary oxygen store for the muscle. In addition all skeletal muscle contains the Fe-porphyrin pigments *cytochromes* a, b and c † and also cytochrome oxidase and dehydrogenase, all of which have important functions in oxidation.

Other constituents are :—*Hypoxanthine*, which is present in muscle extracts, is chiefly derived from the adenylic acid of the tissue, and only to a small extent from the nuclein of the cell nuclei.

Carnosine is a dipeptide, β-alanyl histidine. It is present to about 0·3 per cent., but its functions are unknown. In some animals it is replaced by a methyl derivative called anserine.

Inositol ($C_6H_{12}O_6 . 2H_2O$) is hexahydroxybenzene; its significance is unknown.

Fat, Lecithin and Cholesterol in traces.

Inorganic Constituents. The ash of muscle consists chiefly of potassium phosphate (K, = about 0·3 per cent. of the wet weight), with traces of Ca, Na, Mg and Fe in the fresh tissues. The high K content helps to keep the myosin in a suitable physical state, perhaps in solution: it also plays an important part in the maintenance of electrical polarisation of the plasma membrane. Most of the bases are normally combined with the proteins, while the phosphate is present in the various organic forms mentioned above. We therefore find that the phosphate and potassium do not diffuse out from the living resting muscle, though they do so to some extent after stimulation. This, as we shall see later, is because of temporary liberation from organic combination.

Enzymes. Various enzymes (some crystalline) have been prepared from muscle, and play an important part in bringing about the chemical changes which occur in connection with contraction; thus there are enzymes which produce and hydrolyse the phosphoric esters, and by the successive action of many enzymes we may get conversion of glycogen into lactic acid, or final oxidation to CO_2 and water.

THE CHEMICAL CHANGES WHICH ACCOMPANY CONTRACTION

The energy of the contraction of muscle must ultimately be derived from chemical changes occurring in it. In seeking out the nature of these changes four methods are open to us:

(1) We can examine the changes in the muscle either *in situ*, or surviving.

(2) We can investigate the changes in the blood or in an artificial medium surrounding the muscle. Muscle may be exposed in nitrogen or oxygen in a confined space, and its gaseous interchanges during rest and activity compared. The muscle may be suspended in Ringer's solution, with or without oxygenation, or we may determine the change in the composition of the blood in passing through the muscle.

(3) In an attempt to analyse the net changes shown by (1) and (2), the chemical reactions brought about by the action, on given substrates, of minced muscle, extracts, or reconstituted enzyme systems can be followed.

(4) We may compare the changes in the total metabolism of the animal during rest and muscular work as a clue to the muscular metabolism itself.

We may begin by dealing with the evidence afforded by these methods of investigation and then see how far our conclusions are borne out by experiments on the metabolism of the whole animal. The results of method (3) will be discussed more fully later on.

It must be admitted at the outset that, despite the enormous labours of some of the world's most eminent biochemists, there are still many gaps in our knowledge. The outstanding features of the net chemical changes after contraction are :—

(i) Oxygen is used, and carbon dioxide produced.

(ii) Glycogen is reduced in amount.

Further inspection suggested that these changes divide into two stages :—

(i) Glycogen is reduced and, in absence of oxygen, lactic acid is formed.

(ii) Lactic acid disappears, O_2 is used up and CO_2 is formed.

---

* THEORELL. *Bioch. Ztschr.*, 1932, **252**, 1.

† KEILIN. *Proc. Roy. Soc.*, 1925, **98B**, 312.

Much experimental work has been concerned with changes that occur independently of oxygen. Under anaerobic conditions it is beyond question that the main changes consist in an increase of lactic acid, with a concomitant increase in hexosemonophosphate and inorganic phosphate, and a reduction in creatine phosphate. These are probably intermediary changes, and are replaced or succeeded in the normal muscle by restitutive reactions in which oxygen is involved; at all events, when oxygen is present these changes are diminished or suppressed.

The changes by which glycogen is built up, and then ultimately disappears by conversion into CO_2 and water are probably much the same in all tissues, and represent the essence of our knowledge of intermediary metabolism of carbohydrate. The focal point of these changes is represented by pyruvic acid, though a more evident intermediary is lactic acid. We may regard lactic acid as the end-product of glycogen breakdown when oxygen is not present, *i.e.* under anaerobic conditions, and we will consider these conditions first.

THE LACTIC ACID CYCLE IN SURVIVING MUSCLE

FORMATION OF LACTIC ACID. The lactic acid content of muscle is estimated by freezing in liquid air, and mincing in an ice-cold solution of trichloracetic acid. After removal of carbohydrate from the extract the lactic acid of the filtrate is determined.

It is easy, by modern methods, to confirm the fact, originally elicited by Fletcher and Hopkins,* that fresh resting muscle contains only minimal amounts of lactic acid, provided that care is taken to avoid injury and to keep its temperature low until it has been killed by the reagent; the rate of formation of lactic acid is quite slow provided the muscle is uninjured and at rest. If the muscle has been stimulated and made to contract immediately before being killed in this way, its lactic acid content is found to be raised considerably, and a few seconds *after* stimulation it is higher still. The total rise in mammalian muscle may be from a resting value of 0·02 per cent. up to a final value of 0·5 per cent. These experiments prove that lactic acid is formed when a muscle contracts, and continues to be formed for a short time after the contraction is over. It is also easy to show that as the lactic acid increases the glycogen content of the muscle proportionally diminishes. If the muscle be damaged, a steady formation of lactic acid takes place, which is more rapid in the first few hours after death, but continues until the muscle passes into rigor.

With the completion of rigor, frog's muscles are found to contain about 0·4 per cent. lactic acid. Above this the amount does not increase. The onset of rigor, and the rate of production of lactic acid, are quickened if the muscle be kept warm and if oxygen be excluded. It is interesting to note that the amount of lactic acid found in rigid muscle is about the same, whatever the previous history of the muscle. Thus, if the fresh muscle be finely minced it is found to contain about 0·2 per cent. lactic acid. If, however, it be allowed to stand after mincing, there is a slow production of lactic acid up to the maximum 0·4 per cent. Again, a muscle which has been tetanised to exhaustion contains about 0·2 per cent. lactic acid. When allowed to undergo rigor, the amount rises to about 0·4 per cent. This maximum depends on the fact that the accumulation of lactic acid inhibits its further formation. If care be taken to neutralise the acid as it is formed by immersing the muscles in weak alkaline solutions, especially of phosphates, *e.g.* Na_2HPO_4, and to exclude oxygen, the whole of the glycogen disappears and as much as 1·2 per cent. lactic acid can be obtained.

In life, the lactic acid which is formed in muscles by their contraction is immediately neutralised. The process is complex, and so perfect that little if any change of reaction occurs until fatigue begins to set in.

In this neutralisation the inorganic salts of the muscle take but a small part, but an important *rôle* in the process is played by the hydrolysis of creatine phosphate and by the buffering action of the proteins of the muscle, which exist as ionised compounds of protein and potassium or sodium—as in the following equation :

---

* FLETCHER and HOPKINS. *J. Physiol.*, 1907, **35**, 247; *Proc. Roy. Soc.*, 1917, **89B**, 444.

$$\underset{\text{(sodium proteinate)}}{Na^+ + P^-} + \underset{\text{(lactic acid)}}{H^+ + L^-} \rightarrow \underset{\text{(sodium lactate)}}{Na^+ + L^-} + \underset{\text{(undissociated protein)}}{HP}$$

Two points regarding lactic acid formation are important. First, the lactic acid formation does not precede or accompany a contraction but *follows* it. Hence it cannot be the cause of the contraction. Second, lactic acid formation occurs independently of any oxygen utilisation and is, indeed an anaerobic phenomenon.

Source of the Lactic Acid. The disappearance of glycogen as lactic acid appears, points to that substance as the precursor of the lactic acid. The conversion of glycogen (or glucose) to lactic acid is called *glycolysis.* Moreover, the maximal amount of lactic acid obtained is never greater than corresponds to the original glycogen content. It might be expected that the glycogen would first be converted to glucose, but this is not what happens : the enzymes of muscle form lactic acid *more rapidly from glycogen than from glucose.* The change requires the presence of phosphates, and takes place by a series of complex phosphorylated intermediary stages, in which hexose and triose phosphates (pp. 31, 34) are important intermediaries.

The following scheme represents in an abridged form some of the principal changes involved, and will be called "*the lactic acid cycle.*" It is held that in the living muscle all these steps are reversible.

Glycogen
⥮
Hexose monophosphates
⥮
Hexose diphosphate
⥮
Triose phosphate
⥮
Pyruvic acid
⥮
Lactic acid.

CHEMICAL CHANGES UNDER AEROBIC CONDITIONS

The arrangements for the supply of oxygen to muscles in the living body are extremely good, and when a muscle carries out only moderately powerful and moderately frequent contractions under these conditions, little if any lactic acid appears. It was at one time supposed that this was because the lactic acid was formed, as under anaerobic conditions, but that in presence of a full oxygen supply this was in part ($\frac{1}{5}$) oxidised and in part ($\frac{4}{5}$) resynthesised to glycogen.

It is now considered that the cross-roads of carbohydrate metabolism is not lactic acid, but pyruvic acid. In absence of oxygen, pyruvic acid is reduced to lactic acid by lactic dehydrogenase, so that under anaerobic conditions, lactic acid accumulates ; in presence of oxygen, pyruvic acid is, instead, completely oxidised to CO_2 and water, the net reaction being :—

$$CH_3CO.COOH + 50 = 3CO_2 + 2H_2O$$

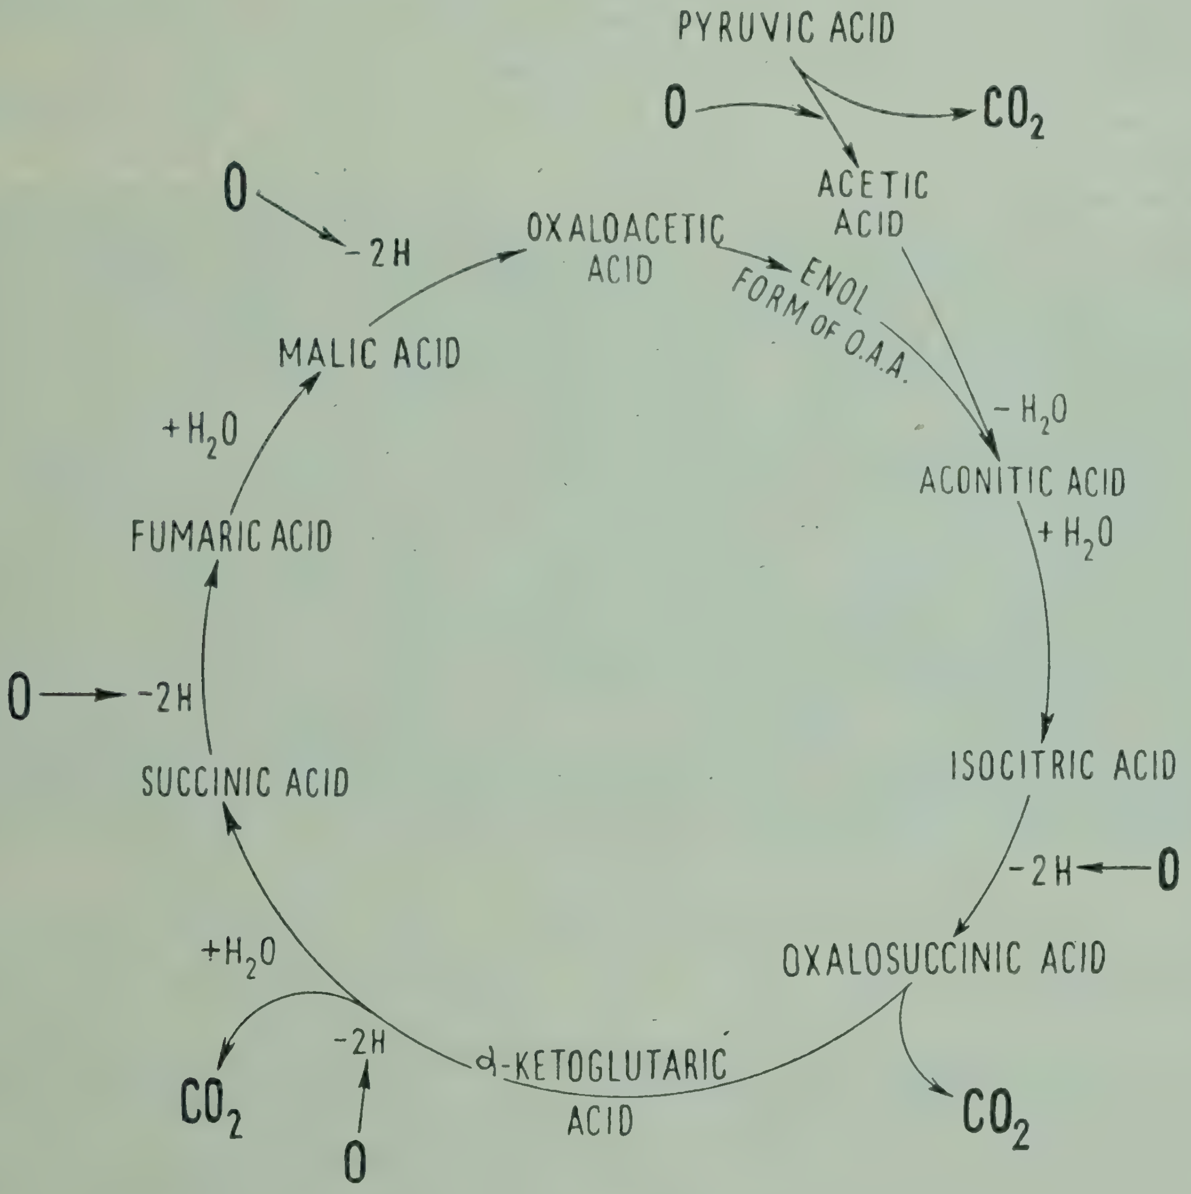
This final result, which represents the end stage of the oxidation of carbohydrate to CO_2 and water, is reached by an interesting series of intermediate reactions, each controlled by a specific enzyme. The details of these reactions will be found in text-books of biochemistry and can only be briefly summarised here.

The first change is the oxidative decarboxylation of pyruvic acid with immediate liberation of the first molecule of CO_2 by the reaction :—

$$CH_3.CO.COOH + O = CH_3COOH + CO_2$$

For this oxidative decarboxylation to occur, coenzyme I, A.D.P., phosphate, Mg ions and the pyrophosphate of vitamin B_1 are all essential. The last named is sometimes called co-carboxylase, and in conditions of lack of vitamin B_1, pyruvic and lactic acids accumulate in the brain, because the pyruvic acid cannot be removed by oxidative decarboxylation.

The next step in the final oxidation of pyruvic acid is that the acetic acid formed as above enters the so-called "tricarboxylic acid cycle." This is a cyclic series of changes which begins with the 4- carbon *di*carboxylic acid, oxaloacetic acid. The acetic acid, by condensing with the *enol*- form of oxaloacetic acid, forms the 5- carbon *tri*-carboxylic acid aconitic acid; this then passes into isocitric acid by adding on H_2O; then by dehydrogenation this acid is converted into oxalosuccinic acid; this is then decarboxylated to give the 5- carbon *di*carboxylic, α-ketoglutaric acid, together with a second molecule of CO_2; the α-ketoglutaric acid is then further decarboxylated, giving the third molecule of CO_2 and succinic acid (a 4- carbon dicarboxylic acid): the succinic then passes by dehydrogenation to fumaric acid, this by hydrolysis to malic acid, which then by dehydrogenation gives oxaloacetic acid with which the cycle began. A small amount of oxaloacetic acid can thus, by repeating this cycle of changes over and over again, continue to oxidise pyruvic acid to CO_2 and water, one molecule of pyruvic acid being taken up at each cycle and yielding 3 molecules of CO_2 as shown in the scheme below:—



The structural formulæ of the intermediary compounds in the cycle are given on p. 31. Each of the changes is effected by a specific enzyme, and in the 5 cases where these are dehydrogenases, the 2H abstracted is passed on in each case through the cytochrome oxidase system, as explained on p. 100, to an atom of oxygen. Hence, as shown in the scheme, we get 3 molecules of CO_2 formed and 5 atoms of oxygen used for each molecule of pyruvic acid broken down, which summarises in the equation:—

$$CH_3CO.COOH + 5O = 3CO_2 + 2H_2O.$$

In the complete oxidation of a carbohydrate, *e.g.*, glucose, the volume of oxygen used is always equal to that of the CO_2 produced, but in the above equation an atom less of oxygen is required. The explanation is that, when half a molecule of a hexose is being broken down under aerobic conditions, there is, in the stages leading to pyruvic acid, an oxidation of 2H (*via* cytochrome) by O, as a consequence of dehydrogenation reactions: hence, in all $3O_2$ is used for oxidation of half the hexose molecule, and $3CO_2$ produced, as explained on p. 145.

Energy Changes in Muscle

The energy of muscular contraction is ultimately derived from the complete oxidation of glycogen to CO_2 and water. It is true that, in absence of oxygen, muscle can for a while develop contractile energy, but this is done (1) by drawing upon stores of energy which are laid down in the form of energy-rich phosphate bonds (*v.* p. 52), in the form of A.T.P. and creatine phosphate, and (2) by energy set free by glycolysis, by which these phosphate bonds are restored. This last source of energy, however, only results in a loss of free energy of about 57 cal. per unit mole of hexose derived from glycogen, of which about 30 cal. is stored as energy-rich phosphate bonds, *i.e.* 3 (~). In complete oxidation of the 6-carbon unit of glycogen, however, there is a loss of free energy about twelve times as much as in glycolysis, *i.e.* of about 720 cal. which would possibly be equivalent to creation of about 36 (~).

We do not know at exactly what stages in the oxidative breakdown of pyruvic acid the new energy-rich bonds are generated, but it is certain that in the long run it is the oxidative changes that yield most of the energy, and this appears partly as heat and partly in the storage form of energy-rich bonds, by the utilisation of which future contractions are provided for.

Probable Sequence of Reactions. A sequence of reactions of glycolysis of glycogen is given in detail in the table below, and the enzymes concerned are shown.

Reaction No.	Enzyme system.	Reacting systems
1	Myosin I + $Ca^{\cdot\cdot}$	A.T P. → A.D P. + H_3PO_4
2	Phosphorylase (protein-Mg-adenylic acid).	Glycogen + H_3PO_4 ⇌ glucose 1-phosphate.
3	Phosphoglucomutase (protein-Mg).	Glucose-1-phosphate ⇌ glucose 6-phosphate.
4	Oxoisomerase (protein-M*).	Glucose 6-phosphate ⇌ fructose 6-phosphate.
5	Phosphohexokinase (protein-ATP)	Fructose 6-phosphate + A T.P. ⇌ fructose 1:6-phosphate + A.D P.
6	Adenyltriphosphatase.	A.T.P.+creatine ⇌ A.D.P.+creatine phosphate.
7	Zymohexase (protein-M*)	Fructose 1:6-phosphate ⇌ dioxyacetone phosphate. Fructose 1:6-phosphate ⇌ 3-glyceraldehyde phosphate.
8	Phosphotriose isomerase (protein-M*).	Dioxyacetone phosphate ⇌ 3-glyceraldehyde phosphate.
9	Nonenzymatic.	3-Glyceraldehyde phosphate + H_3PO_4 ⇌ 1:3-diphosphoglyceraldehyde.
10	Triosephosphate dehydrogenase (protein-DPN) (=Co.I.)	1:3-Diphosphoglyceraldehyde + Co.I. ⇌ 1:3-diphosphoglycerate + Co.I.H_2.
11	A phosphokinase.	1:3-Diphosphoglycerate + A.D.P. ⇌ 3-phosphoglycerate + A.T.P.
12	Phosphoglycere mutase (protein-M*).	3-Phosphyglycerate ⇌ 2-phosphoglycerate.
13	Enolase (protein-Mg).	2-Phosphoglycerate+H_2O⇌ phosphopyruvate.
14	Phosphopyruvate phosphatase (protein-ADP-Mg).	Phosphopyruvate + A.D.P. → pyruvate + A.T.P.
15	Lactic Dehydrogenase.	Pyruvate + Co.I.H_2 ⇌ Lactate + Co.I.

* M = metal.

It will be seen from these reactions that phosphoric acid from A.T.P. is passed on from one compound to another, and ultimately restored.

In formation of lactic acid from glucose (glycolysis), the first enzyme is *hexokinase.* This causes the reaction : Glucose + A.T.P. ⇌ glucose 6-phosphate + ADP. Thereafter the reaction proceeds as in No. 4 onwards. It should be noted that the reduced Co.I formed in reaction 10 is oxidised again in reaction 15, when anaerobic conditions prevail, the 2H lost being used to reduce pyruvic to lactic acid. When oxygen is present, reaction 15 does not occur, but instead we get the two reactions :—

(*a*) $CH_3.CO.COOH + 5O = 3CO_2 + 2H_2O$, as explained above.
(*b*) $Co.I.H_2 + O = Co.I + H_2O$,

the net result of which is that $3O_2$ is used and $3CO_2$ formed.

The reverse change of conversion of lactic acid into glycogen is slow, and does not occur at all in the absence of oxygen. When oxygen is available, and if the muscle is allowed to rest, the lactic acid is removed, and glycogen returns ; it is, however, so slow a process that we may doubt whether such recovery plays a large part in restoring glycogen to muscles *in vivo.*

The Oxygen Usage of Muscle. If we stimulate a muscle repeatedly in an atmosphere of oxygen, it ultimately becomes fatigued and incapable of further contraction. On allowing the muscle to rest, however, it recovers considerably and can execute a further series of contractions, again resulting in fatigue. The recovery is hastened by washing the muscle in oxygenated Ringer's solution.

The muscle can also contract equally well to start with if placed in an atmosphere of nitrogen. Fatigue finally sets in ; but on cessation of the stimulation the muscle in nitrogen does not recover, or recovers very little, and soon passes into rigor * (Fig. 68).

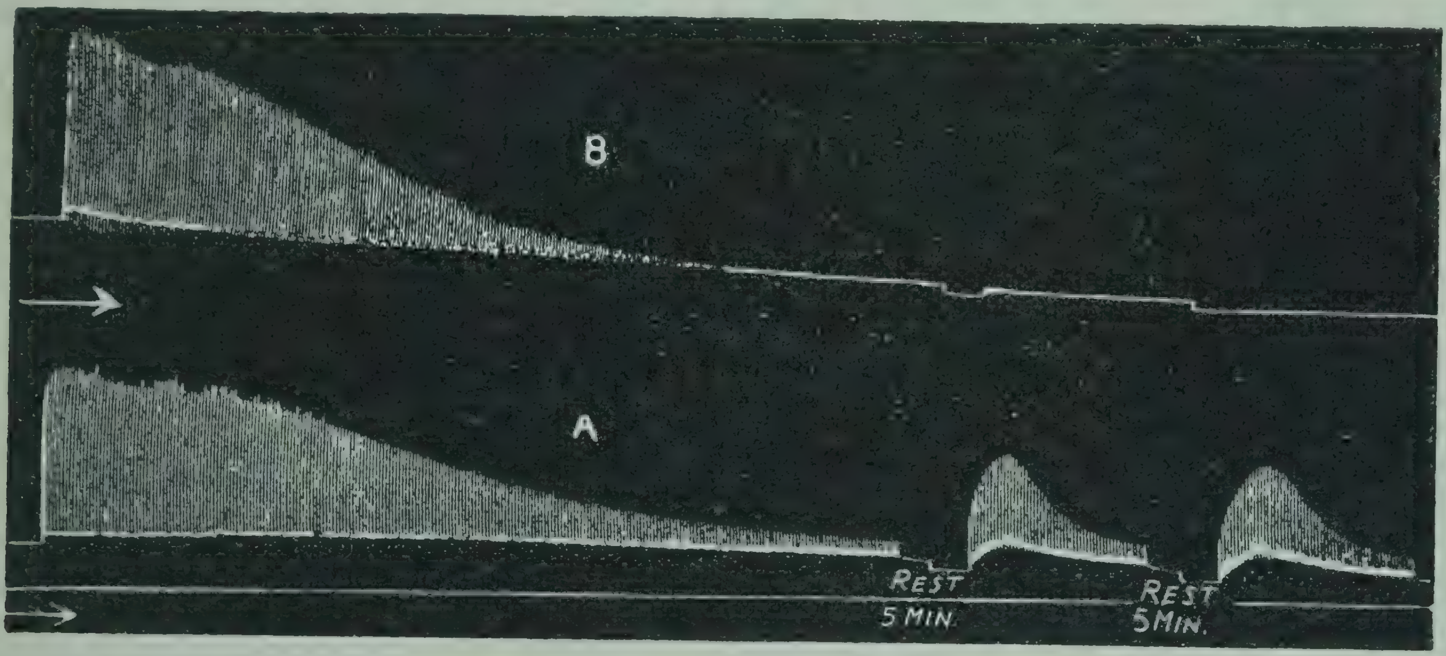


FIG. 68. Fatigue in a Pair of Sartorii. (FLETCHER.)
Max. break shocks one per second. Load 6 grammes. Temp. 19° C.
A. Exposed to oxygen. *B.* Exposed to nitrogen.

These facts suggest that, although oxygen is not essential for contraction it is necessary for recovery. It is therefore of interest to examine the oxygen usage of excised frog's muscle, both resting and fatigued.

For the investigation of the oxygen utilisation of isolated tissues much use has been made of the *microrespirometer,*† the principle of which is illustrated by Fig. 69. The two small flasks A and B are of equal size, and are connected each with one limb of a fine-bore manometer filled with kerosene and provided with a millimetre scale. On the bottom of each of the flasks is a receptacle (*a*, *b*) in which are placed a few drops of potash solution ; the tissue, on a thin sheet, or minced, is floated in Ringer's or other suitable solution in the bottom of one flask, the other containing Ringer's solution only. The bottles are placed in a thermostat and filled with oxygen. The menisci of the manometer are read, and the whole apparatus is continuously agitated in a horizontal direction to and fro to keep the solution saturated with oxygen. At intervals the reading of the meniscus in each limb of the manometer is taken. The level of the kerosene ascends in the manometer on the side connected with the bottle containing the tissue, and falls on the other side. The carbon dioxide produced by the tissue is absorbed by the potash, so that the movement of the kerosene is entirely due to the oxygen absorbed, the volume of which can thus be calculated. Thus the oxygen utilisation of the tissue under given conditions can be found over any required period of time.

† KROGH. *Bioch. Ztschr.*, 1914, **62**, 266. There are many patterns of microrespirometer. *v.* DIXON. *Manometric Methods*, 1934. (Cambr. Univ. Press.)

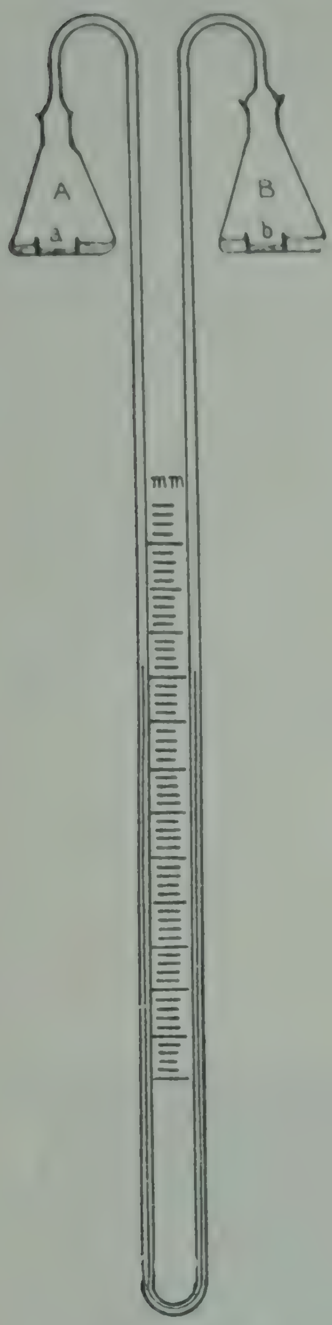

Fig. 69.

If a parallel experiment is made with omission of the potash from the receptacles the change of volume is due to the difference between the oxygen used and the carbon dioxide formed, and from this, if the oxygen used is known, the respiratory quotient can be calculated.

If a thin muscle be placed in oxygen in a microrespirometer, its resting oxygen usage is found to be quite small, and its R.Q. is 0·85 to 0·90.*

When muscle is stimulated, its oxygen usage and all its chemical changes are accelerated. If poisoned with sodium azide, NaN_3,† or cyanide, the oxygen utilisation is suppressed.

If the muscle is stimulated in nitrogen, or after cyanide, lactic acid very quickly accumulates, and the "fatigue maximum" is soon reached. If the muscle is a thin one, *e.g.* the frog's sartorius, and it be suspended in oxygen-free Ringer's solution, the lactic acid diffuses away and fatigue does not set in so soon.

When oxygen is readmitted to a muscle which has been brought to fatigue in nitrogen, the oxygen usage is raised above the former resting value, while the "oxygen debt" contracted during the anaerobic period of stimulation is being wiped off ; this corresponds with removal of lactic acid and recovery of excitability of the muscle. This increased oxygen usage ("excess oxygen") following activity is at first high ; it subsides, at first quickly, then more slowly, to the original basal level, which may only be reached after many hours. As soon as the oxygen usage has returned to the resting level, but not before, the lactic acid is also found to have the low value which characterises the resting tissue. The "excess CO_2," is found to be equal to the excess oxygen, so that the respiratory quotient of the recovery process is unity ; that is to say, it suggests that the oxygen which is utilised in recovery burns up either lactic acid or carbohydrate.

But when we compare the excess oxygen usage in recovery with the *amount* of lactic acid which has disappeared it at once becomes clear that the whole of the lactic acid cannot have been removed by oxidation, for, according to the equation

$$\begin{array}{llll} C_3H_6O_3 + & 3\,O_2 = & 3\,CO_2 + & 3\,H_2O \\ (90\text{ g.}) & (67\text{ l.}) & (67\text{ l.}) & \end{array}$$

each mg. of lactic acid removed should require 744 c.mm. of oxygen for its oxidation, whereas under usual conditions a usage of only 149 c.mm. of oxygen per mg. of lactic acid lost is an average figure, that is, about one-fifth of the amount which would be needed for complete oxidation of the lactic acid that has gone.

The fate of the lactic acid which is *not* oxidised becomes clear when the glycogen content of the muscle is followed during recovery, for there is an increase in the glycogen content of the muscle which is equivalent to the amount of lactic acid removed, but not oxidised. We can thus write the following equations for the separated anaerobic and recovery stages concerned in the formation and subsequent removal of 1 g. of lactic acid, assuming recovery efficiency of one-fifth.

(1) $\underset{\text{Glycogen.}}{C_6H_{10}O_5} + H_2O = \underset{\text{Lactic acid.}}{2\,C_3H_6O_3}$

$162\text{ g.} \longrightarrow 180\text{ g.}$

$\therefore\ 0{\cdot}9\text{ g.} \longrightarrow 1\text{ g.}$ (O_2 usage missed in anaerobic period = 149 c.c.)

Anaerobic period

(2) 1 g. lactic acid → 0·2 g. oxidised

$\underset{(0{\cdot}2\text{ g.})}{C_3H_6O_3} + \underset{(149\text{ c.c.})}{3\,O_2} = \underset{(149\text{ c.c.})}{3\,CO_2} + 3\,H_2O$

→ 0·8 g. converted to glycogen (0·72 g.)

$\underset{(0{\cdot}8\text{ g.})}{2\,C_3H_6O_3} = \underset{(0{\cdot}72\text{ g.})}{C_6H_{10}O_5} + H_2O$

Recovery period

The lactic acid cycle now becomes:—

$$\begin{tikzcd}
\text{glycogen} \arrow[d, bend left=0] \\
\text{Lactic acid} \arrow[u, bend right, "\frac{4}{5}"'] \arrow[d] \\
\frac{1}{5}\text{ oxidised to } CO_2 + H_2O
\end{tikzcd}$$

In an atmosphere of oxygen the effect of stimulating the muscle is to raise its oxygen usage to ten or fifteen times the resting value ; if the muscle were thin enough to allow of access of oxygen to all its parts, lactic acid would not accumulate, as other reactions occur and lactic acid is not formed.

OTHER CHEMICAL CHANGES RESULTING FROM CONTRACTION

Associated with the contraction of muscle are a remarkable series of interlocked reactions. The changes most studied are the anaerobic ones, and many of the reactions concerned have been reproduced in cell-free extracts or enzyme solutions. We shall first deal mainly with the anaerobic changes, and later enquire in what way the changes are different when aerobic conditions prevail. Most of the changes too, are recovery changes, *i.e.*, they occur *after* the actual contraction of the muscle, and serve to prepare it for the next contraction. Several of the reactions are coupled ones, *i.e.* two separate reactions run simultaneously, and the occurrence of one of them depends on the possibility for the concurrence of the other. This is often because one of them is associated with a gain, and the other with a loss, of free energy ; the former reaction cannot occur unless the other is proceeding simultaneously and thus able to provide the necessary energy required for the first. Of the substances involved some are individual compounds, and some are teams, or systems.

Among the important changes on contraction are changes in creatine phosphoric acid. After contraction the unstable creatine phosphoric acid rapidly breaks down into creatine and phosphoric acid. Almost immediately after the contraction, even in absence of oxygen, part of the creatine phosphoric acid is resynthesised, and in presence of oxygen it is all rapidly reformed.[*]

Contraction without Lactic Acid Formation. The correlation between muscular contraction and lactic acid formation led, very naturally, to the view that the initial reaction was the conversion of glycogen into lactic acid, with the corollary that the presence of the lactic acid in the muscle in some way caused

[*] EGGLETON and EGGLETON. *J. Physiol.*, 1928, **65**, 15.

it to contract, or, if in sufficient amount, led to rigor. It is now evident that the lactic acid formation follows the contraction, and is itself a sequel to earlier changes. This, while adding further detail, in no way invalidates what had been discovered concerning the lactic acid cycle.

This change of viewpoint arose in consequence of the discovery by Lundsgaard in 1930 * that it is possible to get contraction without lactic acid formation, in muscles poisoned by monoiodoacetic acid. If a frog's muscle be soaked in Ringer's solution containing 1 : 20000 of sodium iodoacetate it can still respond by contraction to stimulation like a normal muscle. When it has given, say, 150 contractions, however, it is fatigued. Whereas in unpoisoned muscle this would lead to the formation of about 0·05 per cent. lactic acid, in the poisoned muscle there is no increase of lactic acid at all. The poisoned muscle, once fatigued, fails to recover when allowed to rest in oxygen, as a normal muscle would do, and soon passes into rigor ; and then, instead of the usual high concentration of lactic acid, there is again found to be no increase over the resting value. The glycogen, however, has disappeared as in unpoisoned muscle.

From these facts it is evident that lactic acid formation is not an essential concomitant of contraction ; yet when lactic acid formation is inhibited the muscle is only capable of a limited number of contractions.

When the creatine phosphate of the muscle is studied after poisoning, it is found that it is broken down after contraction much in the normal manner, but, unlike the unpoisoned muscle, there is no resynthesis of creatine phosphate when the muscle is allowed to rest in absence of oxygen, though there is some restoration in oxygen : moreover, the phosphate set free is converted to a great extent into hexose monophosphate and diphosphate.

A.T.P. and Muscular Contraction. It now seems certain that adenosine triphosphate plays a fundamental *rôle* in all biological processes involving energy liberation, of which muscle contraction is one example. Probably the first event in the onset of contraction is a physical one, as a result of which A.T.P. is brought into contact with an enzyme by which it is broken down to A.D.P. and phosphate,

$$\underset{\text{(A.T.P.)}}{\textcircled{\scriptsize Ad}\text{-HPO}_3 \sim \text{ph} \sim \text{ph}} \longrightarrow \underset{\text{(A.D.P.)}}{\textcircled{\scriptsize Ad}\text{-HPO}_3 \sim \text{ph}} + \text{H}_3\text{PO}_4$$

thereby resolving an energy-rich bond, and liberating about 10 cals. of free energy per mole. The first striking fact is that the enzyme (adenosine-triphosphatase) which does this is normally very closely bound to the muscle protein myosin, *i.e.* the contractile machinery itself. The primary importance of A.T.P. in contraction is further shown by the fact that when applied in minute amounts directly to isolated single fibres of frog muscle, even if curarised, tetanic contractions with action potentials result,† and contraction of mammalian muscle also results on close arterial injection of A.T.P.‡

The second important fact is that the free energy so made available can probably be transformed with little loss into the mechanical strain of the contractile process ; this is almost certainly effected by intramolecular changes, tending to shortening of the long myosin molecules, akin to those which stretched keratin undergoes on contraction (p. 43). Perhaps also the folding of the long molecular chain may be made more rigid by the fugitive appearance of cross-linkages, *e.g.* of the thio-ether type, which are resolved again on relaxation.

Very soon afterwards the A.T.P. is resynthesised again, and the machinery is thus set for a fresh contraction. This resynthesis of course restores the energy-rich bond, and it is done by the transference of the energy-rich bond from creatine phosphate :—

---

* LUNDSGAARD. *Bioch. Ztschr.*, 1930, **217**, 162.

† BUCHTHAL *et al.* *Acta. Physiol. Skand.*, 1944, **8**, 271.

‡ BUCHTHAL and KAHLSON. *Ibid.*, **8**, 317, 325.

$$\mathrm{Cr} \sim \mathrm{ph} + \textcircled{\scriptsize Ad} - \mathrm{HPO_3} \sim \mathrm{ph} \longrightarrow \textcircled{\scriptsize Ad} - \mathrm{HPO_3} \sim \mathrm{ph} \sim \mathrm{ph} + \mathrm{Cr.}$$

The next stage in the normal recovery process must now be the resynthesis of creatine phosphate, with creation of a new energy-rich phosphate bond. This is brought about by pyruvic acid formation, and other later changes, by which energy is set aside for this synthesis. In the formation of 2 molecules of pyruvic acid from glycogen four energy-rich bonds are created in the form of a synthesis of A.T.P. from A.D.P. (*v.* reactions 11 and 14 in table, p. 144).

One of these new molecules of A.T.P. is used up to regenerate creatine phosphate by the reversal of the previous reaction :—

$$\mathrm{Cr} + \textcircled{\scriptsize Ad} - \mathrm{HPO_3} \sim \mathrm{ph} \sim \mathrm{ph} \longrightarrow \mathrm{Cr} \sim \mathrm{ph} + \textcircled{\scriptsize Ad} - \mathrm{PHO_3} \sim \mathrm{ph.}$$

The high free energy content of A.T.P. is therefore in the long run derived (under anaerobic conditions) from energy interchanges connected with the formation of pyruvic acid ; the immediate resynthesis of A.T.P. is ensured by transfer of the phosphate group from creatine phosphate ; it is only later on, during anaerobic recovery, that A.T.P. is regenerated by the slower processes connected with pyruvic acid formation, and then, when there is a piling-up of A.T.P., the creatine phosphate is synthesised again by reversal of the reaction by which it was formed.

The energy-rich phosphate bond can be likened to money. When in the form of A.T.P. it resembles actual cash in hand ready for instant use. This cash can be quickly replaced by drawing at once on a current account at a bank (creatine phosphate). The amounts taken from the bank can be restored by earning money by expending energy in doing work (pyruvic acid formation): but this may be slow and laborious.

It would seem that monoiodoacetic acid checks the formation of pyruvic or of lactic acid by interfering with the breakdown of the triose phosphate. Fluorides poison the conversion of phosphoglyceric acid to phosphopyruvic acid.

HYDROGEN-ION CHANGES DURING CONTRACTION. Muscle is provided with several types of buffer, by which its reaction, normally pH 6·9, is prevented from changing rapidly during contraction.

First, we have the products formed when creatine phosphate breaks up : the base (creatine) then liberated at first causes a slight rise in pH, which reaches a maximum just after relaxation.* Under conditions of free oxygen supply little if any lactic acid is formed, and $\mathrm{CO_2}$ produced is mainly carried away, the excess being dealt with by the muscle buffers, such as salts of proteins. When oxygen supply is less abundant, lactic acid is formed, mainly after relaxation has occurred, and then, in spite of these buffers the hydrogen ion concentration of the muscle does increase after prolonged activity, though not greatly. Then, in prolonged activity we have traces of ammonia liberated by the deamination of adenylic acid (derived from A.T.P.).

FORMATION OF HISTAMINE. It has been claimed that during contraction, and also under the influence of curare, histamine is liberated from a pre-existing store in the muscle and may be detected in the venous blood from muscles.† The amount set free by curare is large and generally admitted, but the liberation of histamine by contraction is small, and some deny that any is formed.

LACTIC ACID CYCLE IN THE INTACT BODY

When we turn to experiments on the whole animal (or on man) we obtain some confirmation, but also some modification, of the views derived from experiments on isolated frogs' muscles.

The total energy of the body is derived ultimately from the oxidation of foodstuffs. The products of oxidation are excreted partly with the urine, partly with the expired air, so that examination of these, combined with a measurement of the oxygen taken into the body, serves as a measure of the total oxidations. Many experiments on the effect of exercise have shown that the excretion of nitrogenous substances is not immediately affected,* while on the other hand any change in the amount of muscular activity is reflected at once in a corresponding alteration in the respiratory exchanges. When a man runs he becomes "out of breath," and this is associated with an increased intake of oxygen and excretion of CO_2. We must conclude, therefore, that the main source of muscular energy is the oxidation of carbon, either in the form of carbohydrate or of fat.

---

* D. K. HILL. *J. Physiol.*, 1940, **98**, 467.

† ANREP *et al.* *J. Physiol.*, **96**, 1935, **85**, 409 ; 1939, 240.

A man at rest absorbs from the respired air about 300 c.c. oxygen per minute, and gives out about 250 c.c. CO_2. The quotient of the volumes of CO_2 given out by oxygen absorbed is called the "respiratory quotient," and, when measured over sufficiently long periods, its magnitude depends on the nature of the substances undergoing oxidation. If these were entirely carbohydrate (or lactic acid) the respiratory quotient CO_2/O_2 would be equal to 1 :

$$C_6H_{12}O_6 + 6O_2 = 6CO_2 + 6H_2O$$

If fats alone were being utilised, the respiratory quotient would be 0·71; with proteins alone, it would be 0·81. In man, on a mixed diet, the respiratory quotient at rest is somewhere about 0·85.

Even the mildest form of exercise increases the intake of oxygen and output of CO_2. Work which raises the oxygen consumption to less than threefold the resting value may be called light or moderate ; hard or heavy work raises it to from 3 to 8 times, and maximal work may for a short period bring it to 10 times the resting level, or even higher. On ceasing exercise the increased pulmonary ventilation rapidly falls, and after a period varying from ten minutes to half an hour the respiration and the oxygen intake have returned nearly to their previous amounts.

When the body is at rest, the circulating blood contains about 15 mg. lactic acid per 100 c.c. This originates from glucose in the circulating blood by *glycolysis* :—

$$\underset{\text{Glucose}}{C_6H_{12}O_6} = \underset{\text{Lactic acid}}{2C_3H_6O_3}$$

Glycolysis is always occurring in normal blood, but is accelerated if, as by deep breathing, the blood carbon dioxide is reduced and the blood thereby rendered more alkaline. It is also accelerated as the blood traverses the lungs, the tissue of which exerts a glycolytic action.† Lactic acid is also being removed constantly from the blood as it is formed ; a considerable amount is removed and utilised by the heart,‡ a little may re-enter muscle and there be converted to glycogen, but the largest part of it is taken up by the liver and converted again into glycogen, probably by a process similar to, but quicker than, that which takes place in the muscle. The glycogen formed in the liver can then be converted into blood glucose, from which the muscles form glycogen more readily than from lactic acid. Hence, when at rest, the blood lactate, which represents a balance between formation and removal, remains constant.

In the living body the richness of the capillary supply, by offering oxygen freely, gives favourable conditions for complete oxidation of the pyruvic acid, as shown above. When exercise is taken, unless this be brisk, there is no increase in the lactate of the blood,§ because no lactate is formed in the muscles. When the exercise is violent, however, the oxygen supply is inadequate, and lactic acid is set free. This easily happens under experimental conditions in mammals; within half a minute after a short tetanic contraction, the venous blood coming away from the muscle contains lactic acid at a concentration almost equal to that in the muscle, and very soon the arterial lactate also reaches a high value ||

(see Fig. 70). A rise of blood lactate also suggests that under normal conditions in man some lactic acid is produced in violent contractions and passes out from the muscle into the blood stream. During the subsequent recovery period the blood lactate rapidly falls again owing to removal by liver, heart and muscles, and for upwards of an hour by excretion in the urine.

It will be seen that when the body as a whole is considered, the net result of exercise and recovery therefrom is the same as in the isolated frog muscle, namely, glycogen is burned, and any lactic acid formed is subsequently removed; but whereas in isolated frog muscle the removal of lactic acid is very slow, and is accomplished by combustion and reconversion (of four-fifths) into glycogen, removal of lactic acid from the intact body after violent exercise is relatively rapid, and is effected by reconversion into glycogen in the liver.

When exercise can be maintained indefinitely, the processes of recovery, according to this theory, are keeping pace with the processes of contraction, *i.e.* any lactic acid that is formed during contraction is being steadily removed and replaced as glycogen, so that there is no great accumulation of this substance either in the muscles or in the blood. Indeed, in such exercise as walking at 4·0 to 4·5 miles per hour there is no increase of blood lactate at all. The glycogen is replenished from the blood sugar, as it is used up.

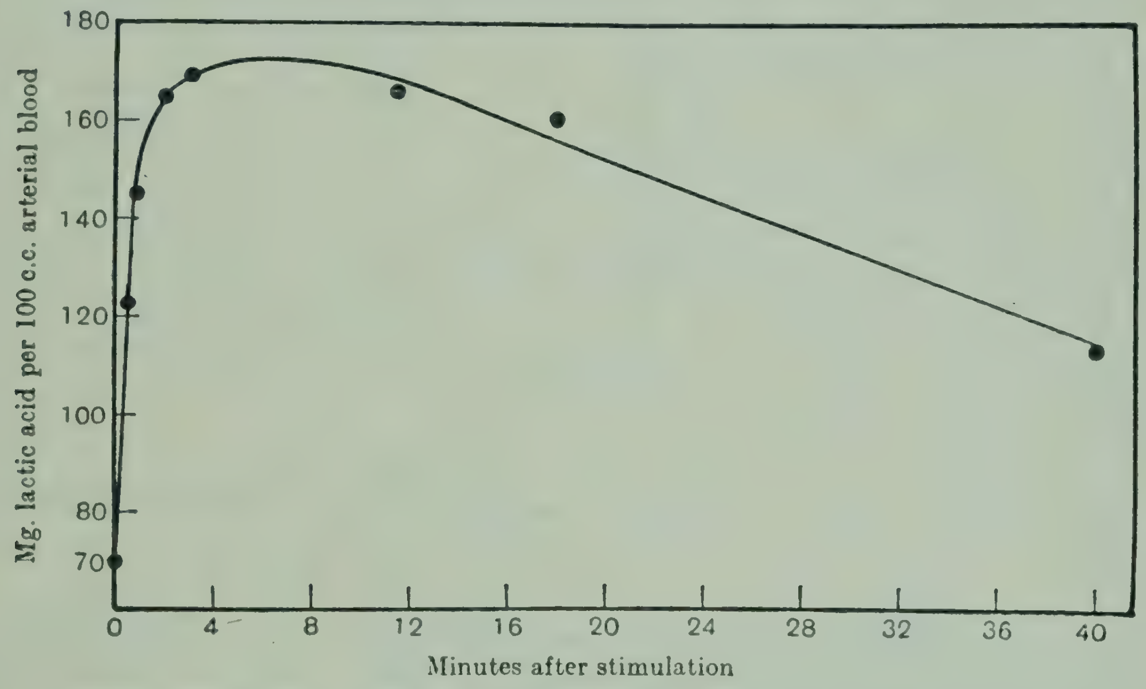

Fig. 70. Lactic acid of arterial blood of anæsthetised dog following powerful muscular contractions resulting from electrical stimulation of legs and trunk. (M. Grace Eggleton and Lovatt Evans, *J. Physiol.*)

When exercise commences the oxygen consumption is accelerated. It may be supposed that the more rapidly pyruvic acid is formed in the muscle, the faster becomes the oxidative removal. Ultimately (assuming the exercise to be moderate) the speed of the recovery process becomes equal to that of the breakdown process.* The oxygen intake per minute rises from the resting level, finally to reach a uniform rate which can be kept up for a considerable length of time (Fig. 71, A and B). This uniform rate is called the "*steady state,*" and signifies the attainment of a steady rate of oxygen usage, together with the upkeep of a constant, but probably quite small, content of pyruvic acid in the muscle by balance of the rates of formation and removal. The more severe the exercise, the higher will be the oxygen usage and pyruvic acid content when the steady state has been reached (Fig. 71). Pyruvic acid, however, does not escape into the blood stream at any time, except in minute amounts, because if the oxygen supply is adequate it is oxidised to CO_2 and water, and if inadequate it is reduced to lactic acid. With normal men taking such exercise as leads to an oxygen usage up to 1·8 l/min. (*i.e.* up to 6 or 7 times the resting intake), as by walking at speeds up to $4\frac{1}{2}$ miles per hour, oxygen usage is adequate either to prevent lactate formation, or to ensure removal of lactate from the muscle without any escape into the blood stream. Whether there is some increase in lactic acid in the muscle, however, is uncertain.*

---

* Hill, Long and Lupton. *Proc. Roy. Soc.*, 1924, **96B**, 438.

As the severity of the exercise is increased the supply of oxygen begins to lag behind the requirement, and some lactic acid begins to be formed in the muscle, some of it overflowing into the blood stream. But so long as the oxygen (blood) supply to the muscles is not grossly inadequate, the lactic acid remains low, so that the total amount present in muscle or blood, and the corresponding oxygen debt, are not excessive. But if the exercise becomes really severe the oxygen supply becomes seriously inadequate and cannot be further increased because the heart cannot pump blood any faster; then the steady state is no longer possible, and lactic acid accumulates more and more, rises to a high level in the blood, and finally brings the performance to an end. In such cases the oxygen debt is a very heavy one, and the process of recovery is prolonged (Fig. 71, curve C, and Fig. 72, curve C).

The maximum severity of this exercise depends on the training of the individual, and physiologically on the extent to which his circulatory system and lungs can provide the working muscles with oxygen in proportion to their needs. The maximum intake of oxygen which, even in an ordinary athlete, can be carried by the blood and pumped round by the heart to the muscles is about 4,000 c.c. per minute. Much severer forms of exercise are, however, possible for brief spells than could be met by such an oxygen supply. In the ten or eleven seconds occupied in a 100 yards sprint, there is not time enough for the oxygen intake to be raised much above the resting level. Immediately after completing the course the man pants violently and in the next few minutes will take in an excess of, say, 4 litres of oxygen. During these eleven seconds the man's muscles have been contracting practically anaerobically, with considerable production of lactic acid. The oxidative removal of this lactic acid, whether in muscle or elsewhere, has been postponed to the end of the race. The man has thus "gone into debt" for oxygen, and the extent to which he can run into debt depends on the amount of lactic acid which can accumulate in the working muscles without stopping their activity. After any severe form of exercise this oxygen debt is apparent (Figs, 71, C; 72). The lactic acid which has accumulated in the muscle during the severe bout of exercise continues to escape when the exercise comes to an end, so that for the first few

* Flock, Ingle and Bollman. *J. Biol. Chem.*, 1939, **129**, 99.

minutes its percentage amount in the blood first rises and then falls steadily as the lactic acid is taken up by the liver and muscles and converted into glycogen again.

In spite of the apparent simplicity of the case as presented above, there are certain facts which point to its not being in reality quite so simple. Thus injection of lactate into the blood stream should cause increased oxygen usage, but does not. The calculations based on blood lactate in exercise are thus probably misleading except in so far as they provide a guide to muscle lactate concentrations as an index of extensive but incomplete breakdown of glycogen, and other components of muscle. In all probability very little blood lactate returns to the muscle, most of it being taken up by heart and liver. Hence the failure of attempts to show a close correlation between oxygen usage and fall of blood lactate after exercise.

No doubt the increased oxygen usage known as oxygen debt represents an active oxidation of some component, by which is provided the energy needed to restore the potential energy of the muscle to its resting value by making good the energy-rich bonds resolved by contraction. But we do not know whether lactic acid is the substance, or the only one, so oxidised.

Effect on Respiratory Quotient. Though moderate exercise does not alter the respiratory quotient, very considerable disturbances are brought about by severe exercise. These are due to driving out of CO_2 during the exercise, followed by compensatory retention of CO_2 afterwards.

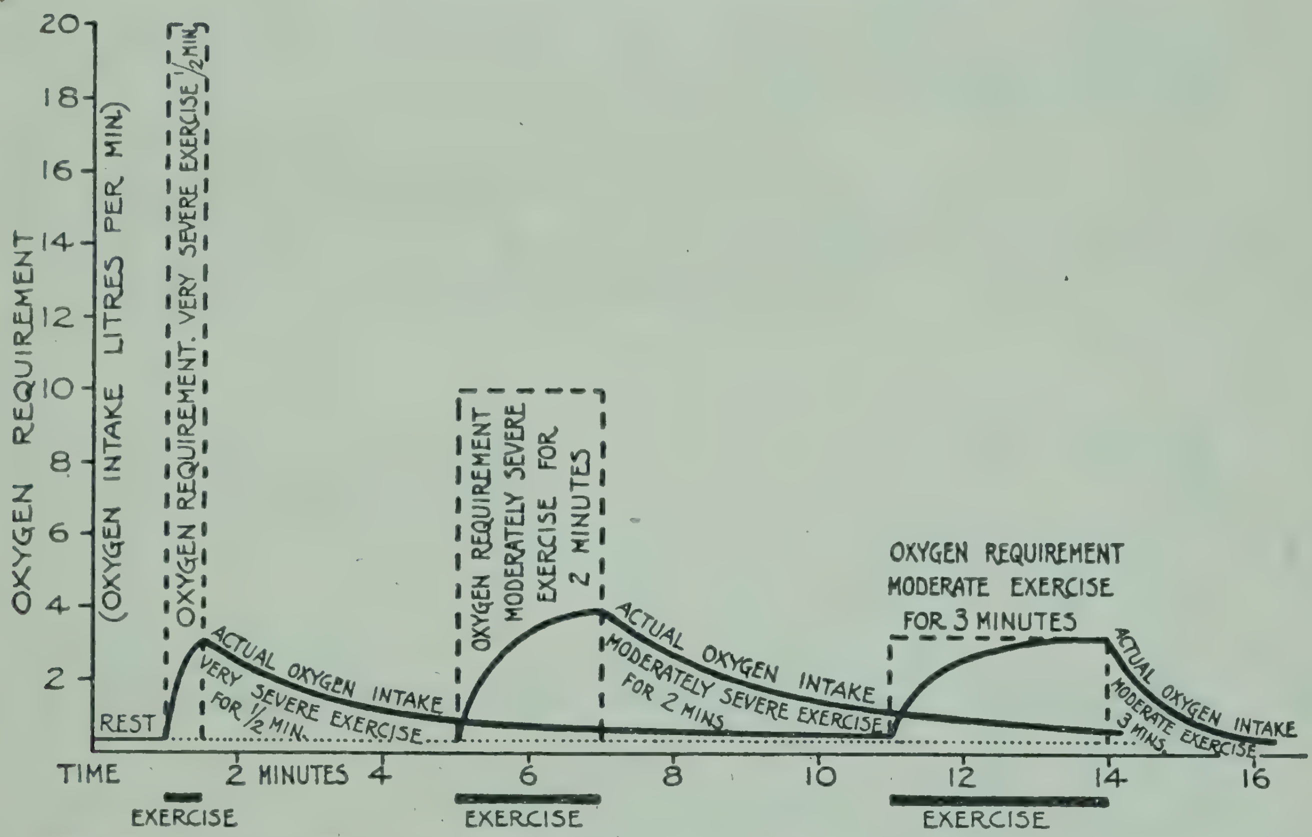

FIG. 74. Diagram to illustrate the Meaning of "Oxygen Requirement," and the Distinction between "Oxygen Requirement" and "Oxygen Intake."

The area of an oxygen requirement rectangle is, by definition, the same as that of the complete oxygen intake curve, each being measured from the level of the resting oxygen intake (shown dotted). Three periods of exercise of different severity.

During exercise, there is considerable stimulation of the respiratory movements. Such a stimulation is necessary for the increased intake of oxygen, but it also simultaneously, and to a greater degree, quickens the elimination of CO_2. Moreover, the ultimate escape of lactic acid into the blood, when the exercise is violent, will drive out CO_2 and will further increase its elimination by the lungs. Thus an amount of carbon dioxide would be blown off from the lungs in excess of that produced by the metabolism of the body. For example, if the true metabolism during exercise were: oxygen 3 litres per minute, CO_2 2·4 litres per minute, the true respiratory quotient would be 0·8. If, however, 3 litres extra of carbon dioxide were displaced, and this was eliminated in ten minutes, the apparent respiratory quotient would be raised to 0·9. This rise of CO_2 output and of respiratory quotient would be the initial event in any steady form of exercise, so that the increased breathing would be more marked while this extra CO_2 was being eliminated. After its elimination the organism enters into a steady state: the excessive breathlessness disappears, the individual having attained "second wind." With severe exercise of short duration, when a considerable oxygen debt is incurred, the escape of lactic acid into the blood causes a great dyspnœa immediately after the exercise, with a large output of CO_2. The apparent respiratory quotient under these circumstances may rise to 1·5 or even to 2. During the process of recovery the lactic acid is gradually removed, the base by which it was neutralised is liberated, and the excess CO_2 which has been given off from the body is once more retained. We therefore find that the high respiratory quotient immediately after heavy exercise is followed later on by a long lasting fall of the respiratory quotient below the resting level.

Substances Consumed by Working Muscle. For brief exercise of moderate severity it has been argued that if we make due allowance for these fluctuations in the respiratory quotient, due to the initial driving off of the CO_2 and its subsequent retention as the lactic acid disappears, we arrive at the corrected respiratory quotient of the exchanges, directly due to muscular exercise of short duration. In making this calculation it is customary to deduct the oxygen usage and CO_2 production during rest and to call the remainder the "excess metabolism" of exercise plus recovery. One of the difficulties in this type of experiment is that of deciding how long a time is necessary for return of the respiratory exchange to the normal resting level. It has been claimed that this excess metabolism has a R.Q. of about 1·0. We are therefore perhaps entitled to conclude that in the whole animal, as in the isolated frog's muscle, the energy of muscular contraction, when this is of moderate severity, is normally derived ultimately from the oxidation of a carbohydrate, to CO_2 and water. In support of this, too, is the fact that during exercise the blood sugar is often lowered, presumably by acceleration of uptake by the muscles.

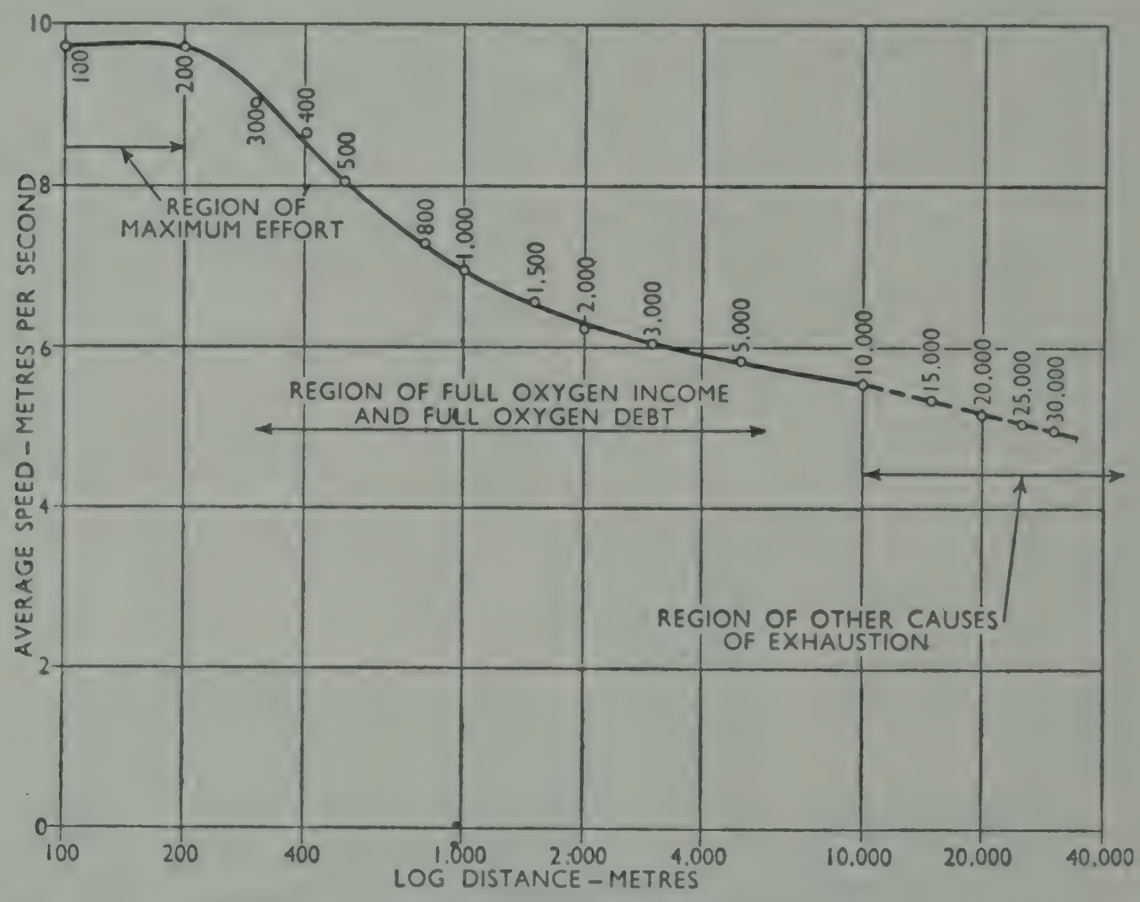

Fig. 75. Athletic records. Average speed plotted against log distance. (A. V. Hill.)

That carbohydrate, though the choice, is not the sole possible source of muscular energy, however, is indicated by several converging lines of evidence. The carbohydrate stores of the muscles can be brought to a low level by fasting, or by a diet consisting almost entirely of fat, and containing no carbohydrate. After three days of such a diet the subject is disinclined for exercise and easily susceptible to fatigue. Ketones derived from fat metabolism are present in blood and urine; when exercise is taken the amount of these is reduced instead of the blood sugar being lowered. After the exercise the amount of ketone bodies increases still further, suggesting that the liver has furnished them at an accelerated rate.*

It has been shown both for man and dog that prolonged and violent exercise can be taken in which the material consumed amounts to ten times the carbohydrate content of the entire body.† Whether under these circumstances fat or protein is consumed direct or whether these are first converted into carbohydrate is uncertain, but it would seem most probable that it is the latter.*

---

* Neufeld and Ross. *Amer. J. Physiol.*, 1943, **138**, 747.

† Dill, Jones and Edwards. *Le travail humain*, 1934, **2**, 1.

With very intense exercise the R.Q. of the excess metabolism may be very high (up to 1·7), a result as yet unexplained.†

THE "MECHANICAL EFFICIENCY" OF HUMAN EXERTION. It is possible to calculate the amount of mechanical energy liberated (theoretical maximal work) by men carrying out various exercises under normal conditions, and then by determining their oxygen utilisation during the work and recovery, to compute the mechanical efficiency of the performance. This is, under favourable conditions, about 20 per cent.‡ Many approximations have to be made and sources of error allowed for, but it is surprising with what constancy an experienced athlete can perform. In running, which has been chiefly studied, the allowances to be made include those for starting up and stopping and for onset of fatigue. In running, little actual mechanical work is done, the energy set free being used for imparting velocity to the body, a good deal of it being lost in overcoming viscous or other resistance in the muscles and other structures. The speed reached depends on the ratio of propelling force to resistance, chiefly that of his own muscles, as viscosity, and that represented by starting and stopping the movements. The resistance of the air is normally small, and may be allowed for. The superiority of first-class athletes over others of equal muscular strength appears to be due to the smaller "viscosity" of their muscular apparatus, using this term in its widest sense to mean that in them less force is wasted in overcoming the resistances represented by putting their limbs in motion.

In maximal performances, such as those involved in athletic records, the man is exhausted when his oxygen debt reaches, say, 15 l., while his maximal oxygen intake is usually about 4 l./min. Lash, who created a world's record for a 2-mile run, used 5·35 l./min. when running at 21·6 km./hr.: in runs at 18·7 km./hr. for 5 min. he reached 5·1 l./min. and at the finish had only about 48 mg./100 c.c. of blood lactate.§ Hence a man can do work at a greater rate the shorter the total time for exhaustion, so that there is a close relation in athletic records between distance covered by a runner at exhaustion and the speed at which he covers it, as shown by Fig. 75.

During really maximal exertion much of the work is performed anaerobically, and lactic acid is produced at about 3 to 4 g./sec., and as a maximal tolerable amount is about 90 grammes, it is calculated that the severest exertions can only last for about 30 sec. This agrees with the practical experience of athletes.

THE HEAT PRODUCTION IN MUSCULAR CONTRACTION

Although chemical investigation has yielded valuable information as to the various stages by which net chemical changes occur, it does not give full information as to the course of events occurring during contraction, relaxation and recovery. All we can do is to examine the summated results of a long series of contractions or to study the action of individual enzymes. A single twitch will give no detectable chemical change, yet energy has been set free, and part of this appears in the form of heat. Methods for detecting small differences of temperature are now so exact that we are able to measure not only the heat production during a single twitch but also the time-course of its evolution.

In large animals the production of heat in muscular contraction can be easily shown by a thermometer. This observation is confirmed when we investigate the contraction of an isolated muscle outside the body. If a frog's

muscle at 20° C. is tetanised, its temperature rises about 0·03° C. per second o stimulation, and for each single twitch from 0·001° to 0·005° C.

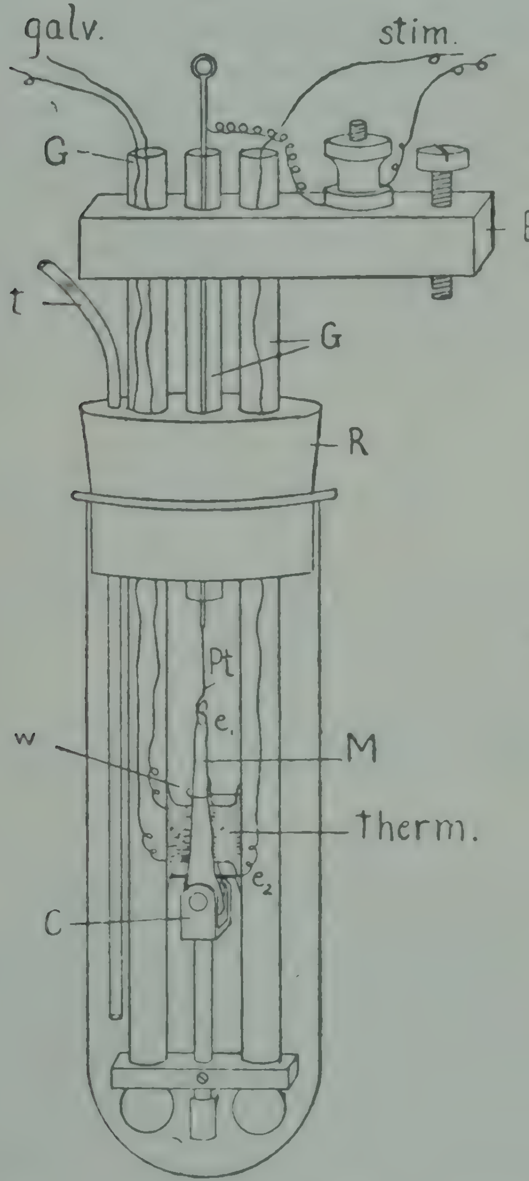

FIG. 78. Arrangement of Thermopile and Muscle for measuring Heat Production during Contraction. E is an ebonite block by which the whole apparatus is secured upright in the water bath; *w* is a platinum wire guide for the muscle to insure good contact with the thermopile; *t* is a fine glass tube through which Ringer's solution or oxygen can be introduced into the chamber; C is an ebonite clamp to hold the muscle; it is secured to the glass rods by means of an ebonite bar at the base and a silver-plated set screw. (W. O. FENN, *J. Physiol.*, 1923, **58**, 175.)

These small changes in temperature can be estimated by thermoelectric junctions. When two or more junctions of a circuit made of two metals are at different temperatures, a current of electricity flows through the circuit, and can be measured by means of a galvanometer. Thus in the circuit (Fig. 76) composed of antimony and bismuth, if the upper junctions be warmed there will be a current flowing in the direction of the arrows, and this current will within limits be proportional to the difference of temperature between the warm and cool junctions. In such a series of junctions, alternately warmed and cooled, the currents are added together; this is the thermopile.

To measure the rise of temperature in a muscle during its contraction, the thermopile is made in the form of a grid. It consists of forty or more turns made with alternate segments of fine iron and constantan wire soldered together with silver solder and wound between the arms of a U-shaped insulating frame (Fig. 77) so that two sets of junctions lie half-way between the arms of the U and the other two sets on the outside edges of these arms. A slip of mica is inserted between the front and back parts of the spiral, and the wire insulated throughout wit a coating of shellac varnish. A pair of muscle (*e.g.* sartorii) is used, and is arranged so as to straddle the grid, each muscle lying close against the middle ("warm") junctions, while the oute junctions are maintained at a constant temperature. For this purpose the arrangement show in Fig. 78 may be used. Through the rubbe bung, R, of a large test tube pass three glass tubes G. Between these the thermopile is fastened The leads from the thermopile to the galvanomete pass through two holes in one of the glass tubes The muscle is stimulated by the electrodes, e and e_2. The lower electrode e_2 is connected wit the stimulating circuit by means of a copper wir leading up through the other glass tube. Th upper electrode e_1 consists of an 8-shaped loo of platinum tied between the two muscles, an soldered to a fine steel rod, which makes electrica connection with the stimulating circuit, an mechanical connection with the lever whic records the contractions of the pair of muscle The whole apparatus is kept at as constant temperature as possible. The leads from the thermopile are taken to a very sensitive galvanometer of low resistance.

The thermopile and galvanometer can be calibrated so that the rate of heat production by the muscle may be deduced directly from the galvanometer excursions. For this calibration, the muscle at the end of the experiment is killed, and the heating effect observed on passage of an alternating current. Knowing the strength of the current and the resistance of the dead muscle, the exact amount of heat required to produce an observed deflection can be calculated.*

Calorimetric Method. For the determination of the total heat production in a muscle or group of muscles over a considerable time we may use microcalorimeters.†

Two small Dewar flasks are used (Fig. 79). In each of these are suspended several frogs' muscles immersed in Ringer's fluid and arranged so that they can be stimulated. Thermojunctions are immersed in the fluid in the two flasks. Any difference of temperature between the two vessels as revealed by the galvanometer is therefore due to liberation of heat in the muscles which are being excited.

Valuable results have been obtained with the above-mentioned methods on the heat production during muscular contraction. By the calorimetric method it was shown that in anaerobic muscular contractions the formation of 1 g. of lactic acid is attended with the evolution of about 370 gramme-calories.‡ The thermopile shows that this heat does not come off at once, but in two phases, there being an evolution of "*initial heat*" immediately following on excitation, and a subsequent evolution of "*anaerobic delayed heat,*" following relaxation.

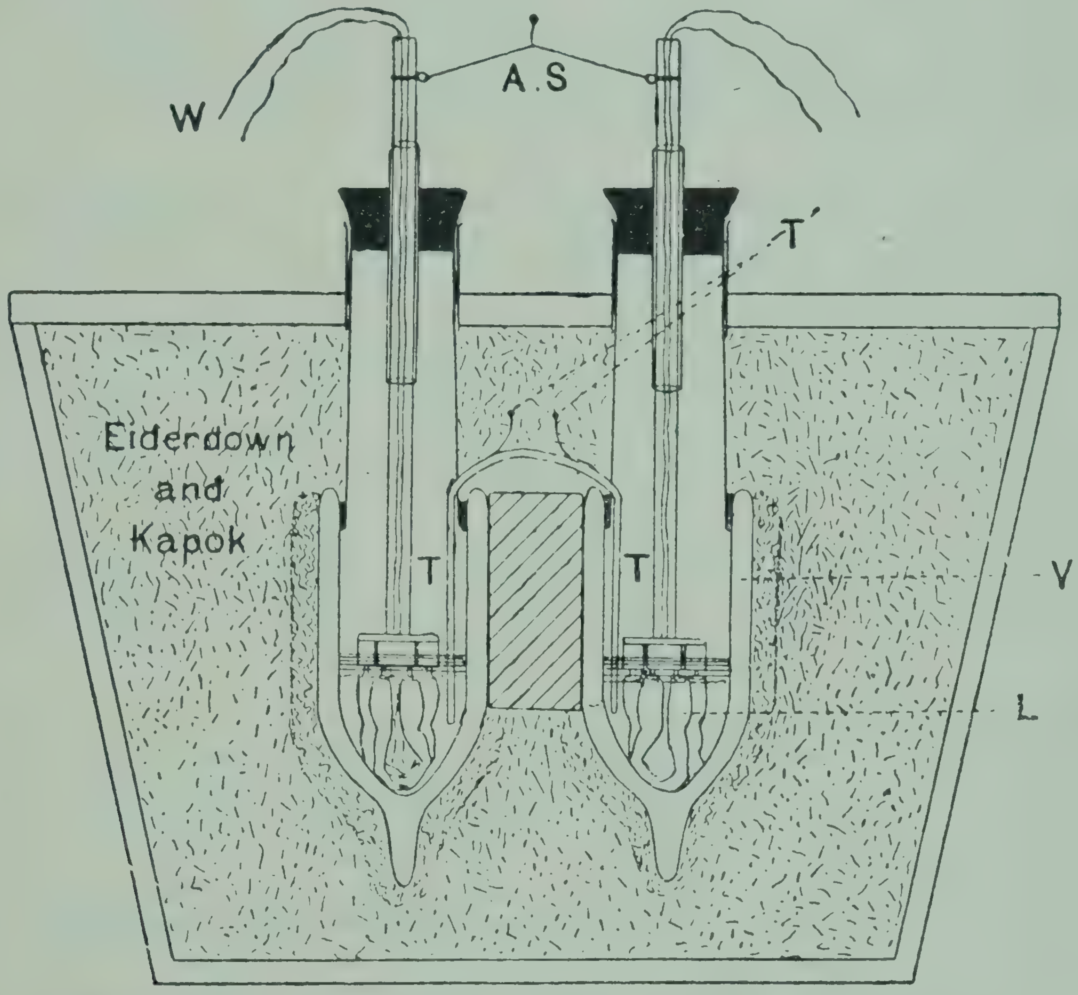

Fig. 79. Arrangement of two Dewar Flasks for studying the Production of Heat in Muscles over a considerable period of time. (R. A. Peters.)

During recovery in oxygen there is, accompanying the disappearance of lactic acid, a further prolonged evolution of heat, "*delayed aerobic heat.*" It has been shown, by cooling frog muscles to 0° so that changes are slowed down, that the time course of the oxidative delayed heat is the same as that of oxygen consumption.§ As this is only a further 370 calories per gramme of lactic acid removed, and since oxidation of 1 gramme of this substance involves the liberation of 3,600 calories, it is clear that either the oxidation of lactic acid to CO_2 and water is incomplete, or else must be coupled with some other reactions which are accompanied by considerable absorption of energy. Meyerhof's explanation was that about one-fifth of the lactic acid undergoes complete oxidation, but that only part of the energy of this oxidation appears as heat, while the rest of it is absorbed in the endothermic reconversion of lactic acid into glycogen.

ISOMETRIC CONTRACTIONS. For technical reasons, a great deal of work has been carried out on the heat production in isometric contraction, and it was supposed that the only difference on isotonic contraction was that the tension of the isometric contraction was more or less completely converted into work if the muscle was allowed to shorten. As already explained, however, isometric contraction is somewhat of a myth when considered from the energy standpoint, and moreover, the relation between isometric and isotonic contractions cannot be arbitrarily simplified in the manner stated.

Though much has been learned by study of the isometric contraction, recent improvements in technique have enabled the simpler case of the isotonic contraction to be adequately studied.

The total initial heat formed in isometric contraction and relaxation is a measure of the total energy set free by the muscle in the act of its contraction, and, as Hill showed, the tension set up under isometric conditions bears a constant relationship to the heat production, the ratio Tl/H (where T = tension, l length of muscle, and H the heat produced) remaining constant at an average value of 8, under a variety of conditions. This ratio is a measure of the perfection with which the chemical potential energy is converted into mechanical potential energy, *i.e.* of the efficiency of the muscle.

Increase of initial extension causes a rise of the heat production, as well as of tension production, up to a certain maximum, beyond which there is a decline in both (*v.* Fig. 54).

Isotonic Contractions. It has been shown by Fenn * that a muscle develops more heat on isotonic than on isometric contraction. This may be interpreted as meaning that the isotonic contraction does not merely utilise tension energy liberated at the commencement, as though the muscle were a stretched spring, but that it continues to develop further power as the shortening progresses. In accordance with this it has been shown that the relation between force exerted and rate of shortening is not as simple as a viscous elastic model would suggest, *i.e.* the decrease of force with increase in speed is not linear, as viscous change would demand, but exponential.†

The heat associated with contraction consists of *initial heat* and *recovery heat*, the former occurring in a sudden burst during contraction, and the latter much more slowly during recovery, *i.e. after* relaxation has ended. Recovery heat is much reduced under anaerobic conditions. Heat is also produced in further amount in maintaining a contraction, and is called "*maintenance heat.*" The relations are roughly :—

(1) *Contraction heat*		
(*a*) Shortening heat		1·0
(*b*) Work heat	varies	
(*c*) Maintenance heat	varies	
(2) *Relaxation heat*	varies	
(3) *Recovery heat*		1·0
(*a*) Aerobic		1·0
(*b*) Anaerobic		0·08

The heat production under isotonic conditions is complicated by a *thermo-elastic effect :* resting muscle, like rubber, warms when stretched and cools when it is released again ; contracted muscle does the reverse.

The *initial heat* begins at the same moment as the shortening,‡ starts off at its maximum, and finishes as soon as shortening ends. The amount of *relaxation heat* depends on conditions : if no work is dissipated in relaxation, *e.g.* if the muscle does not have to lower the weight lifted by its shortening, then there is no relaxation heat at all. If the weight does pull on the muscle, then heat is set free in proportion to the load lowered.

---

* FENN. *J. Physiol.*, 1924, **58,** 175, 373.

† FENN and MARSH. *J. Physiol.*, 1935, **85,** 277.

‡ A. V. HILL. *J. Physiol.*, 1948, **107,** 29.P.

The *shortening heat* is proportional to the amount of shortening, but (with maximal stimuli) independent of the load lifted : hence, within a given range, the heavier the load the greater the total energy set free when equal shortenings are considered : but the extra energy appears as work, not as heat. The mechanical efficiency of the contraction may reach 35 per cent.

When a contraction is *sustained*, as in a tetanus, further heat is continuously liberated, and this represents the energy expended in maintaining tension : it is therefore conveniently studied in isometric contraction at different lengths. *Maintenance heat* is increased by increase of initial length of fibre, because this raises the tension that has to be sustained. It is also increased by rise of temperature (2·8 times by 10° C. rise) because tension dissipation is increased by rise of temperature and probably depends on chemical events. The cost of maintenance varies in different muscles and in different species ; it is high in frog as compared with man.

THE MECHANICAL EFFICIENCY OF CONTRACTION. When a muscle contracts it may perform mechanical work, and the energy for this work is derived from the chemical and physical changes associated with contraction and recovery. It is often necessary to consider the *mechanical efficiency* of contractions carried out under certain conditions, *i.e.* to know what fraction of the total energy set free in the contraction is converted into work. Thus if 10 per cent. of the energy set free were converted into work, the remaining 90 per cent. being liberated as heat, the mechanical efficiency would be 0·1 (or 10 per cent.).

The mechanical efficiency will vary, for a given muscle, with conditions, *e.g.* with load lifted, rate of shortening, etc., but will of course never be anything like 100 per cent. In human muscles *in situ* it may be anything up to 20 per cent. and seems to be similar for frog muscle *in vitro*,* when the whole cycle of contraction and recovery is taken into account. For individual muscles speed of contraction largely influences the efficiency, *e.g.* for arm flexion to full extent the optimal time is 0·5 sec., and for a leg flexion about 1 sec. With an isometric contraction, or an isotonic one without any load, the efficiency is, of course, nil.

Mechanical efficiency is measured by finding the work done in the usual way (weight × height) and finding what fraction this is of the energy expended as found by measuring either total heat production, or total oxygen usage. (Knowing that 1 g. cm. = 23·4 micro cal. = $4{\cdot}7 \times 10^{-6}$ c.c. oxygen usage.)

RELATION TO CHEMICAL CHANGE. By analysis of the time relations of the process by the use of thermopiles, and correlation with the chemical changes as discussed above, it would seem that the sequence of events as regards the heat production in muscular contraction and recovery is in outline as follows :

(1) Contraction. The first event is probably the breakdown of A.T.P. into A.D.P. and phosphoric acid, with liberation of heat and energy :—

1 mol. A.T.P. = 1 mol. A.D.P. + H_3PO_4(+ 11,000 cal.).

Then follows the breakdown of creatine phosphate and linked with it the resynthesis of A.T.P. :—

1 mol. creatine phosphate = 1 mol. creatine + H_3PO_4(+ 11,000 cal.).
A.D.P. + H_3PO_4 = A.T.P. (− 11,000 cal.).

(2) Relaxation. Next, three reactions occur simultaneously :—

1 mol. hexose equivalent (glycogen) = 2 mol. lactic acid (+ 32,000 cal.).
2 mol. lactic acid neutralised by proteins, etc. (= + 16,000 cal.).
4 mol. creatine + 4 H_3PO_4 = 4 mol. creatine phosphate (− 44,000 cal.).

and, as will be seen, the net heat exchange is + 4,000 cal.

After relaxation has occurred there is formation of lactic acid and resynthesis of creatine phosphate. There is a further and much slower production of heat.† In actual experiments on muscles, in absence of oxygen this, the delayed anaerobic heat, is much less per g. lactic acid formed than we should calculate. The heat liberated represents the algebraic sum of at least four simultaneous processes :

(*a*) Lactic acid formation—evolution of heat . . . .
(*b*) Lactic acid neutralisation by protein-evolution of heat .
(*c*) Creatine phosphate resynthesis-absorption of heat . .
(*d*) Re-ionisation of protein-absorption of heat . . .

Total = +200 to 300 cal. per g. lactic acid.

* HILL. *Proc. Roy. Soc.*, 1939, **127B**, 434 ; **128B**, 263.

† HARTREE and HILL. *J. Physiol.*, 1922, **56**, 367 ; 1923, **58**, 127. BLASCHKO. *J Physiol.*, 1930, **70**, 96.

When the muscle has been poisoned with iodoacetic acid, stage (1) occurs, but not stage (2), and as we have seen, there is no lactic acid formation. Hence it is concluded that the heat available from the formation of lactic acid does not all appear, since some of it is absorbed in the endothermic reactions (*c*) and (*d*) and some perhaps in other ways.

(3) In presence of oxygen the delayed heat is much increased (Recovery heat), though its rate of formation is only $\frac{1}{600}$ as rapid as that of the initial heat.[*] This again is due to a balance of exothermic and endothermic processes :—

(*a*) Complete creatine phosphate resynthesis—(absorption of heat)	total about 370 cal. per gramme L.A. removed.
(*b*) Oxidation of lactic acid (or carbohydrate)—(evolution) .	
(*c*) Re-formation of glycogen (absorption)	

The results of the thermal investigations thus enable us to supplement those obtained by chemical methods but final agreement has not yet been reached.

OTHER PHYSICAL CHANGES ASSOCIATED WITH CONTRACTION

Various other physical changes are associated with contraction ; thus there are changes in double refraction (diminished), volume (decreased), translucency (diminished), and impedance (increased in isometric, decreased in isotonic contraction). Increase of pressure to 300 atm. can cause contraction of muscle.[†] Although these changes have not been very extensively studied, the close correspondence between their time relations and the time relations of the tension curves and heat production indicate that the processes are closely related. Generally speaking, the curves for all these changes show two phases, one during the contraction and the other during relaxation. The former is thought to be related to changes in adenosine triphosphate, and the latter to creatine phosphate and lactic acid changes. In muscles poisoned with iodoacetic acid, or under anaerobic conditions, the time relations of all five changes are also very similar.

THE ULTIMATE CAUSE OF MUSCULAR CONTRACTION

The means by which the chemical energy of the contracting muscle is converted into the mechanical energy of the contractile process is unknown. Accordingly, theories are numerous.

We know now that there can be no question of a conversion of heat energy into work, because the necessary local high temperature could not be reached without killing the muscle.

As a net result, there is no doubt that the source of the energy is oxidative processes. Experiments on the metabolism of the body as a whole, and of mechanically functioning

organs like the heart, show that the performance of work involves an increase of the oxidative processes with a corresponding evolution of energy, of which at least four-fifths will appear as heat while at most one-fifth may be transformed into mechanical work.*

Among theories that have been at various times in vogue are (1) that of attraction between structures of opposite electric charge; (2) that lactic acid liberation caused a physical change akin to coagulation, or that creatine phosphate breakdown was the responsible factor; (3) that increase of surface tension on the surface of, or of osmotic pressure within, some small structural elements, caused the shortening; (4) that it was due to swelling of colloidal particles.

At present opinion is converging upon the view that the ultimate machinery of contraction is the long myosin molecule,† and that in the act of contraction this becomes folded or looped, and so becomes shorter. Since the myosin forms an important fraction of the cytoplasm of the fibre, this leads to shortening of the fibre. The evidence that the myosin molecule is of the long fibrous type is convincing, and it is supposed that in the resting state the molecule is stretched out, as shown above.

The NH– groups have a positive charge and the CO– groups a negative one and so these tend to attract one another; but they are kept at a distance because the molecule is fixed by some subsidiary linkages, *e.g.* by S–S bonds, or by repulsions between other bonds or side-groups, *e.g.* between NH_2 groups of lysine residues. When the muscle is stimulated we may suppose that the enzyme adenosine triphosphatase is set free, or made active; by this A.T.P. is broken down to A.D.P., setting free a phosphate group and about 10,000 cal. of energy per mole of A.T.P. This liberated energy may be in some way responsible for releasing the bonds that keep the myosin molecule in the elongated form, thus allowing full play to the force tending to crumple up the long chain, as shown above. Or the shortening may be brought about by transfer of the phosphate group to the myosin molecule, *e.g.* to the NH_2 group of lysine residues. A liberation of calcium, or of potassium, from a bound form has also been considered a possible factor in releasing the crumpling process, but there is as yet no clear evidence as to what starts the process off.

Whatever the precise mechanism, there is reasonably good evidence, first, that A.T.P. is a prime mover, and second, that the fundamental process is a crumpling of the myosin chains. When the muscle relaxes, these processes are reversed: if any energy is transferred in order to "re-wind the spring" and set the myosin molecule back in the elongated form, it would appear to be transferred quantitatively, without loss as heat, since, as we have seen, relaxation may occur without heat production. But the energy-rich phosphate bonds are, in fact, believed to be transferable without loss. Such a transfer would only be of the nature of a temporary borrowing, to be made good at a slower rate later on. Subsequently, in fact, energy is used, in oxidative reactions, as we have already seen, and the recovery heat is an expression of this energy generation which restores the muscle to its original condition.

CHAPTER XI

PLAIN MUSCLE AND OTHER CONTRACTILE TISSUES

OUR knowledge of the physiology of unstriated (also called smooth, plain, or involuntary) muscle is derived from experiments on viscera or organs in which it predominates, *e.g.* in mammals, the uterus, arteries, stomach, intestine, ureter, bladder, nictitating membrane and retractor penis, and in special muscles of invertebrates.* Plain muscle often differs from voluntary muscle in containing numerous plexuses of nerve fibres (non-medullated) and ganglion cells, so that it is difficult to be certain whether some results are due to the muscle fibres themselves, or to the nerves and nerve cells which are so intimately connected with them; especially as we have as yet no convenient drug like curare by aid of which we might discriminate between action on muscle and action on nerve.

A further difficulty is that the physiological properties of plain muscle differ with its source, so that it is unsafe to generalise from the results of experiments with tissue from only one source. The tissue occurs in two extreme forms, and there are intermediate types.

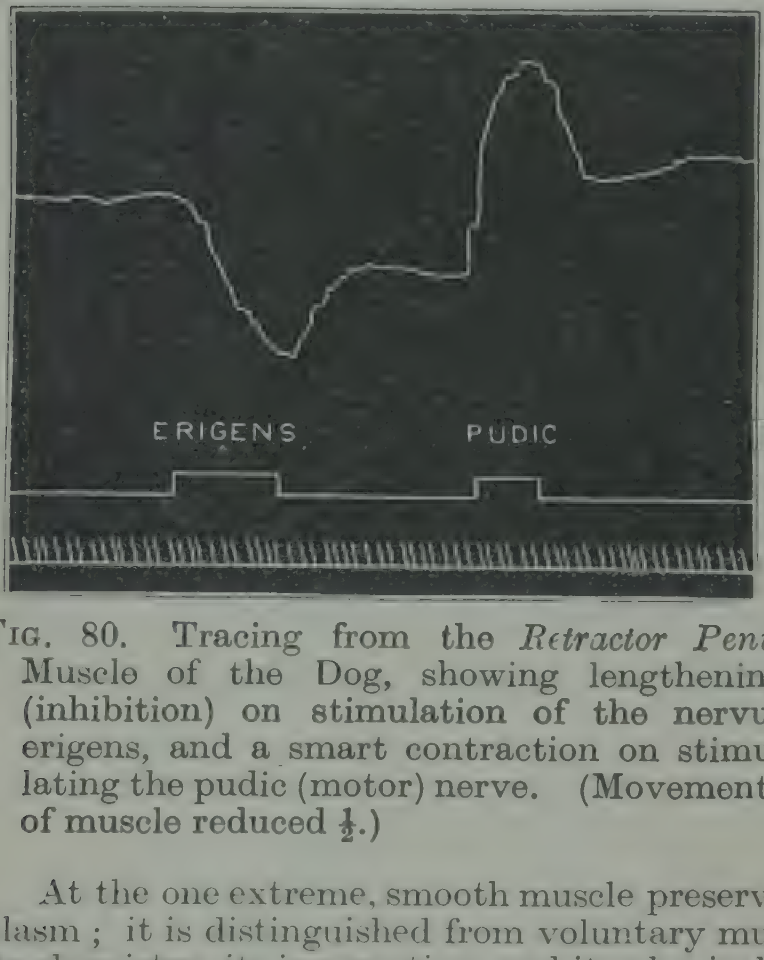

FIG. 80. Tracing from the *Retractor Penis* Muscle of the Dog, showing lengthening (inhibition) on stimulation of the nervus erigens, and a smart contraction on stimulating the pudic (motor) nerve. (Movements of muscle reduced ½.)

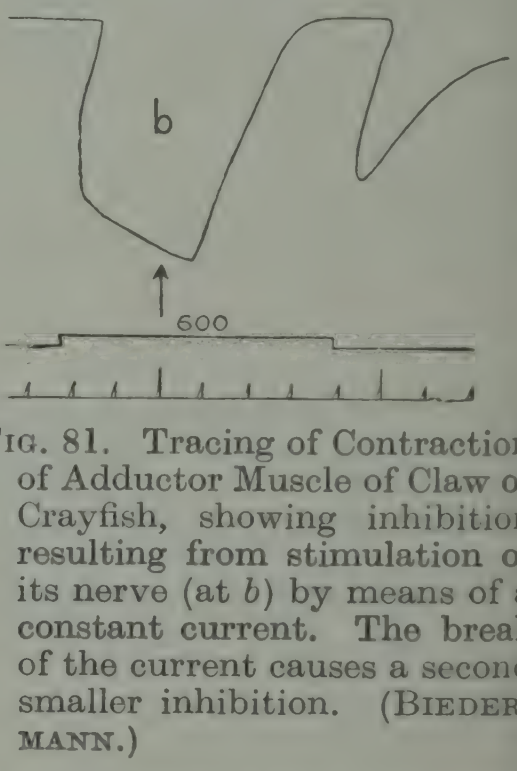

FIG. 81. Tracing of Contraction of Adductor Muscle of Claw of Crayfish, showing inhibition resulting from stimulation of its nerve (at *b*) by means of a constant current. The break of the current causes a second smaller inhibition. (BIEDERMANN.)

At the one extreme, smooth muscle preserves many of the properties of primitive protoplasm; it is distinguished from voluntary muscle not only by its histological structure, in its chemistry, its innervation, and its physical properties, but especially by the phenomena of independent tonus and rhythmic contraction. The nerve supply is often in the form of a nerve net, but is not indispensable for contraction, though capable of causing it and of modifying it. The plain muscle of hollow viscera is of this type. The individual fibres are fusiform cells with an oval centrally placed nucleus; the cytoplasm in the living cell appears to be structureless, and there is a delicate cell wall. The cells are probably connected together by fine intercellular bridges to form a syncytium, by which in all probability the excitatory process can be transmitted from cell to cell, though under conditions which are at present unknown.

---

* The *retractor penis*, found in the dog, cat, horse, hedgehog (but not in rabbit or man), is a thin band of longitudinally arranged unstriated muscle, which is inserted at the attachment of the prepuce and is continued backwards in a sheath of connective tissue to the bulb, where it divides into two slips, which pass on either side of the anus. It is innervated from two sources, the *motor* fibres being derived from the lumbar sympathetic and running to the muscle in the internal pudic nerve, while the *inhibitory* fibres run in the pelvic visceral nerves (*nervi erigentes*) and are derived from the second and third sacral nerve roots. (LANGLEY and ANDERSON. *J. Physiol.*, 1895, **19**, 88.)

The other extreme type, though similar in histological appearance, is under more precise and localised control, through the action of nerves. It does not show, or shows less readily, rhythmic spontaneous contractions. The plain muscle of blood vessels, the *arrectores pilorum*, the nictitating membrane, the intrinsic eye muscles, and the retractor penis belong to this type.

In most smooth muscle, there is a double nerve supply, one variety being motor, and causing contraction, the other kind inhibitory, and causing cessation of a previous contraction. All these fibres belong to the autonomic system, *i.e.* they arise from ganglion cells outside the central nervous system, and only receive impulses from the central nervous system through the intermediation of these ganglia. Usually one supply is sympathetic, and the other parasympathetic, *e.g.* to the intestinal muscle, sympathetic and vagus: their ultimate ramifications in the muscle form a plexus, and are non-medullated, and not infrequently the ganglion cells from which they arise are also contained in the nerve net near to or among the plain muscle cells which they supply. It is believed that both sources of supply are present in the nerve plexus, *e.g.* both vagus and sympathetic fibres are present in the plexus of Auerbach in the intestine.

The physiological significance of the double supply is evident from the fact that, even when deprived of all nerves, plain muscle may exhibit either sustained spontaneous contractions, known as tonic, or else intermittent rhythmic contractions, so that control of both contraction and relaxation is feasible (Fig. 80). In some invertebrates many voluntary striated muscles also possess a double nerve supply, one causing contraction of the relaxed muscle, and one causing relaxation of the contracted muscle (Fig. 81).

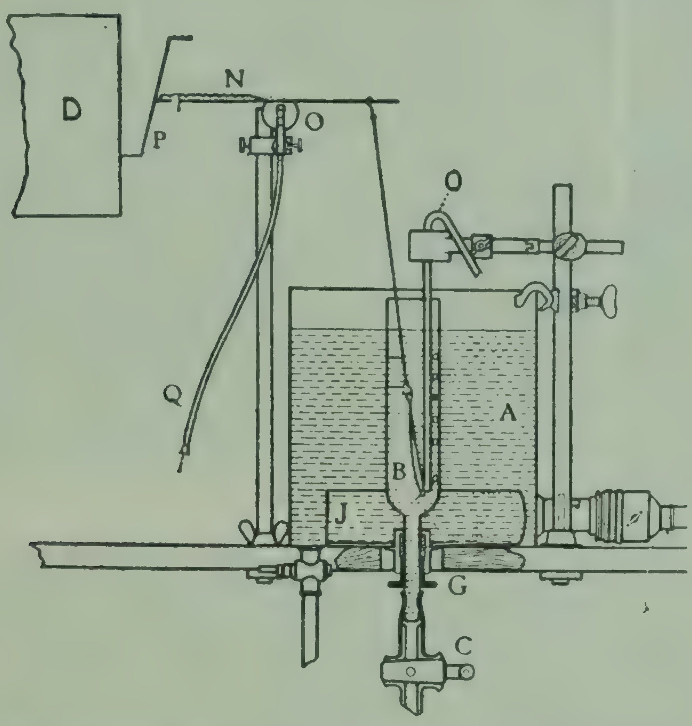

FIG. 82. Thermostat Bath for Investigation of Plain Muscle. A = copper water-bath, kept warm by the lamp J. B = Glass vessel filled with warm saline which can be changed by the tap C. O = the oxygen tube, at the bottom of which is a platinum pin with which the tissue is transfixed. N = a frontal writing lever, to which the tissue is attached by a hair. O, Q = a small brake for fixing the lever while the fluid is changed in B. D = recording drum. (BURN and DALE.)

Physiological Properties. In studying the responses of plain muscle it is not customary, as with amphibian skeletal muscle, to use the moist tissue suspended in air, because under these conditions the tissue behaves irregularly, but, instead, to suspend it in a bath of saline solution of suitable composition, *e.g.* Ringer's fluid, which is kept at the proper temperature and oxygenated with a constant stream of oxygen bubbles. A suitable arrangement is shown in Fig. 82.

TONUS. Plain muscle, isolated in this manner, is very readily extensible, so that when a small weight is applied to it the tissue may extend to several times its former length. The extension is, however, usually very slow, as though the cell contents were extremely viscous; also, the amount of lengthening finally produced by a weight will depend on the degree of *tonus* which the preparation has, and this varies with the source.* Thus the cat's uterus is highly tonic and requires a much larger weight to stretch it than does a guinea-pig's uterus of the same size. Many drugs have the property of affecting the

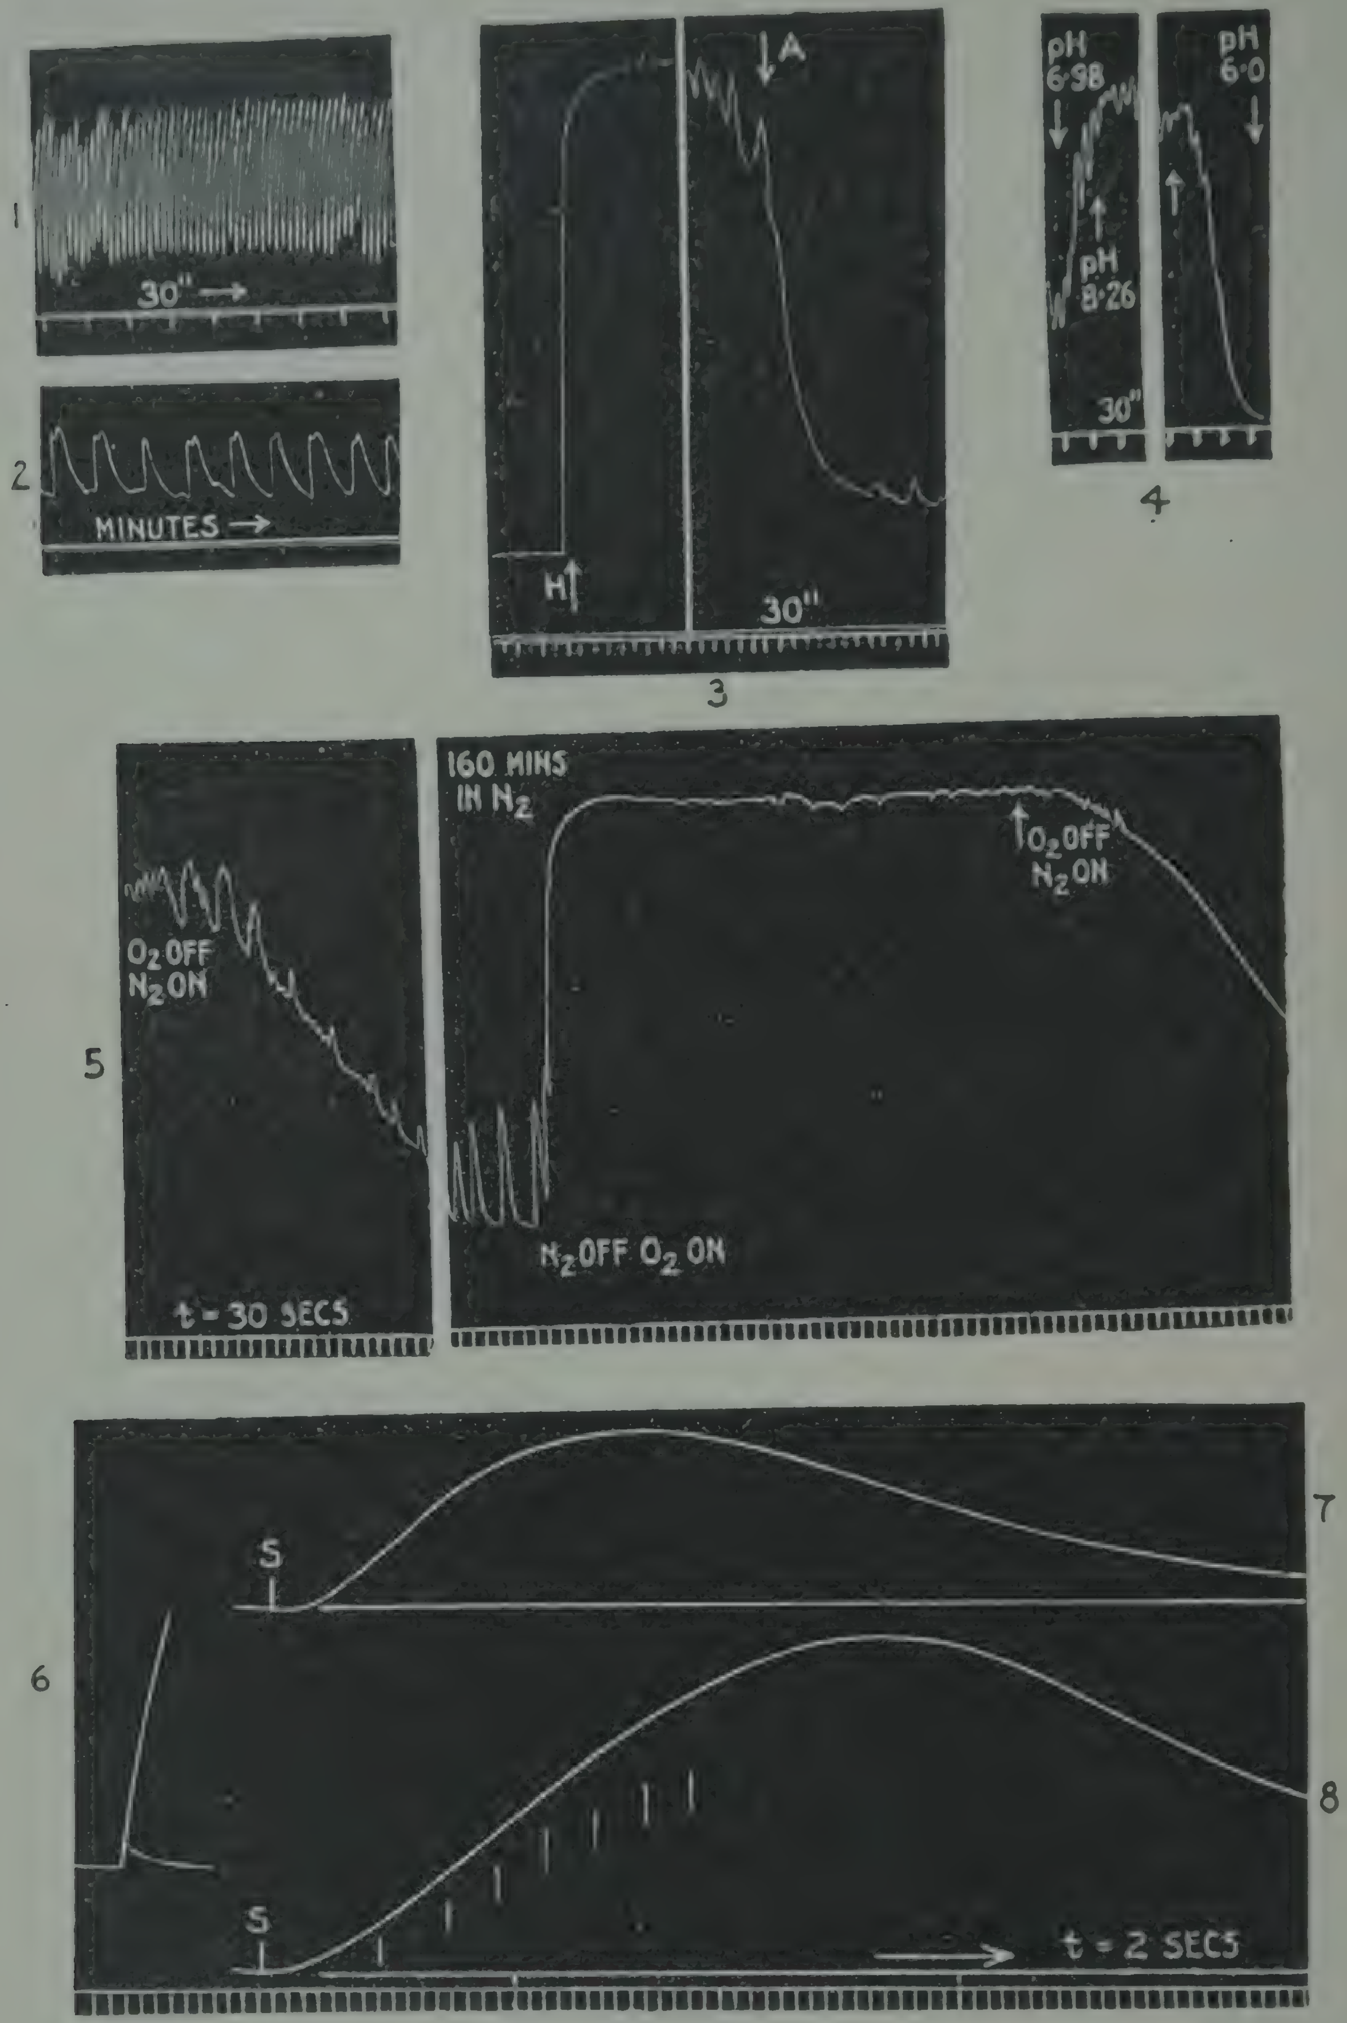

FIG. 83. 1. Isolated jejunum of rabbit, showing rhythmic contractions. Time tracing = 30 seconds.

2. Slow rhythmic contractions of guinea-pig uterus. (Time = minutes.)

3. Guinea-pig uterus. At H, histamine 1 in 1 million; at A, adrenaline, 1 in 4 million. Time = 30 seconds.

4. Small intestine of cat, showing contraction on raising, and relaxation on lowering the *p*H of the fluid in the bath. Time = 30 seconds; *p*H measurements taken at arrow. (EVANS and UNDERHILL.)

5. Uterus of cat, showing effect of oxygen lack caused by replacing oxygen bubbles by nitrogen. The second portion is taken after about two and a half hours in nitrogen.

6. On left, contraction of frog's gastrocnemius to compare with contraction of frog's stomach (7) on same slow drum. Point of stimulation = S. 8. Summation of contraction in frog's stomach. The first stimulus is followed by seven others at the points shown.

tonus of plain muscle, perhaps by causing polarisation changes at the surface of the cells. Thus adrenaline will cause the uterus to relax (if tonic), while acetyl choline even in high dilutions (*e.g.* 1 part in 10 million of saline) or histamine causes intense tonic contraction (Fig. 83, 3). Adrenaline in many other respects reproduces the action of the sympathetic nerves, and is therefore called *sympathicomimetic*, while acetyl choline reproduces the action of the parasympathetic nerve supply.

The maintenance of the sustained tonus is apparently not associated with increased expenditure of energy,[*] for the tissue, while in this condition, uses no more oxygen than when in the relaxed state, even though it may be exerting quite considerable tension; consequently no signs of fatigue are manifested.

Thus in the bivalve mollusc Pecten, there is a large striated adductor muscle which can close the shell rapidly but then relaxes, and a smaller smooth muscle whose office it is to hold the two valves together. The weight required to separate the valves, when this latter muscle is contracted, is many times that which will prevent the closure of the shell when open. Thus the smooth adductor muscle can support a weight which it cannot raise. This "catch action" is under the control of the central nervous system by two nerves from the cerebral ganglion. Stimulation of one of these causes contraction, and the muscle remains contracted even after the nerve is divided. Stimulation of the other nerve causes the muscle to relax. Apparently the action of these nerves is to allow the length of the muscle to alter, and it then remains at that length until the other nerve is stimulated. Somewhat similar phenomena may be observed in the smooth muscle of higher animals, and it may be that most smooth muscles are capable of two kinds of shortening, one followed by passive relaxation and the other by fixation at a diminished length without the expenditure of extra energy.

Although plain muscle can execute contractions for some time after being completely deprived of oxygen, and although, when in the tonic state, the muscle uses no more oxygen than when it is relaxed, yet the presence of oxygen is essential for the maintenance of tonus (Fig. 83, 5). It would seem as though oxygen, though not essential for the act of shortening, plays some part in maintaining the integrity of the cell structures which are concerned in fixing the tissue at the shorter length. (Garry.)[†]

Rhythmic Contractions. Many varieties of plain muscle when slightly stretched normally exhibit rhythmic contractions at fairly regular intervals, both in the body and when isolated. The strength and frequency of these rhythmic contractions vary very much according to conditions; in some types of plain muscle, *e.g.* that of the small intestine, they are regular, frequent and powerful (Fig. 83, 1), whereas in other cases they are slow (Fig. 83, 2), often irregular, and of variable amplitude, being occasionally negligible.

There is strong evidence that they originate in the plain muscle cells themselves, *i.e.* they are myogenic; for example, the cells in the chick amnion, which are devoid of nerves, show these rhythmic contractions[‡]; further, strips of the inner muscular coat of the small intestine, also free from nerve structures, were found[§] to exhibit rhythmic contractions.

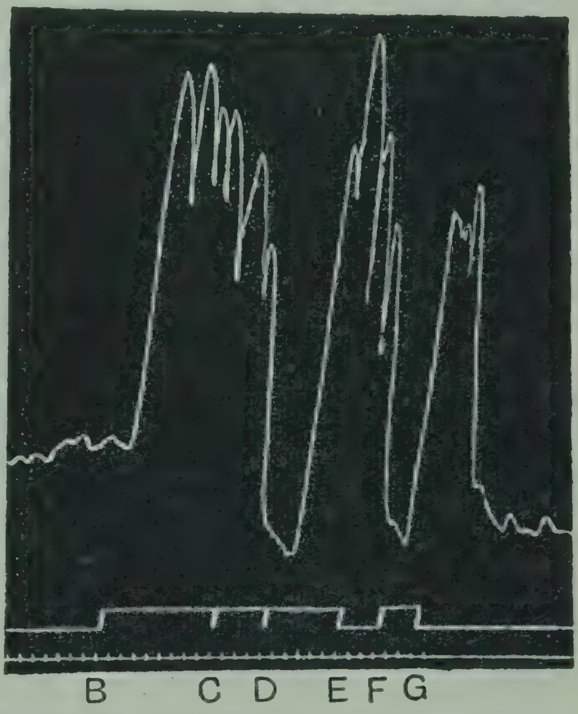

Fig. 84. Double-nerve preparation of cat stomach fundus. The vagus supply was stimulated (faradic) from B to E. At CD stimulation of sympathetic supply also, 12 shocks per sec., causing relaxation. The same stimuli to sympathetic alone at FG. (McSwiney and Robson.)

Stimulation. Smooth muscle responds to very various stimuli—electrical, mechanical, thermal, light, chemical, etc. As we should expect, however, from the sluggish response of this kind of contractile tissue (high chronaxie), the optimum rate of change of current which excites is very much slower than in the case of

[*] Lovatt Evans. *J. Physiol.*, 1923, **58**, 22.

[†] Garry. *J. Physiol.*, 1928, **66**, 235.

[‡] Ferguson. *Amer. J. Physiol.*, 1940, **131**, 524.

[§] Gunn and Underhill. *Quart. J. Exp. Physiol.*, 1914, **8**, 275.

striated muscle. Thus in many instances a single induction shock is powerless to excite contraction. A better stimulus is the make of a constant current.

Nerve-muscle preparations of mammalian plain muscle (stomach) with either or both of the nerves may be made.* Stimulation of the sympathetic supply with slow shocks usually caused contraction ; with more rapid stimuli relaxation. Stimulation of the vagus supply caused contraction. When sympathetic stimulation was applied during contraction due to vagal stimulation, the muscle relaxed, though the same stimulus to the sympathetic alone caused contraction (Fig. 84).

The contraction curve of plain muscle, though very variable, is much slower than that of voluntary muscle, and the phenomena of latent period, shortening, and relaxation can easily be followed with the eye. The latent period may be from 0·2 to one or two seconds, and the period of contraction from half a second to a few minutes, with proportional durations of relaxation (Fig. 83, 7) ; the stronger the stimulus the shorter the latent period and the higher the contraction.

As in voluntary muscle, if one stimulus follows another at a sufficiently short interval, we may have an increased liberation of energy due to repetition of the stimulus during the rise of the excitatory condition (*summation of contractions*) (Fig. 83, 8). As might be expected the refractory period is also longer in involuntary muscle.

In all involuntary muscle we may observe summation of the effects of stimuli, when each individual stimulus is insufficient to produce any excitation. Thus we may find a strength of induction shock which, applied singly, is just insufficient to evoke any response. If, however, the shocks are repeated at intervals of a second, it will be found that the first three or four stimuli are ineffective, and then the muscle enters into a contraction which increases with each succeeding stimulus until it has attained its maximum. There is thus *latent addition* of excitation. Each stimulus, in fact, alters the state of the contractile tissue and makes it more ready to respond to the next stimulus.

Latent addition is a general phenomenon of excitation, but appears to be of special importance in plain muscle. A plain muscle fibre may receive several nerve fibres and may only respond after the effects of several nerve impulses have been summated.†

It has been shown ‡ § that, as with other forms of muscle, the tension developed on contraction by plain muscle increases with increase of initial length, a very important property in view of the common occurrence of plain muscle in the walls of hollow viscera, where it is subjected to various degrees of extension.

Chemical Stimulation. The tissue is very sensitive to alterations in the hydrogen ion concentration ; within limits, lowering of H-ion causes contraction or tonus, with increased rate of rhythmic contractions, while‖ increase causes the reverse (Fig. 83, 4). Many drugs, such as eserine, salts of lead and barium, histamine, acetyl choline, pilocarpine, may cause contraction. As one would expect, however, from the greater independence of the smooth muscle, the action of these drugs varies from organ to organ, muscle fibres apparently histologically identical reacting diversely according to their origin. Some drugs, *e.g.* barium salts and perhaps pituitrin, appear to act directly on the muscle cells, while others may exert their action on the accompanying nerves or their endings. Adrenaline and acetyl choline in general evoke the same effects as stimulation of sympathetic or parasympathetic nerves respectively.

The question arises whether nervous stimulation may not produce its effects by the liberation of active chemical substances at the nerve terminations, or in the nerve network.

‖ Lovatt Evans and Underhill. *J. Physiol.*, 1923, **58**, 1 ; McSwiney and Newton. *J. Physiol.*, 1927, **63**, 51.

Extracts of plain muscle certainly contain substances which can cause other plain muscle to contract,* and the active constituent in some extracts is probably acetyl choline.† It has been shown also that when plain muscle is made to contract by stimulation of nerve, substances are set free which can cause other plain muscle to contract. The action of these substances, like that of acetyl choline, is enhanced by eserine and counteracted by atropine.

Similar relations have been found by Finkleman ‡ and by Cannon and his associates § for sympathetic stimulation. When the sympathetic supply to almost any plain muscle is stimulated an adrenaline-like substance which Cannon has called "sympathin" is liberated and may enter the blood stream, in which case it causes acceleration of the denervated heart and other manifestations of sympathetic activity.

Mechanical Stimulation. Smooth muscle is very sensitive to mechanical stimuli, and may respond by a local or a general (propagated) contraction. One form of mechanical stimulation is that produced by tension. The effect of increasing the tension on smooth muscle may be twofold: in the first place extension and in the second excitation with increased contraction. These two effects are illustrated in the bladder. If this has all its connections with the central nervous system severed, it is when empty in a state of tonic contraction. If fluid be injected into it rapidly, there is a great rise of pressure in its cavity due to the forcible distension. If, however, the fluid be injected slowly, the bladder muscle relaxes to make room for it, so that a considerable amount of fluid may be accommodated in the bladder without any great rise of pressure. If the injection of fluid be continued, the walls begin to be stretched passively, and this increased tension acts as a stimulus causing rhythmic contractions of the whole bladder.

A peculiar property of plain muscle is that a stimulus (*e.g.* electrical or mechanical) which, when applied to the relaxed muscle, causes a contraction, will, when applied to the tonically contracted muscle, often provoke a rapid relaxation, and *vice versa*. The same even holds true in some instances for the effects of stimuli applied to the nerves supplying plain muscle. This property is perhaps responsible for the occurrence of rhythmic contractions when the muscle is given the constant stimulus of a slight stretch; this alternately excites the extended muscle to contract and the contracted muscle to relax.

ELECTRICAL POTENTIAL CHANGES. The visceral plain muscle, which is practically a syncytium, shows spontaneous contractions, and these are preceded by propagated potential changes, which are usually proportional to the power of the contraction, *i.e.* to the number of cells involved simultaneously. In tonic contractions there may be no propagated potentials, because the fibres are contracting asynchronously.

When the tissue responds to nerve impulses, the potential changes are complex and, owing to the smallness of the units, difficult to interpret. The nictitating membrane of the cat ‖ responds by contraction when the cervical sympathetic is stimulated. A volley too small to give a contraction may nevertheless yield an electrical response, the N-wave, of units subliminally excited, and while this lasts spatial facilitation can be obtained, as is the case with striated muscle and with nerve. A stronger stimulus, which means that stimuli from more nerve fibres impinge on each of the plain muscle cells, gives, after a shorter latent period (about 10 msec.) a complex of up to three negative waves, N, A, B, followed by a positive wave (Fig. 85). The contraction begins after the potential waves; the latent period of contraction is shorter the more powerful the stimulus to the nerve, but is usually about 150 msec. The A and B waves are diphasic, propagated, and are followed by a refractory period of about 50 msec. They are due to all-or-none response of a number of units. The A wave is not seen in weak contractions, but in strong ones tends to replace the B one, which has a longer latent period.

When a volley is increased beyond a certain point, so that a contraction of some power results, there is a series of repetitive waves (R in Fig. 85) following the initial complex and at intervals of $\frac{1}{3}$ to $1\frac{1}{2}$ seconds. Since the injection of adrenaline gives rise to similar repetitive waves, it is concluded that the R waves following a volley of nerve impulses are likewise due to the action of an adrenaline-like excitant liberated at the nerve terminals.

A second volley of wave impulses causes summation of contractions, and if it falls after the refractory period of the muscle this is easily understood. But it also may cause summation when it follows the first stimulus by a much shorter interval; the summation in this case is accompanied by R waves and is explained as due to the action of the second volley liberating adrenaline, although not directly exciting the muscle cells.

‖ ECCLES and MAGLADERY. *J. Physiol.*, 1937, **90,** 31, 68.

Propagation of the Excitatory State, or Wave of Contraction. In voluntary muscle there is no propagation from muscle fibre to muscle fibre, a contraction of the whole muscle being possible only when there is simultaneous excitation of all its fibres. This isolation of the excitatory state is not so evident in plain muscle. Frequently a stimulus applied to any part of a sheet of plain fibres may travel all over the sheet just as if it were a single fibre. Indeed there is protoplasmic continuity by means of fine bridge-like processes between adjacent cells in some varieties of plain muscle, such as in those occurring in the hollow viscera, and such tissues could act as syncytia.

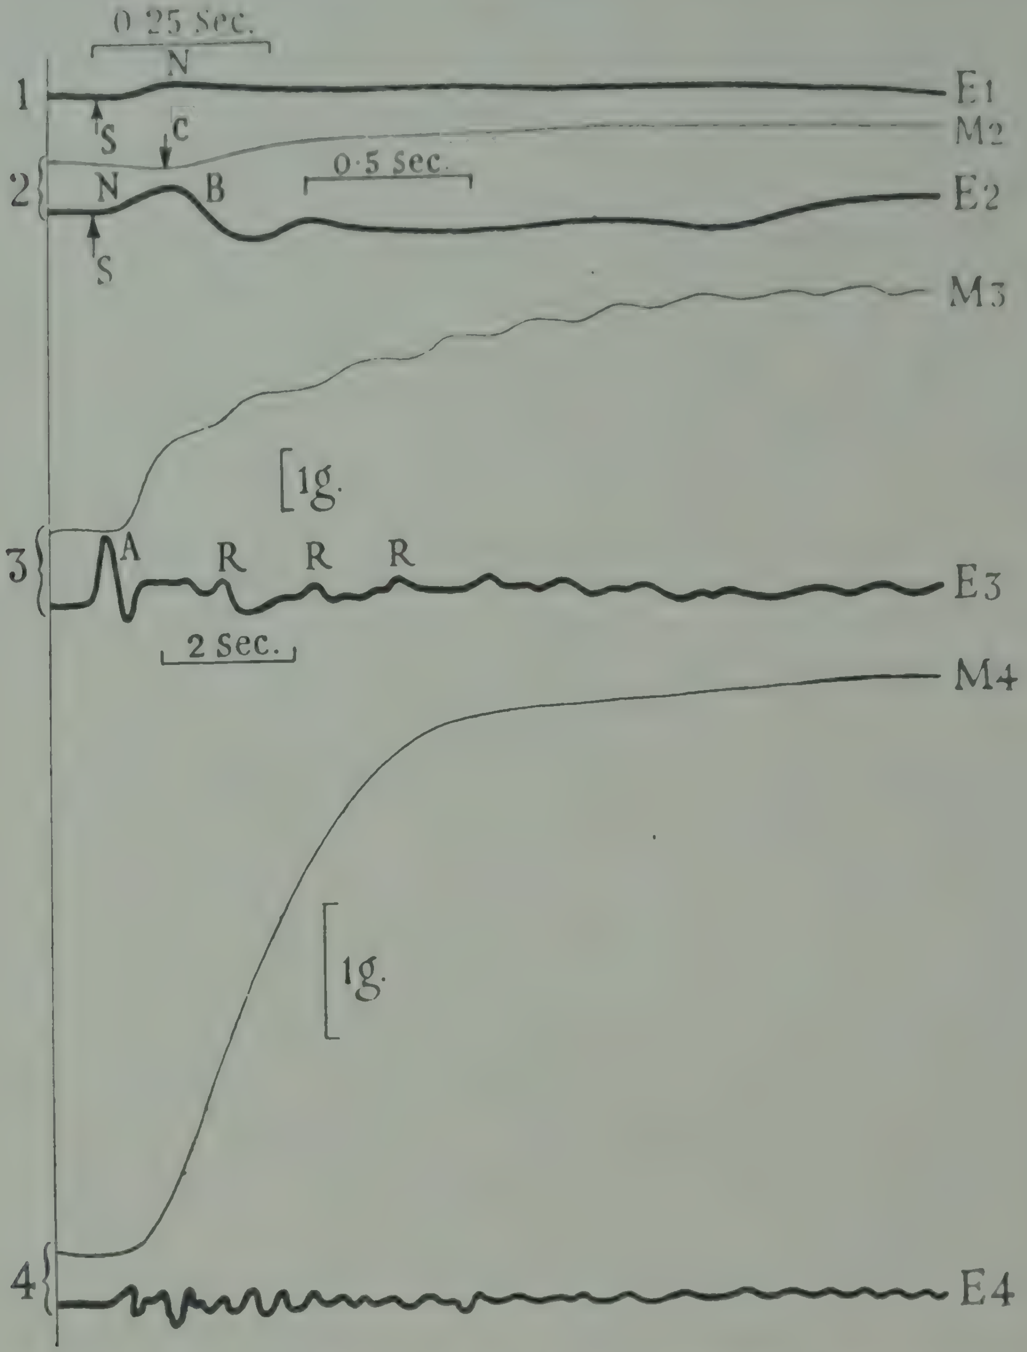

Fig. 85. Electrical potentials E (upward = negativity of attached border), and mechanical record of contraction, M (no contraction in 1), of nictitating membrane of cat resulting from stimulation of cervical sympathetic with stimuli of increasing strength from 1, to 3, and at 4 from injection of 50μg. of adrenaline into the circulation. S, stimulus ; C, commencement of contraction : N, A, B, initial potential changes : R, rhythmic waves. (Eccles and Magladery, *J. Physiol.*, 1937, **90**, 31, 68.)

It is claimed that each fibre of smooth muscle gives an all-or-none response to a stimulus.* Probably the contraction curve as commonly recorded represents the simultaneous or the successive action of the component cells, and a feeble contraction is probably due to the all-or-none response of only a few of them. It is certain, for instance, that feeble stimuli may produce only local contraction, especially in fatigued tissue and in those forms of plain muscle more directly under nerve control, and perhaps not possessing cell bridges. Thus, in the retractor penis of the dog, we get graded contractions from graded stimuli, and it is noticeable that with increasing strength of stimulus a greater extent of muscle enters into contraction.

It must be remembered that in most unstriated muscle the fibres are surrounded by a network of non-medullated nerve fibres. Some physiologists are inclined to ascribe to these fibres an important part in the propagation of the contraction wave.

---

* Fletcher. *J. Physiol.*, 1938, **91**, 172.

Influence of Temperature. Plain muscle is extremely susceptible to changes of temperature; as a rule, warming causes relaxation, while application of cold causes a tonic contraction. The condition of the muscle at any given time depends not only on its actual temperature, but also on the rapidity with which that temperature has been reached. Thus a rapid cooling of the retractor penis muscle of a dog from 35° to 25° may cause a contraction as extensive as would be produced by a slow cooling to 5° C. On warming plain muscle from 30° to 50° C. it lengthens gradually up to about 40°, and it may then undergo a marked heat contraction (varying in degree in different muscles) at about 50° C., which may pass off at a somewhat higher temperature. It is first paralysed and then killed somewhere between 40° and 50° C.* It seems very doubtful whether any true rigor mortis occurs in smooth muscle. The hard contracted appearance of the smooth muscle in a recently dead animal is chiefly conditioned by the fall of temperature. On excising the muscle and warming it up to body temperature it may again relax and show signs of excitability two or three days after the death of the animal.

The Chemistry of Contraction in plain muscle, so far as it has been studied, is very similar to that in striated muscle.† The most striking differences in chemical composition between striated and plain muscle are that the latter contains much less soluble protein, only very small quantities of creatine (and phosphagen), smaller amounts of glycogen, less potassium and phosphate and more sodium than the former. In the mussel, *mytilus*, arginine phosphate, the phosphagen of invertebrates, is broken down after prolonged stimuli and restored by recovery. Glycogen disappears and lactic acid arises when the muscle contracts, or when it is asphyxiated or treated with arsenates. The action of caffeine is, however, different, for this retards lactic acid formation in plain muscle. During recovery from contraction lactic acid is removed and glycogen restored. The amounts of lactic acid produced and of glycogen removed in contraction are relatively small, as would be expected in view of the small amount of energy it yields.

AMŒBOID MOVEMENT

Amœboid movement is seen in the unicellular organisms such as the amœba and in the polymorphonuclear blood corpuscles. It can occur only within certain limits of temperature (about 0° to 40° C.); within these limits it is the more active the higher the temperature. At about 45° the cell goes into a condition resembling heat rigor.

The fluid in which the corpuscles are suspended is of great importance. Distilled water, almost all salts, acids and alkalies, if strong enough, stop the action and kill the cell.

The movements are also arrested by CO_2 or by absence of oxygen.

Artificial excitation, whether electrical, chemical or thermal, causes withdrawal of the pseudopodia and contraction of the corpuscle, which therefore assumes the spherical form. Electrical stimulation also causes (*e.g.* in *Amœba*) a sudden gelation of the cytoplasm, which sets quite suddenly; ‡ after the stimulus is over, the fluid state returns.

CILIARY MOVEMENT

Cilia are met with in man in nearly the whole of the respiratory passages and the cavities opening into them, in the generative organs, in the Fallopian tubes of the female and the epididymis of the male, and on the ependyma of the central canal of the spinal cord and its continuation into the cerebral ventricles.

The cilia are delicate tapering filaments which project from the hyaline border of the epithelial cells. There may be twenty or thirty to each cell. The hyaline border is really made up of the enlarged basal portions of the cilia and seems to consist of a row of multiple centrioles.

The trachea of a mammal slit open along the back and pinned out under warm oxygenated Ringer's solution forms a suitable object for demonstrating ciliary action. If a drop of graphite suspension be placed on the mucous membrane, it will be seen to become entangled in mucus and pushed towards the upper end of the trachea at the rate of 1 to 2 cm. per minute. By this means any dust particles trapped on the ciliated surfaces of the respiratory tract are swept upwards to the mouth.

In action the cilia bend suddenly down into a hook or sickle form, and then return slowly to the erect position. This movement is repeated many (twelve to twenty) times a second, and thus serves to move forward mucus, dust or an ovum, as the case may be.

---

* Lovatt Evans. *J. Physiol.*, 1921, **54**, Proc. cxxxix.
† Lovatt Evans. *Biochem. J.*, 1925, **19**, 1115; 1926, **20**, 893.
‡ Bayliss. *Proc. Roy. Soc.*, 1919, **91B**, 196.

During the rapid, or effective, phase the cilium appears to be rigid, while during the slower return phase it is limp. No structure is demonstrable within the cilium to account for its power of movement. The minuteness of the object has up to now prevented us from deciding whether the cilium is itself actively motile, but the somewhat similar flagellum of certain unicellular organisms does seem to generate at least part of its own energy, irrespective of the attached cell.* An attractive suggestion, due to Gray, is that the movement may be due to a rhythmic alteration in the distribution of water in the cilium ; for example, a transference of water to one side would cause that side to swell, and so, like paper wetted on one surface, to bend over. The movement is apparently dependent upon connection of the cilia with their basal granules, since when the ciliated hem is stripped away, movement ceases at once.

There seems to be a functional connection between all the cells of a ciliated epithelial surface. The action is passed from cell to cell and from cilium to cilium, in succession. When looked at from above, a series of waves (*metachronal waves*) are seen to pass in regular sequence, over the ciliated surface, just as, when the wind blows, waves of bending pass over a field of corn.

Ciliary movement is not dependent upon nervous action, though in some instances it can be accelerated or inhibited through the action of nerves. Thus Seo claims that the rate of ciliary movement in the palate of the frog is accelerated by stimulation of appropriate nerves which are distributed to the palate and form a nerve-net. By the use of a " nerve-cilia " preparation consisting of the palate and palatine nerve, he finds that the velocity with which red blood cells can be swept along the ciliated surface is accelerated 7–20 times by stimulation of the nerve. This acceleration is due to more rapid metachronal waves, greater speed of effective phase and greater amplitude of movement of cilia. Normally he claims that the regulation of ciliary action is a reflex confined to the same side of the palate as the stimuli.

The conditions of ciliary action are the same as those for amœboid movement of naked cells. Acids or excess of calcium ions slow, and alkalies or potassium ions hasten, the rate of action. Rise of temperature, within limits, hastens, and cold slows, the rate, but over most of these ranges the amplitude of the movement is constant. Oxygen is utilised at a rate proportional to the rate of ciliary action, and though ciliary action will persist for a time in its absence, the movement ultimately fails if it is withheld (Gray).

CHAPTER XII

NERVE FIBRES

THE STRUCTURE OF NERVE FIBRES

A STIMULATION of the nerve of a nerve-muscle preparation is followed after a very short interval by a contraction of the muscle. This observation illustrates the two functions of nerve fibres, excitability and conductivity—that is to say, a suitable stimulus can set up in any part of the nerve a disturbance which is propagated along the nerve without any visible effects occurring in it; and it is not until this *nervous impulse* has reached the muscle that a visible effect is observed in the shape of a contraction. In the animal body a direct excitation of the nerve fibre in its course never takes place normally. The only function

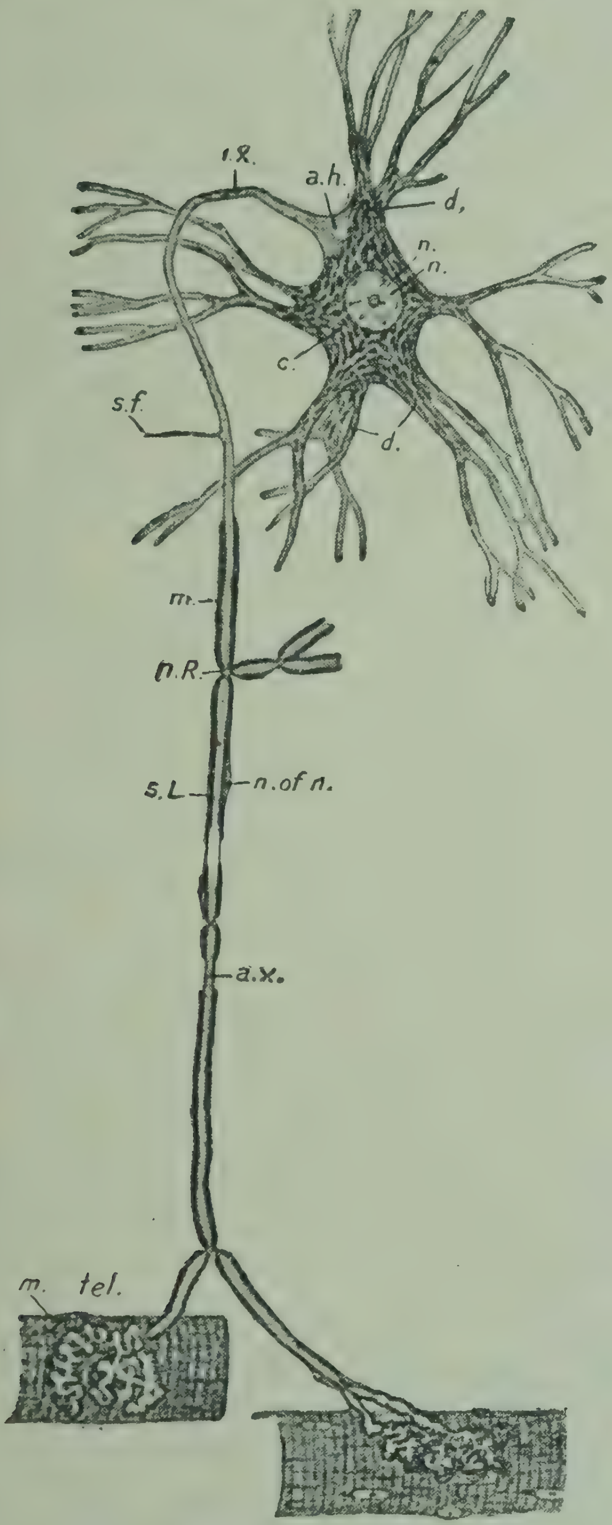

FIG. 86. Diagram of a Motor Nerve Cell with its Nerve Fibre and two motor-endplates. (After BARKER.) *a.h.* axon hillock; *d*, dendrites; *a.x*, axis cylinder; *m*, medullary sheath; *n.R*, node of Ranvier.

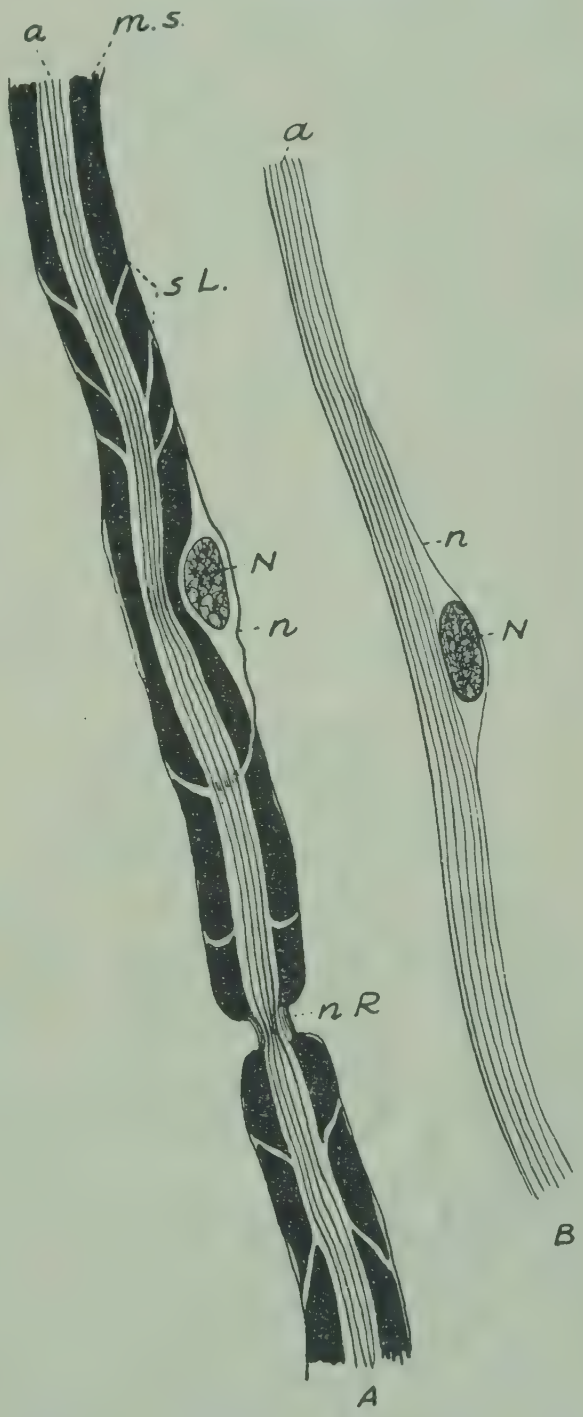

FIG. 87. A, portion of a medullated nerve fibre. *a*, the axis-cylinder, containing neurofibrils *m.s.*, the medullary sheath; *n*, the neurolemma; N, a nucleus; *n*.R, a node of Ranvier; *s*.L, segments of Lantermann (artefacts); B, portion of a non-medullated fibre. Lettering as for A.

the nerve fibre has to perform is that of conducting impulses, either afferent ones from the sense organs at the periphery to the central nervous system, or efferent impulses from this to the muscles or other effector organs. Hence it is essential that there should be continuity along the whole length of the fibre. Damage to any part, such as by crushing or heat, or cooling, causes a block to the passage of an impulse.

A nerve fibre is essentially a long process of a nerve cell (Fig. 86). The cell is in the higher animals usually withdrawn from the surface into a special collection of cells such as the posterior root ganglion, or may be one of the mass of cells and fibres making up the central nervous system. All nerves are alike in possessing as their conducting part the continuous strand of protoplasm produced from the nerve cell and known as the *axon* or *axis cylinder*, carried in a delicate tubular sheath, the *axolemma*. In the fresh condition the axon appears to be a homogeneous fluid, though after fixation special staining methods bring out the presence of *fibrillæ* or *neurofibrils*, embedded in a clear material, the *axoplasm* (Fig. 87). There is a difference of opinion as to the existence of neurofibrils in the living nerve fibre. In the giant nerve fibres of Cephalopods, which may reach 1 mm. in diameter, the contents are fluid and run out when the fibre is cut across.* But micro-dissection of living nerve fibres in other invertebrates and also in vertebrates shows the contents of the axis cylinder to be gelatinous and to contain neurofibrils as tough threads.† It is conceivable that gelation results from the manipulations. Claims have been made that there is normally a continuous flow of axoplasm from the cell body along the axon.

The electron microscope shows ‡ a new and characteristic structure consisting of long, thin fibres (200–1,000 A. diam.) with dense edges and a less dense axis, and which show periodic cross-bandings; they appear to be tubular and are called "neurotubules."

In the course of growth the nerves develop certain histological differences, which appear to bear some relation to the character of their parent cell. Thus many, or, all the fibres which are given off from and which enter the central nervous system, *i.e.* the brain and spinal cord, belong to the class known as *medullated*. In this type the axon is surrounded with a layer of material known as *myelin*, forming the *medullary sheath*. This sheath consists of a fatty material composed largely of lecithin, and staining black with osmic acid. Study of the optical properties of the myelin shows that the lipoid molecules are oriented radially to the axon, in concentric shells two molecules thick, and with protein between the successive double layers. The myelin is supported in the interstices of a network formed of a horny substance known as *neurokeratin*. The medullary sheath is surrounded by a structureless membrane, the primitive sheath or *neurolemma*. At regular intervals a break occurs in the medullary sheath, the neurolemma coming in close contact with the axis cylinder which is constricted at that place. This break is the *node of Ranvier*, the intervening portions of medullated nerve being the *internodes*. In each internode, lying closely under the neurolemma, is an oval nucleus. The medullated nerve fibres vary considerably in diameter, the largest fibres being distributed to the muscles and skin, the smallest carrying impulses from the central nervous system to the viscera (Fig. 88). The latter all come to an end in some collection of ganglion cells of the sympathetic chain or peripheral ganglia, the impulses being carried on to their destination by a fresh relay of non-medullated nerve fibres.

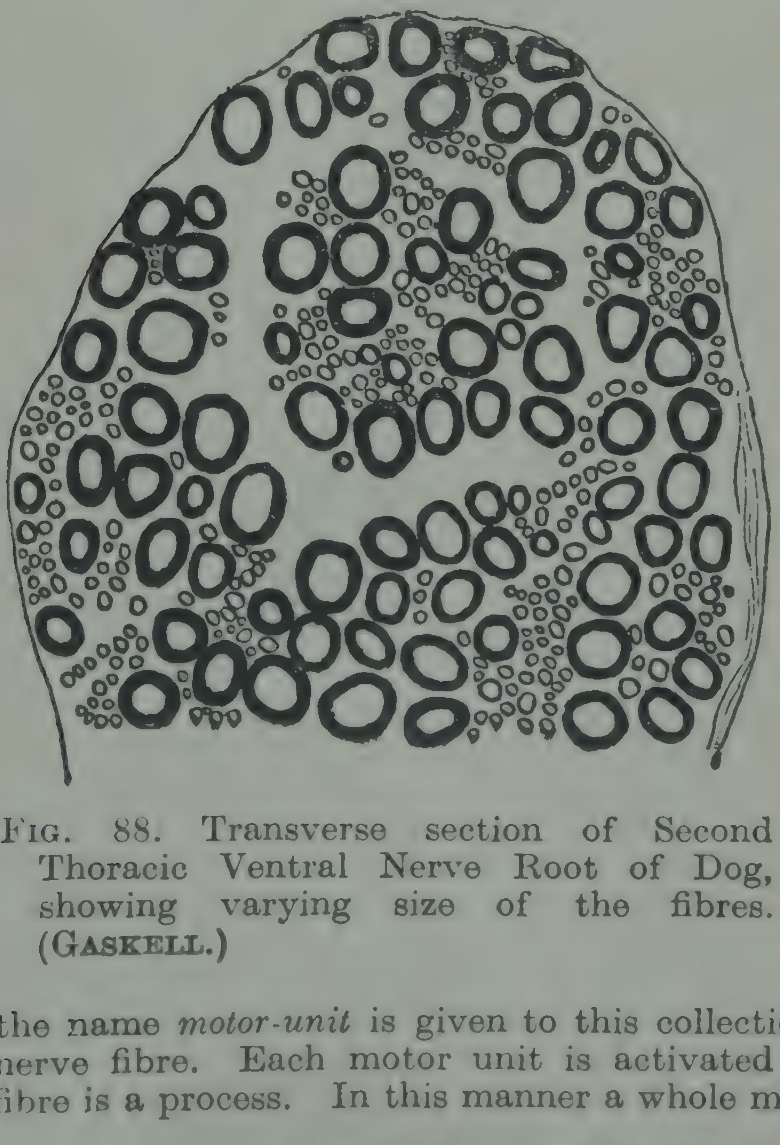

FIG. 88. Transverse section of Second Thoracic Ventral Nerve Root of Dog, showing varying size of the fibres. (GASKELL.)

The medullated nerves are bound together by connective tissue (*endoneurium*) into small bundles, which are again united by tougher connective tissue into larger nerve trunks. The fibres as a rule branch only when in close proximity to their destination, and then the branching always occurs at a node of Ranvier. The number of branches may be large; thus each motor fibre which arises from a motor cell may supply as many as 150 muscle fibres, and the name *motor-unit* is given to this collection of muscle fibres, together with its motor nerve fibre. Each motor unit is activated by one nerve cell, from which the motor fibre is a process. In this manner a whole muscle may be under the control of relatively few motor nerve cells and motor nerve fibres—*e.g.* the soleus of the cat has 30,000 muscle fibres grouped into 230 motor-units, *i.e.* its motor nerve contains only 230 fibres.

† DE RENYI. *J. Comp. Neurol.*, 1929, **48**, 441.

‡ DE ROBERTS and SCHMITT. *J. Cell. and Comp. Physiol.*, 1948, **31**, 1.

The blood supply to nerve trunks is small, but abundant for their needs, and indispensable for their functions.*

The *non-medullated fibres* (Fig. 87B) differ from the medullated simply in the absence of a medullary sheath. They possess a neurolemma, under which we find nuclei lying closely on the side of the fibre and bulging out the sheath. In their ultimate ramifications they tend to form close networks or plexuses and appear to lose the last traces of a sheath.

As to the functions of the myelin sheath in the medullated nerve fibre, very little is known. It does not make its appearance until the axis cylinder is formed, and is apparently derived from a series of cells which grow out from the spongioblasts of the central nervous system and form a chain surrounding the out-growing axons. In the regeneration of a nerve fibre after section, the myelin sheath appears later than the axon in the peripheral part of the nerve. It has been supposed to act as a sort of insulator ensuring isolated conduction within any given nerve fibre.

The Degeneration of Nerve Fibres. When an axon is severed, either by actual division, or functionally by localised damage by chemical or physical means, and so cut off from the cell upon which its life depends, the part so cut off undergoes rapid degenerative changes. For a few millimetres on either side of the cut there are acute changes known as *traumatic degeneration.* But the peripheral portion also shows, simultaneously along its whole length,† the changes of secondary or *Wallerian degeneration*, which commence in the first hour and progress to complete degeneration in a few days ; loss of excitability to stimuli is complete after three days. The central portion of the fibre does not undergo secondary degeneration, though it may atrophy later on (retrograde degeneration) as may the cell body, if no fibre regeneration takes place.

The structural changes during degeneration are initiated by the appearance of swellings and fusion in the neurofibrils and shortly afterwards the axis cylinder breaks up irregularly into short lengths. The myelin sheath, in medullated nerves, breaks up into irregular droplets and undergoes chemical changes, among which is the liberation of highly unsaturated fatty acids. In consequence of this the degenerating medullated nerve fibres are stained black when treated with Marchi's method, a fact of great importance for mapping out the tracts of the central nervous system. Meanwhile the cells of the neurolemma rapidly proliferate. Lastly, the proliferated neurolemma cells, together with histiocytes of the surrounding connective tissue, digest and absorb the remnants of the axis cylinder and myelin sheath, so that all that ultimately remains of the fibre is a thin thread consisting of modified neurolemma cells. The specialised terminal nervous structures in motor end-plates, sensory endings, etc., also undergo degeneration, but the protoplasm of the end-plates persists for months.

Regeneration of Nerve Fibres. Some time after section and degeneration, a process of regeneration may occur in certain nerves. The process occurs by the formation of outgrowths of neurofibrils from the undegenerated stumps which remain connected to their cells. These outgrowths have bulbous ends, and sprout down, probably by some sort of chemiotactic process, into the neurolemmal remains of the degenerated fibre, growing at a rate of about 1·5 mm. to 4 per day.‡ At the same time, if there is a gap, the cells of the old neurolemma proliferate and grow up until they establish continuity with the neurolemma of the fibres in the normal stump. The presence of the old track, preserved by the neurolemma cells, appears to be indispensable for the proper guidance of the growing axons. Hence, if the gap is great, the bulbous ends of the axons grope about in the tissues, and end by forming a tangled mass, or neuroma. Because of the necessity for the neurolemma also, regeneration never takes place in those fibres of the nervous system that have no neurolemma, *e.g.*, in the white matter of the central nervous system, the optic nerve, or the sensory root of the Vth cranial nerve.

* Bentley and Schlapp. *J. Physiol.*, 1943, **102**, 62.

† Sugar. *J. Neurophysiol.*, 1938, **1**, 7.

‡ Seddon *et al.* *J. Physiol.*, 1943, **102**, 191 ; Young. *Physiol. Rev.*, 1942, **22**, 318.

After the establishment of contact of the growing ends of the fibres with the old neurolemma tracks, growth steadily proceeds along these until, the terminations having been reached and regeneration of specific end-structures effected, re-establishment of function becomes possible. The medullary sheath is reformed shortly after the regeneration of the axis cylinder. The regenerated fibres tend to be thinner than the original ones,* except after mere crush injury. The extent to which structural and functional recovery takes place, and also its speed, varies greatly with the conditions attending the section, and with its site. If the division is a purely functional one, as by local crushing, recovery is relatively complete and rapid, especially if the length to be regenerated is a short one. Moreover, the degree of recovery of function is considerable, because each new fibre has a fair chance of growing into its former track.† If the nerve is actually severed and the cut ends sutured together there will be less rapid and less complete recovery of function; it has been found that a fuller recovery ensues in this case if the two ends are not brought together for a week or two, so that preliminary degeneration is complete before reunion is encouraged. If a considerable gap is left between the two divided ends recovery is very slow and often but slight.

These incomplete recoveries are ascribed to the fact that the nerve fibres, when they grow, enter the track of fibres of different function.‡ Thus in a mixed nerve, a sensory axon may grow down into the track of a motor fibre, and no functional result would follow. Or a sensory fibre, say from skin, may grow into another skin sensory track of different function, and in that case abnormal sensations would arise, for the removal of which re-education over a considerable time would be needed.

The reunion of motor nerves of different muscles has found application in surgery. Thus the central end of the divided spinal accessory has been united to the distal end of a paralysed facial nerve, and after regeneration and re-education has given good results.

Langley and Anderson § also united many different nerves, *e.g.* the central end of the vagus with the peripheral end of the cervical sympathetic and showed that the vagus fibres regenerated up to the synapses of the superior cervical ganglion. As a result of their researches, moreover, it is clear that what are now called cholinergic nerves cannot be united to adrenergic nerves.

THE EXCITATION OF NERVE FIBRES

Methods. Many different forms of stimuli, such as thermal, mechanical or chemical stimuli may be used to arouse the activity of nerve. Sudden warming of the nerve always gives rise to excitation. At about 45° C. the nerve dies. A nerve may be rapidly cooled without any excitation taking place.

A nerve may be excited mechanically by crushing or cutting, or by carefully graduated taps. The chemical stimuli most used are strong salt solutions, glycerol or weak acids.

None of these forms of stimuli can be adequately controlled either as to strength or duration, and all cause some damage. We therefore use electrical stimuli. For this purpose we may use either the make and break of a constant current, the induced current, the discharge of a condenser, or alternating currents. A valuable method is provided by an electronic device furnishing square waves of any desired voltage, duration or frequency.

‡ Stopford. Sensation and the Sensory Pathway. London. Longmans, Green. 1930.

§ Langley and Anderson. *J. Physiol.*, 1904, **31**, 365.

The relation of current strength and duration to excitation in nerve fibres is determined by methods similar to those used for muscle, and strength-duration curves having similar significance can be plotted, as already discussed. A nerve cannot be excited by currents passed transversely across it, the threshold for stimulation being inversely proportional to the cosine of the angle between current and nerve (cos 90° = 0).

Criteria of Excitation. As evidence that excitation (and conduction) has taken place we have the effects produced (*e.g.* in the muscle in the case of a motor nerve) at the tissue supplied, and also the passage of a wave of electrical disturbance along the nerve.

THE ELECTRIC POTENTIAL. The basal facts of bioelectric potentials have been dealt with in Chapters VIII and X.

When a nerve is stimulated so as to cause excitation, a transitory state of negativity results at the excited point, and this state of negativity travels as a wave at a definite velocity in both directions along the fibres, to be followed by recovery processes which restore the tissue to the resting state. This travelling disturbance is the nervous impulse. It has been shown that the normal impulses travelling up sensory nerves are of similar nature to those which normally travel down the motor nerves.

It should be made clear to beginners that when we say that an electrical disturbance travels along the nerve, this does not mean that electricity travels along the nerve, any more than if we carry an accumulator across a room it means that electricity travels across it. An electric current can be conducted through a nerve cooled to 0°, but a nervous impulse cannot pass in such a cooled nerve.

Usually each stimulus causes a single nerve impulse, though very powerful ones may cause two or three in succession (repetitive response). Lack of calcium increases the tendency to repetitive response.*

In order to demonstrate the wave-like progression of the electrical change from an excited spot along the nerve, it is now customary to amplify the waves by thermionic valves and to record by means of a cathode ray oscillograph. If we lead off from an injured and an uninjured spot, the passage of each impulse past the uninjured spot will give rise to a monophasic variation ; if both spots are uninjured the variation will be diphasic (Fig. 48). The amplitude is about 25 to 50 millivolts in the fibre.

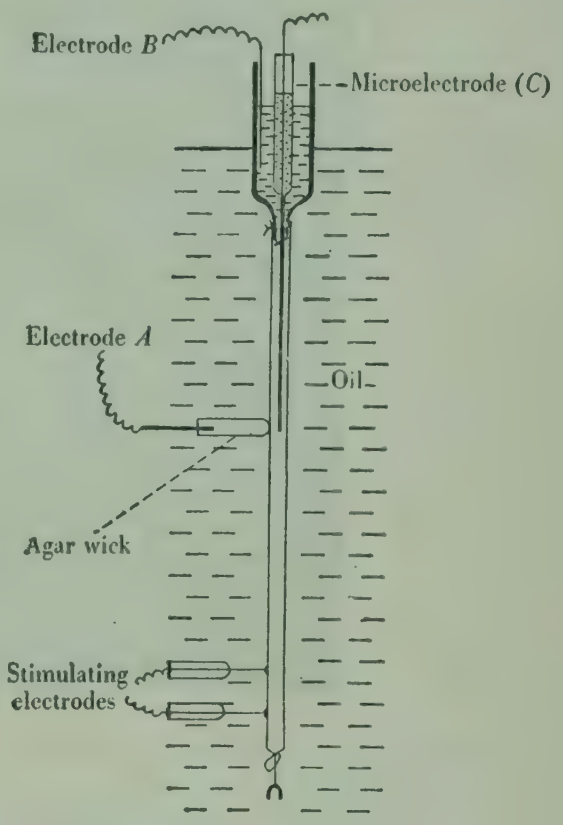

FIG. 89. Diagram of arrangements for recording action potentials in giant nerve fibre. Leads from A and C across membrane : from A and B the potential along membrane to cut end. (HODGKIN and HUXLEY. *J. Physiol.*, 1945, **104**, 176.)

What is important from the theoretical standpoint is the potential difference between the two sides of the plasma membrane, which is presumed to be near to, or identical with, the axolemma. With the usual arrangements for lead-off from the surface of the fibre, there is much short-circuiting, and so the real P.D. across the membrane is not recorded. These difficulties have been overcome by the use of giant non-medullated fibres of the squid, the axons of which may be 0·5 mm. in diameter. Into one of these fibres a cannula is tied and a microelectrode passed through it into the liquid axoplasm : this gives a lead-off from inside the membrane. The outer lead-off is opposite it, and short-circuits are reduced by immersing the fibre in oil (Fig. 89).

With such an arrangement, the resting potential across the membrane is seen to be about 40 millivolts; and this, as explained in Chapter VIII, is due to polarisation of the plasma membrane, the inside layer being negative. Now it has long been known that when an action potential passes along the fibre this resting potential is reduced, *i.e.* the membrane was thought to be depolarised. But in the squid fibre prepared as above, the membrane is not merely depolarised, but has its polarisation reversed, so that the inner surface is now positive to the outer (Fig. 90).

---

* KATZ. *J. Physiol.*, 1937, **88**, 239.

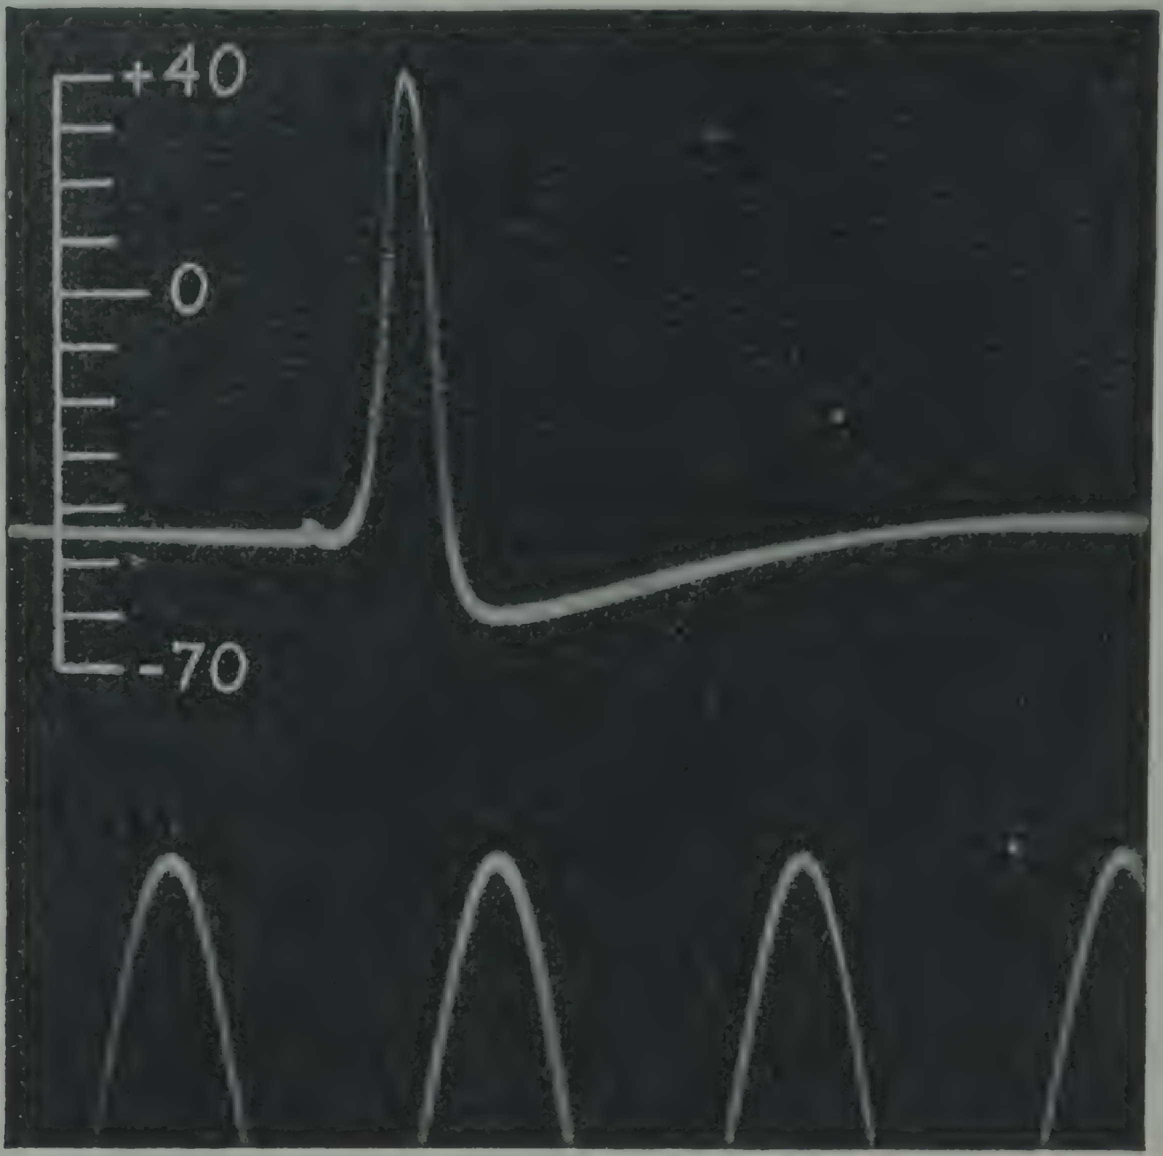

FIG. 90. Action potentials across membrane of single squid axon. The scale reads in mV. and the signs + and − refer to the charge inside the membrane. O = potential of surrounding sea water. On passage of the action potential the charge alters from —43 to + 40. Time = 500/sec. (HODGKIN and HUXLEY. *J. Physiol.*, 1945, **104**, 176.)

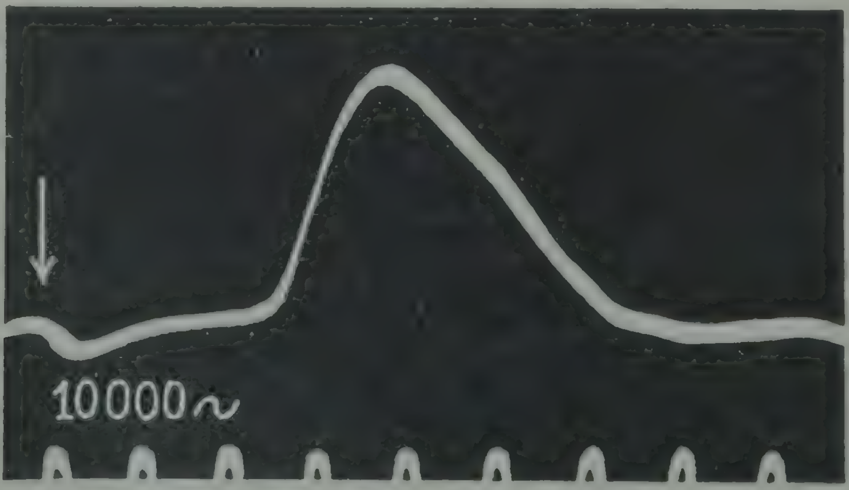

FIG. 91. Spike from single mammalian nerve fibre. Stimulus at arrow. The latent period is made up of true latent period at cathode plus conducting time to the lead. (GASSER. *J. Appl. Physics*, 1938, **9**, 88.)

This result is of great theoretical significance and has already been discussed in Chapter VIII.

The impulse progresses along the nerve at a speed depending upon the nature of the fibres, which fall into three main groups, A, B, and C. It travels at about 100 metres per second in the mammalian A-fibres, and lasts only an extremely short interval of time at each spot; thus the "rising phase" in mammalian A-fibres occupies 0·2 msec. and the total duration 0·4 msec. (Fig. 91), the figures for frog being 0·3 msec. and 0·9 msec. respectively.* Thus the *length* of the excitatory wave in mammalian A-fibres is about 40 mm.

This large monophasic wave is what is generally recorded as a means of recognising the passage of nervous impulses along nerve fibres under any given conditions of experiment, and is now referred to as a "*spike-potential*" to distinguish it from smaller and slower potential changes which modern refinements of technique have shown to follow it. These are respectively the *negative and positive after-potentials*.† (Fig. 92.) In mammalian fibres the positive after-potential cuts into the preceding negative after-potential. In the case of the A-fibres the spike lasts about 0·4 msec.; the negative after-potential continues the fall of negative potential, though more slowly, and may last 15 msec.; the positive after-potential is only about 0·2 per cent. of the magnitude of the spike, but lasts till 70 msec., and may then be succeeded by another negative after-potential. Tetanic stimuli (Fig. 93) or application of veratrine increase both after-potentials. For C fibres the spike lasts 2 msec., the negative after-potential up to 80 msec., and the positive after-potential for 1 to 2 seconds, and is large (1·5 per cent. of spike).

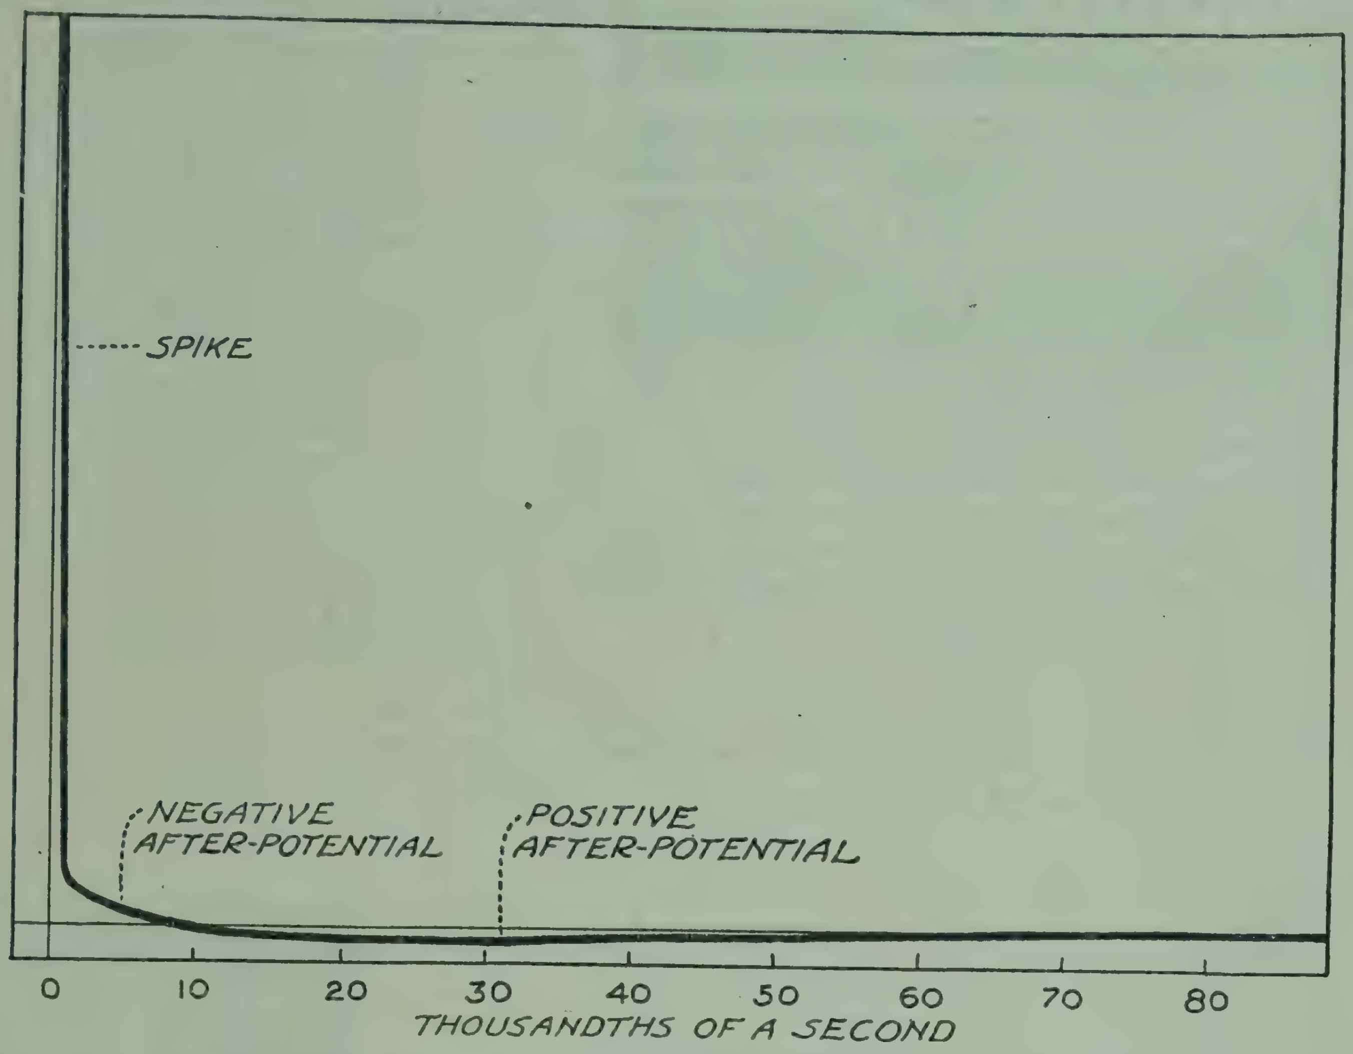

FIG. 92. Diagram of Electrical Potentials in Nerve following Stimulation at 0. The positive after-potential has been exaggerated. (After GASSER. Harvey Lect., 1937.)

The absolute refractory period in a nerve fibre occurs during the spike, the relative refractory phase is short and is followed by a supernormal phase lasting till the end of the negative after-potential, while the succeeding subnormal phase coincides with the positive after-potential.‡ It seems clear therefore that the after-potentials are an indication of the level of excitability, whereas the spike is the actual message carrier.

When by repeated stimulation the nerve is thrown into protracted activity, a study of the spike potentials indicates that the excitatory changes in the nerve fibre are *interrupted*, not continuous. We may compare the passage of such a stream of nerve impulses to the discharge of a stream of machine-gun bullets, rather than to the flow of a stream of water; "continuous" activity of the fibre being represented by a quick succession of these short waves (Fig. 93).

---

* GASSER and ERLANGER. *Amer. J. Physiol.*, 1927, **80**, 522.
† GASSER and GRUNDFEST. *Amer. J. Physiol.*, 1936, **117**, 113.
‡ AMBERSON. *Journ. Physiol.*, 1930, **69**, 60.

The maximum frequency at which the impulses can follow one another is determined by the length of the refractory period, since a second response cannot be obtained until the previous one has subsided. Since the absolute refractory period for mammalian A-fibres is about 0·4 msec., it follows that the maximum frequency is about 2,500 impulses per second ; the relative refractory phase, however, lasts for 3 msec., so that at frequencies greater than about 300 p. sec. all impulses after the first one will be slightly reduced (Fig. 94), and, incidentally, are also conducted along the fibre more slowly. When the frequency of stimulation of A-fibres is less than 300 p. sec., all the impulses are of full size, and this is the case whether the stimulus be strong or weak. In frog's nerve at 20° the maximum frequency is about 500 p. sec.

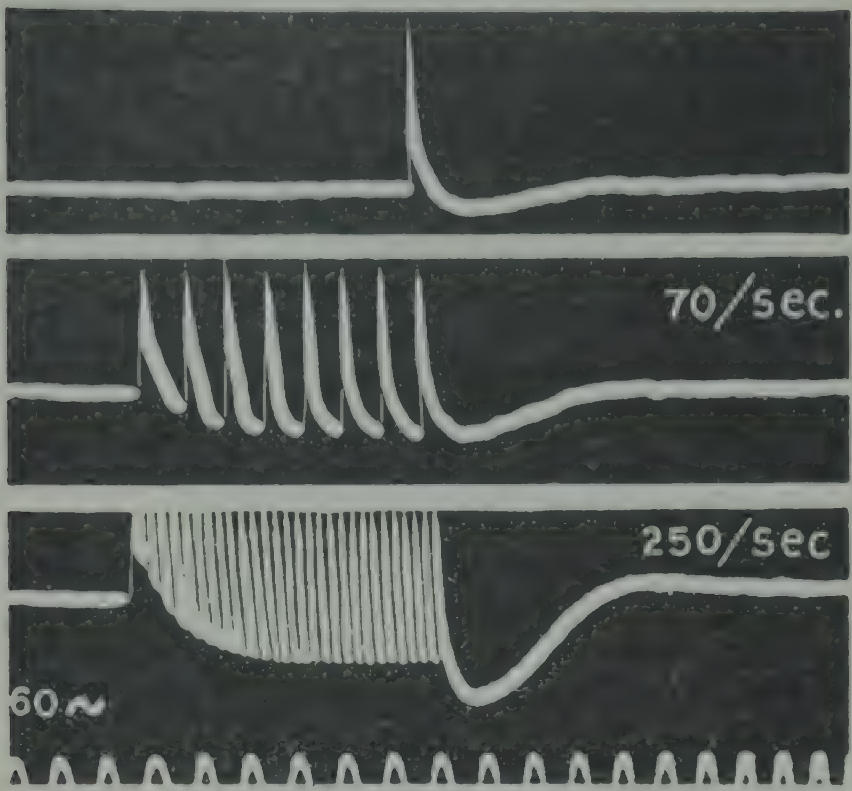

FIG. 93. Action and after-potentials in Phrenic Nerve, from single stimulus, from 8 stimuli at 70/sec., and from numerous stimuli at 250/sec. Note increase in positive after-potentials (dip below zero line) as frequency increases. (GASSER. *J. Appl. Physics*, 1938, **9**, 88.)

Volleys and Trains of Impulses. These two terms in frequent usage must now be explained. If a maximal stimulus be applied to a nerve at a given point, impulses are fired off simultaneously from that point along all the fibres. (A weaker stimulus will start off impulses along fewer fibres.) The result is in either case known as a *volley* of impulses, in fanciful comparison with the firing of a volley of rifle shots, the essence of the matter being that the impulses all start off at once, like scratch runners in a race. Actually there are, so to speak, two sets of runners, starting back to back and travelling in opposite directions, because the stimulus to each nerve fibre in its course initiates two such impulses in opposite directions. It will be seen that this is one way in which many impulses may be sent along a stimulated nerve, one along each fibre in each direction. It is clear that this gives a sort of *spatial summation*, corresponding to quantal summation in a muscle.

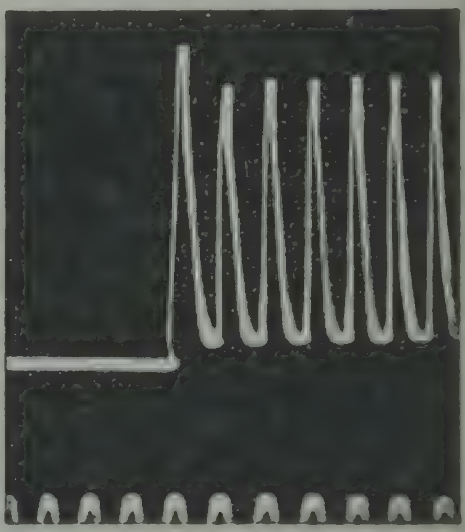

FIG. 94. Stimulation of Phrenic Nerve at 1,075/sec. All but first response are reduced. (GASSER. *J. Appl. Physics.*, 1938, **9**, 88.)

Another type of summation, which may be called *temporal summation*, exists when more than one stimulus is given to a nerve fibre. In this case, within limits to be described later, each stimulus causes a fresh impulse in each fibre, so forming *trains*, consisting of a number of impulses, equal to the number of stimuli, speeding one after the other along the fibre. This does *not* correspond with wave summation in muscle because the nerve impulses never fuse together, but always remain discrete.

By repetitive stimulation of a nerve both types would be combined, *i.e.*, there would be trains of volleys.

Alterations in Excitability. In order to stimulate a nerve, a current must have a certain minimal voltage, and, as we learnt in Chapter X, be applied for not less than a certain minimal time. These minimal values are called thresholds : the more excitable a nerve is, the smaller the threshold intensity and time needed for excitation. In order to measure excitability it is usual to make the duration of the exciting current greater than threshold time and to find the smallest voltage that will excite. It is customary to use condenser discharges for this purpose. Any change in excitability is measured by the change of threshold, and is proportional to its reciprocal. In giving results the initial excitability is called 100, and subsequent ones in percentages.

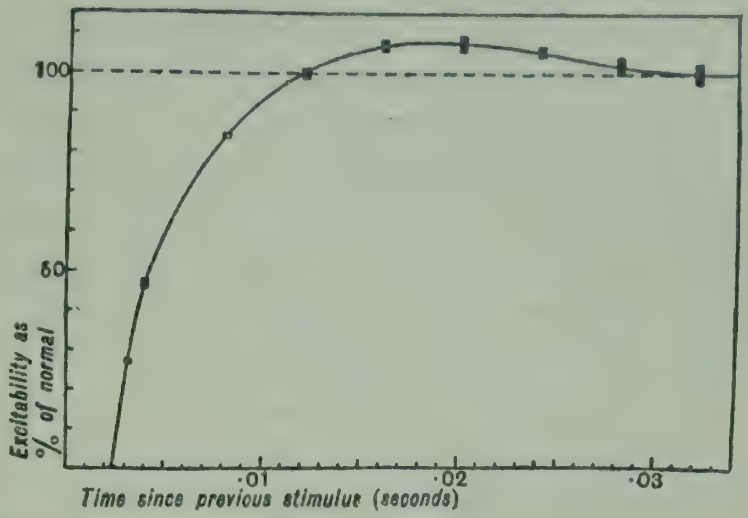

Fig. 95. Recovery of Excitability of Frog's Nerve. (Adrian and Lucas.)

Refractory Period. For a short time after its excitation a nerve fibre is in a state of altered excitability. If two "adequate" stimuli are applied to a frog's sciatic nerve within a sufficiently brief interval, the second stimulus is ineffective. This is the *absolute refractory period.* It is longer the lower the temperature and for frog nerve is about 2 msec. (0·5 msec. to 3·0 msec.) at 10° C.,* the Q10 being 3·0 (*i.e.* the duration being reduced to one-third by a rise of 10° C.). It is lengthened if the excitability of the nerve is depressed by narcotics. Following the absolute refractory period, the nerve remains in a less excitable state than normal for a further short period, during which it may only be excited by stronger stimuli than were needed for the first, or *conditioning*, stimulus, and during which time also the impulses generated are of smaller size. This is the *relative refractory period.*

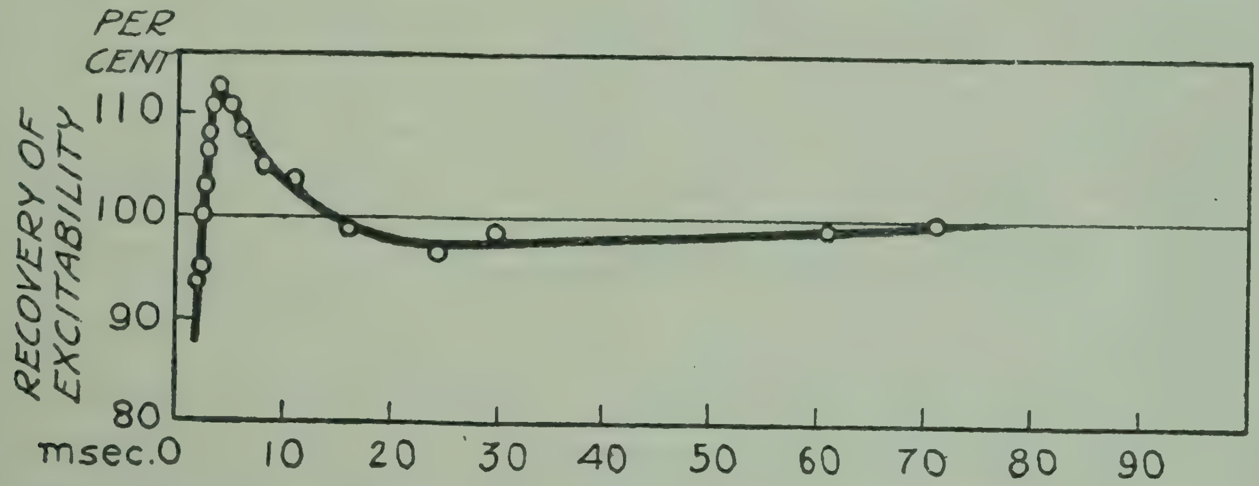

Fig. 96. Recovery of Excitability of Cat's Saphenous Nerve stimulated at 0. (Gasser and Grundfest. *Amer. J. Physiol.*, 1936, **117**, 129.)

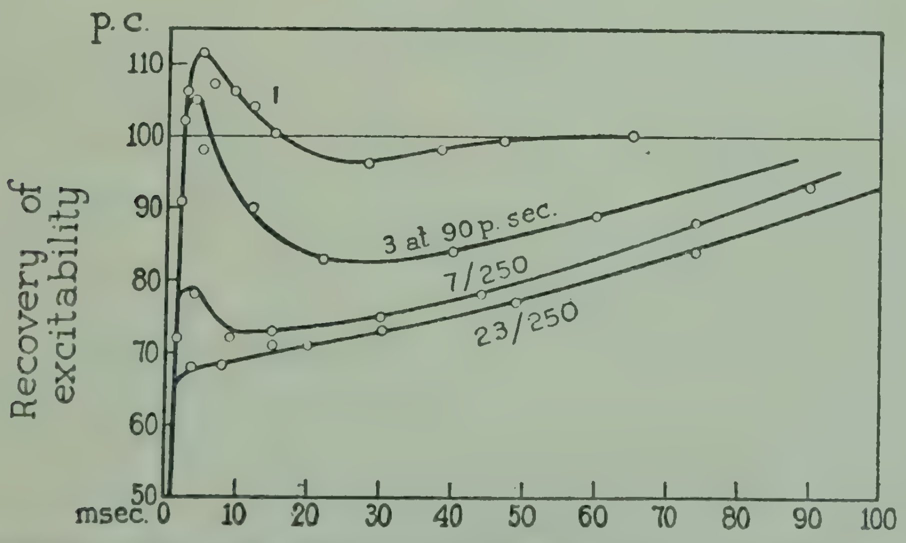

Fig. 97. Excitability of saphenous nerve of cat *in situ.* Ordinates: excitability compared with resting threshold. Abscissæ: intervals between last of the conditioning shocks and testing shock. Numbers over the curves show the number and frequency of the conditioning shocks, *e.g.* 7/250 means 7 shocks at the rate of 250 per second. The upper curve is after one conditioning shock only. (Gasser and Grundfest. *Amer. J. Physiol.*, 1936, 117.)

---

* Graham, Helen T. *Amer. J. Physiol.*, 1935, **111**, 452.

These periods of diminished excitability immediately after the application of a stimulus are succeeded by one during which the nerve is more excitable,[*] the *supernormal phase* (Fig. 96), and this again by another phase of *subnormal excitability*. For the large (A) fibres of mammals the absolute refractory period is about 0·4 msec., relative refractory phase 3 msec., supernormal phase 12 msec., and subnormal phase up to 70 msec. from stimulation (Fig. 96).

When the nerve has been submitted to several "conditioning" stimuli previous to the testing shock, the picture is somewhat altered, inasmuch as the supernormal phase and the negative after-potential are reduced or missing, the extent of the reduction being in proportion to the frequency and number of the preceding stimuli, as is shown in Fig. 97. The positive after-potential, and subnormal phase are proportionately increased.

It is an important consequence of the refractory period phenomenon that if two impulses travelling in opposite directions along the same nerve fibre meet one another, each will enter the refractory phase left behind the other, so that both will be extinguished. Another consequence is that a nerve can only carry a limited number of impulses per second. The refractory period is lengthened during continuous transmission at high frequencies.[†]

Latent Addition. The summation of two *inadequate* stimuli of, say, 95 per cent. threshold strength is possible in a nerve, provided these are not more than 0·5 msec. apart, *i.e.* the first effect is to make the nerve in the stimulated region more excitable. This is called the local excitatory state. For several msec. afterwards, however, the nerve is in a relatively refractory state, even though the stimulus was ineffective.[‡] Hence stimulation by repetition of sub-threshold stimuli may never occur if each stimulus falls in the refractory phase of its predecessor ; or if the stimuli are adequate in strength, but so rapid that (*e.g.* frog's nerve stimulated at 1,000 p. sec.), only the first one is effective (Wedensky inhibition).

Non-conducted Responses. Since the propagation of the impulse depends on the stimulation of each section of the fibre by the preceding one,[§] it should be possible to apply a localised stimulus of a strength so small that the length of nerve depolarised by it is insufficient to pass on the excitation. Hence we shall expect to get a localised and non-conducted response, and this is in fact what happens.[||] At the spot so stimulated, a second stimulus is facilitated by latent addition, and, moreover, the transitory excitation is accompanied by a small and non-propagated action potential.

All-or-None Character of the Impulse. The nervous impulse must be some form of energy transmission, since it is capable of throwing its effector organ into activity. A very important question is that concerning the type of propagation. Is it transmitted passively along the conducting medium like sound, or does the nerve fibre contribute energy which keeps the impulse alive and transmits it from point to point, as, for example, in the travelling of combustion along a train of gunpowder ?

In the former case the impulse must get progressively weaker as it travels along, and its damping-down could, under certain conditions, be greatly accelerated, as, for example, that of sound in encountering a layer of cotton wool ; in other words, the nervous impulse would normally suffer a *decrement* from which, in its further passage along its course, it would not recover.

If the latter case were the correct one, the impulse would maintain a constant (all-or-none) intensity so long as the conditions were constant and, although its progress might be damped down locally, as in a stretch of burning fuse which had been moistened, it would, if it succeeded in emerging from such a region of depression, again flare up to its normal level.

[§] HODGKIN. *J. Physiol.*, 1937, **90**, 183, 211.

[||] RUSHTON. *Proc. Roy. Soc.* (B), 1937, **124**, 210. KATZ. *Proc. Roy. Soc.* (B), 1937, **124**, 244.

Adrian * came to the conclusion that, after having passed through a region of impaired conduction brought about by local narcosis, the nerve impulse did again spring up to its former level on emerging into a normal stretch of nerve, and subsequent work has thoroughly substantiated this conclusion. That the nerve impulse normally suffers no decrement is clearly shown by the fact that the action potential as it passes along a normal nerve fibre remains of the same size. If a part of the nerve is narcotised, the action potentials are reduced in magnitude in that narcotised stretch of nerve, but if not completely quenched become normal again in the non-narcotised portions beyond. †

Adrian ‡ has pointed out that the all-or-none response of nerve is a logical consequence of its having a threshold of excitability and a refractory period. A stimulus in order to excite must produce a certain minimal local change, and the propagated disturbance which is set up as soon as this change has reached its critical value, must therefore be of an all-or-none character. A stimulus beyond threshold strength " may cause the local change to exceed the value required for excitation, but the disturbance will have been set up at the moment when the critical value was reached, and the refractory state accompanying the disturbance will prevent any subsequent change in the local conditions from affecting its size in any way."

THE EFFECT OF TEMPERATURE ON EXCITABILITY. The excitability of a nerve to currents of short duration, such as those of the spike potentials, is lowered by cooling the nerve,§ and, within certain limits, increased by raising its temperature. But to longer lasting currents the excitability is raised by slight cooling. Thus if a frog be cooled to 2° C. for a day, section of the sciatic nerve may send the gastrocnemius into continued contraction, and " closing tetanus " may be obtained with ease. This increase of " excitability " does not, however, imply a diminished chronaxie, but only a reduced rheobase. Actually the chronaxie of both nerve and muscle are increased by cooling, and therefore they are *less* excitable for induction shocks and for galvanic currents of short duration.

When a nerve trunk is warmed to a certain temperature (32° to 40° C. for various species of frogs) it becomes temporarily inexcitable (heat paralysis), but the excitability is restored again by cooling.||

The excitability and conductivity of nerve are both abolished below a certain temperature, *e.g.* 5° C. in the mammal.

THE EFFECT OF INJURY The excitability of the nerve of a nerve-muscle preparation is not equal in all parts of its course, but is greater at the upper end, probably because it is nearer to a site of injury.

Some time after a motor nerve is divided, the increased excitability at the upper end gives way to a decreased excitability, and this decrease goes on till the nerve is no longer excitable. The diminution in excitability gradually extends down the nerve fibre, so that the part of the nerve nearest the muscle remains excitable the longest (the Ritter-Valli law). It is soon followed by definite histological changes in the nerve.

PROPAGATION ALONG NERVE FIBRES

Although nerve fibres have the power of conduction in both directions *the impulse is normally only conducted in one direction*, starting at one end of the fibre and travelling to the other end. In consequence we find in the body a clear differentiation of function between various nerve fibres. Thus Bell and Magendie showed that the ventral spinal roots carry only impulses from spinal cord to periphery, while the dorsal roots carry impulses from periphery to central nervous system. The law known by the name of these observers states, indeed, that a nerve fibre cannot be both motor and sensory. We often find both kinds of fibres contained in a single nerve trunk, but normally each fibre conducts impulses only in one or other direction. (The " axon reflex," referred to later, is an exception to this, which need not be considered here.) Under normal conditions the afferent fibres are excited only at their specialised peripheral endings, while the efferent fibres are excited only at their origin within the

nervous system. The difference in the function of different nerve fibres depends therefore not on the structure of the nerve fibre itself, nor on differences in the impulses conveyed, but on the different connections of the fibres. We can show this experimentally by grafting one set of nerve fibres on to another.* In the same way the finer functional differences between the various forms of sensory nerves seem to be determined by their connections within the central nervous system. Stimulation of the optic nerve by any means whatsoever evokes a sensation of light. One and the same stimulus applied to different nerves will evoke different sensations, *e.g.* a tuning-fork applied to the skin will give a sensation of vibration, to the ear a sensation of sound.

The velocity of propagation along a nerve was first measured by Helmholtz.† In a simple modification of his method, a frog's gastrocnemius is prepared, with a long piece of sciatic nerve attached. The muscle is arranged (Fig. 98) so that its contraction may be recorded on a rapidly moving surface, on which are also shown the moment at which the stimulus is sent into the nerve, and a time tracing. Records are now taken of the contraction of the muscle when the nerve is stimulated: first, at its extreme upper end; secondly, as close as possible to the muscle. It will be found that the latent period, between the point at which the stimulus is sent into the nerve and the point at which the lever begins to rise, is longer in the first case than in the second. The difference in the two latent periods gives the time that the nervous impulse has taken to travel down the length of nerve between the two stimulated points. In this way, the velocity of propagation in frog's nerve is found to be about 30 metres per second. In man and in warm-blooded animals the velocity is about 120 metres per second.‡

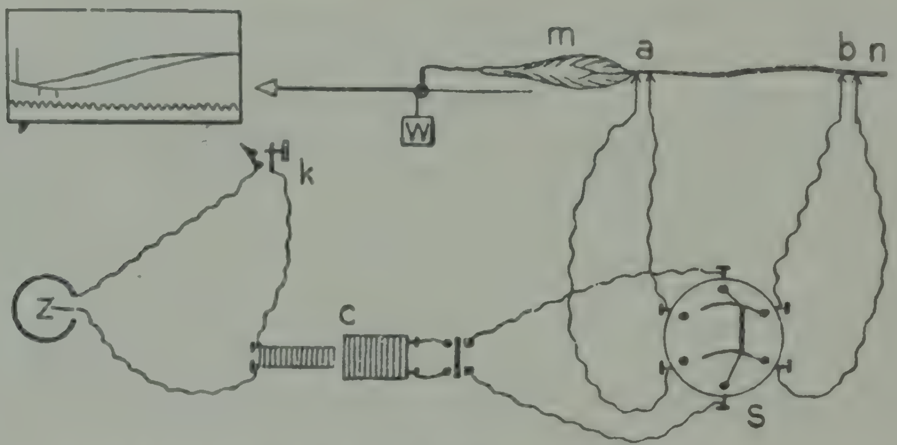

FIG. 98. Diagram of Arrangement of Experiment for the Determination of the Velocity of Transmission of a Motor Impulse down a Nerve.

The battery current passes through the primary coil of the inductorium *c*, and a "kick over" key *k*. By means of the switch *s*, the break shock in the secondary circuit can be sent through the nerve *n*, either at *b* or at *a*. The muscle *m* is arranged to write on the blackened surface, and is excited during the passage of the recording surface by the automatic opening of the key *k*. (The time marker is not shown.)

These values represent the *highest average* velocities in motor nerves. As a matter of fact, the impulses generated in a nerve of mixed function travel at different speeds, the coarse fibres conducting most quickly.§

There is a more refined method of determining the velocity of conduction, which may be used also with sensory fibres. This is by recording the times at which the monophasic potential spike passes two points at a known distance apart along the nerve.‖ We have seen that if a nerve is stimulated a volley of impulses is started simultaneously in many fibres. But, like runners starting from scratch, the farther they go the more the fast ones will outstrip the others.

By taking records at various distances Erlanger and Gasser found that the potentials, at first all so close together as to appear homogeneous, separated out on farther travelling into groups of different speeds, the slower groups appearing as new waves on the descending limb of the composite potential record, as illustrated in Figs. 99 and 100.

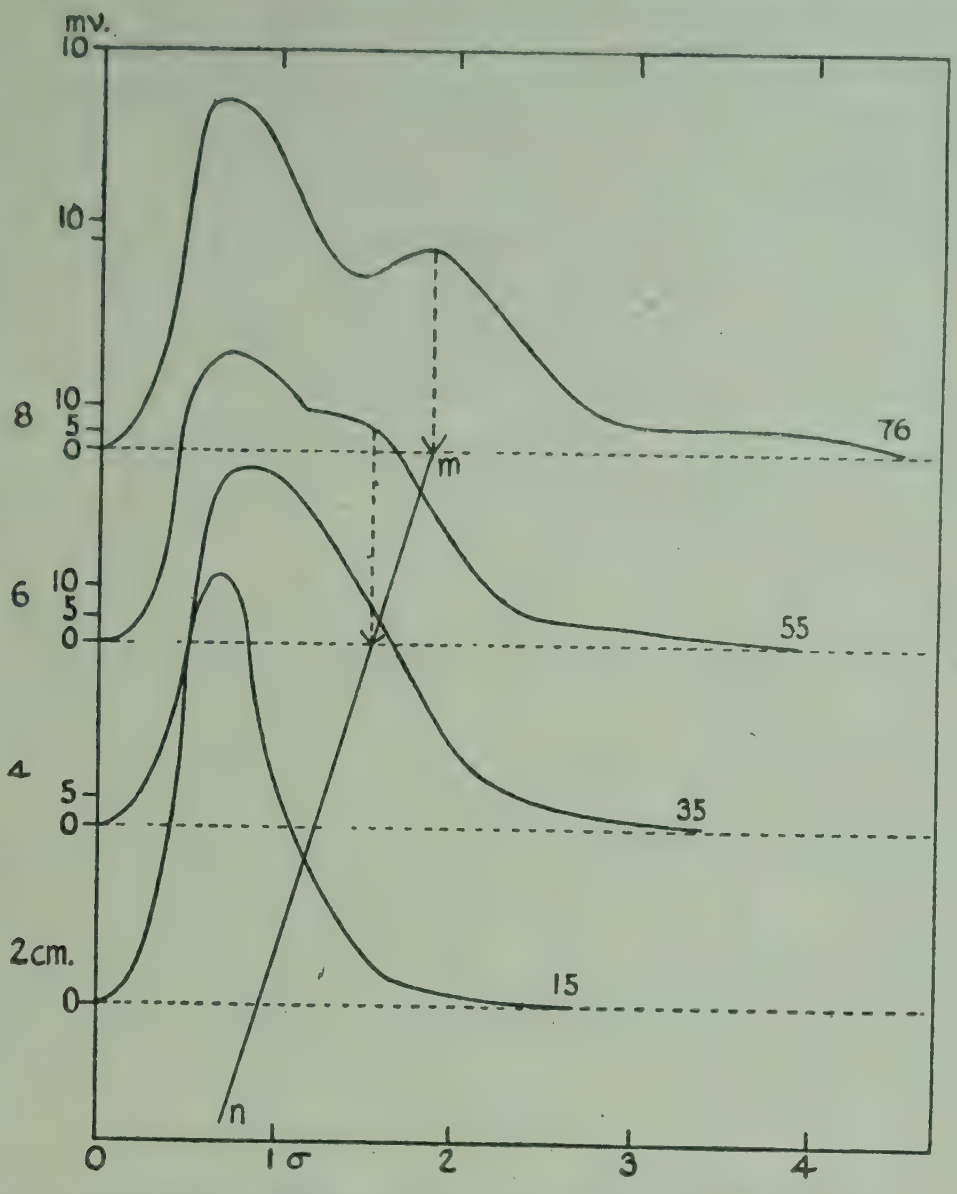

FIG. 99. Separation of Nerve Action Potentials of Frog Nerve into Components of different speeds by leading off at different distances from their origin. The figures on each curve show distance. (GASSER, ERLANGER and BISHOP.)

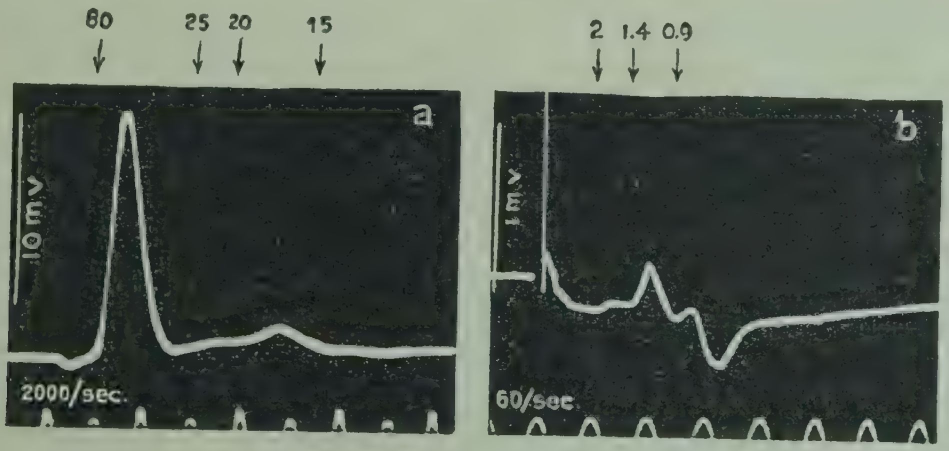

FIG. 100. Saphenous Nerve of Cat. Separation of action potentials after 4 cm. of conduction. On the left the record is on a faster "surface" than on the right and is less amplified. The spike of the left-hand figure is only faintly seen as a line in the right-hand one. The slowly recorded right-hand figure shows that the slow spikes start from a lowered line—the positive after-potential. The figures above indicate position of impulses which travel at the speeds shown (mm. p. sec.). (GASSER. *J. Appl. Physics.*, 1938, **9**, 88.)

Erlanger and Gasser have divided the mammalian fibres as follows :—

Group A are somatic medullated fibres, motor and sensory. The motor ibres are large, up to 20μ in diameter, and, together with the largest sensory bres, are called α-fibres ; these have the shortest chronaxie and the most apid propagation rate—up to 120 m.p.sec. The smaller sensory fibres (down to 1μ), β, γ and δ, have longer chronaxies, and conduction rates down to 60, 40 and 25 m.p.sec. or less ; their functions are separate.

Group B consists of autonomic medullated fibres, of fine calibre, longer chronaxie, and with conduction rates from 14 to 3 m.p.sec.

Group C consists of fine non-medullated fibres. These only conduct at 0·3 to 1·6 m.p.sec.

INTERACTION BETWEEN ADJACENT NERVE FIBRES. We have seen in Chapter X that a nerve may easily be stimulated by the action potential of a muscle placed in contact with it. This being so, the question may well be asked whether the fibres in a nerve trunk would not similarly be affected when adjacent fibres were conducting impulses. The answer seems to be * that they are affected, inasmuch as they show excitability changes, but that the effect is not enough to produce actual excitation. The experiment is carried out, with large non-medullated fibres, as shown in Fig. 101 (*a*). Fig. 101 (*b*) shows

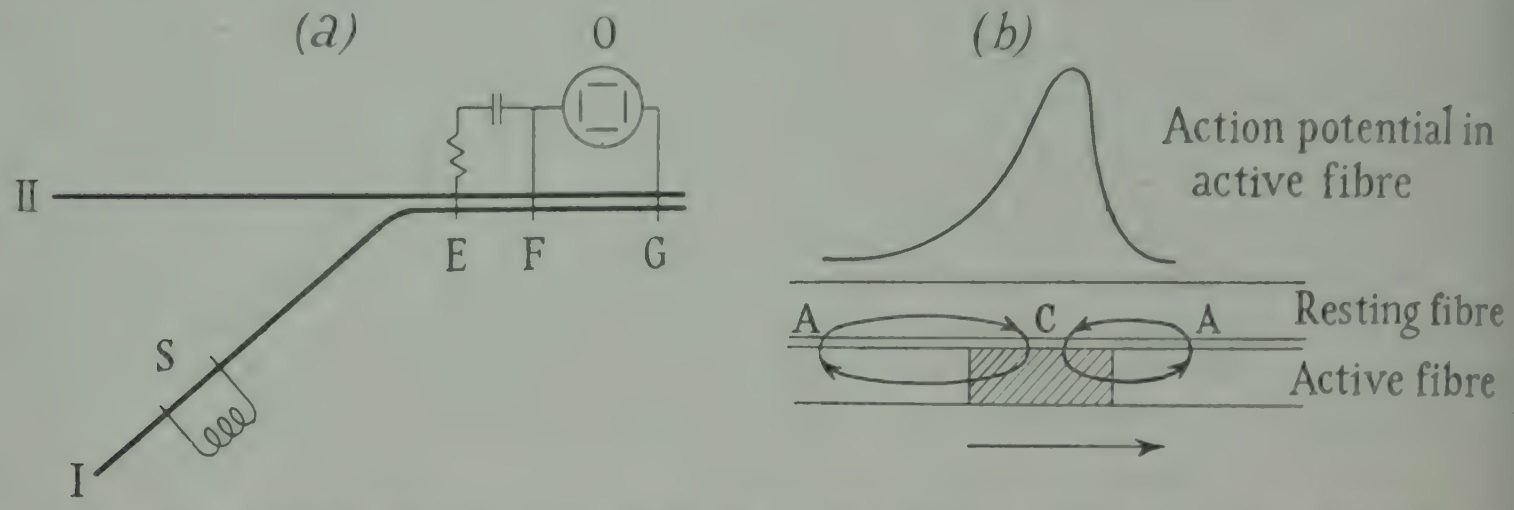

FIG. 101. Effect of action potential on adjacent resting nerve fibre. (*a*) Arrangement of experiment. I, the stimulated fibre ; II, the resting fibre. S, stimulating electrodes ; E, F, electrodes for testing threshold ; F, G, lead-off to cathode ray oscillograph, O.

(*b*) Showing that advancing action potential in active fibre results in consecutive points on resting fibre becoming successively anode, cathode, anode. (KATZ and SCHMITT.)

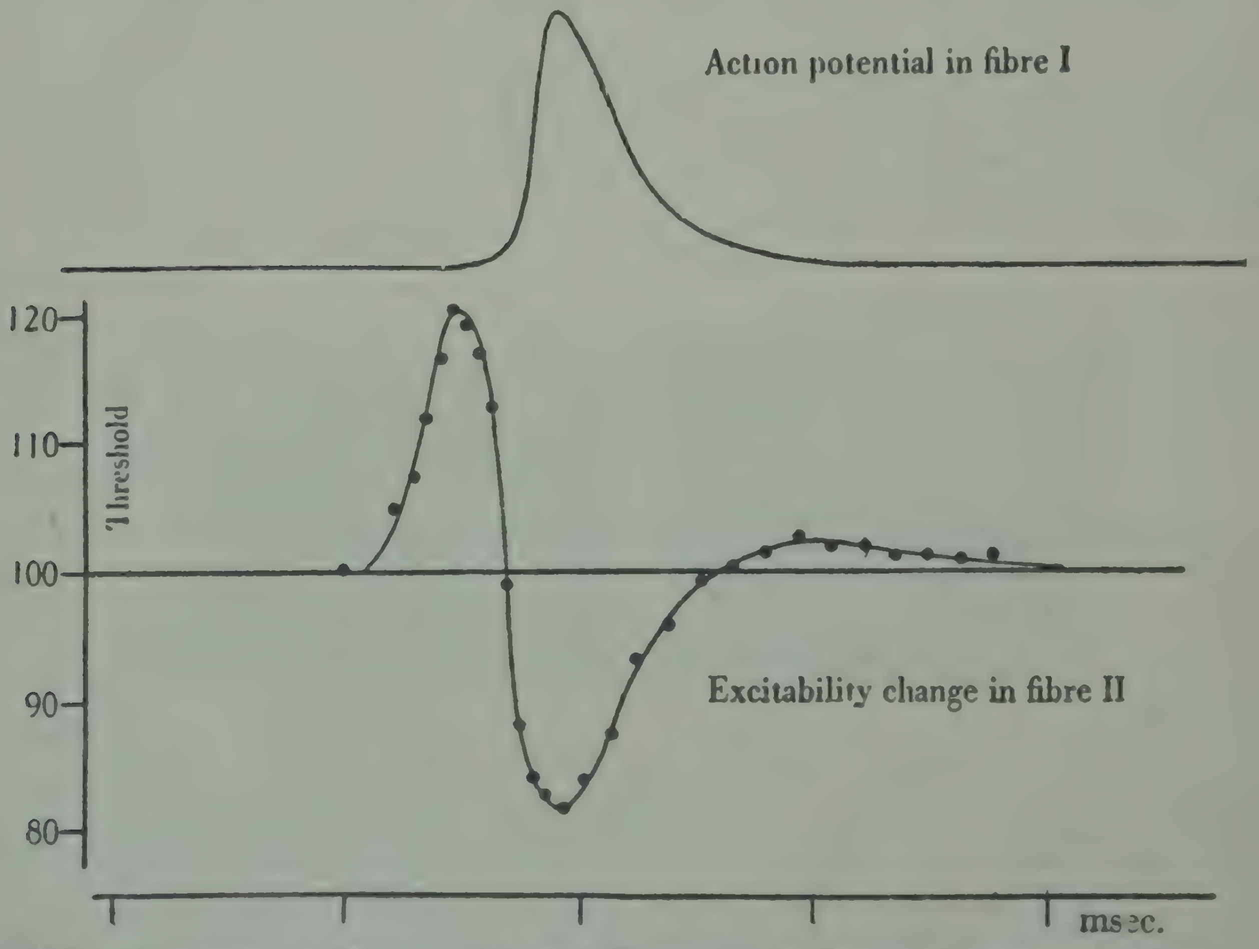

FIG. 102. Changes of Excitability of Fibre II as action potential passes along fibre I. (KATZ and SCHMITT. *J. Physiol.*, 1940, **97**, 471.)

---

* KATZ and SCHMITT. *J. Physiol.*, 1940, **97**, 471 ; 1942, **100**, 369.

that, as the action potential passes along the active fibre, consecutive areas of the resting fibre become first anelectrotonic, then catelectrotonic, and once more anelectrotonic, owing to current conducted from the active fibre. Consequently the excitability of the resting fibre is first reduced (*i.e.* its threshold is raised), then increased, and finally reduced again, as shown in Fig. 102.

There is also an effect when impulses travel simultaneously along fibres lying side by side, whereby the conduction rate of a lagging impulse is speeded up until it catches up with the other, the two thereafter keeping pace. These facts apply to non-medullated nerves, and are less conspicuous in medullated ones, because the axons are insulated.

Chemical and Thermal Changes in the Nerve during Transmission. In nerve, which serves merely as a conducting medium, there is less expenditure of energy on excitation than in muscle. All that is necessary is that each section of the nerve should transmit to the next section just so much energy as is needed to excite it.

That the excitatory process in nerve is dependent upon chemical changes is indicated by the facts that, in the complete absence of oxygen, the nerve fibres lose their excitability, and that this loss of excitability is hastened by repeated stimulation of the nerve. When the excitability has been abolished by stimulation in the absence of oxygen, it may be restored within a few minutes by re-admission of oxygen to the nerve, and still more quickly if the nerve be also washed in Ringer's solution.

Nerve continually uses oxygen and evolves carbon dioxide ; in the absence of oxygen, lactic acid accumulates.* When the nerve is stimulated, the rate of oxygen usage is accelerated.† The substances oxidised are not known. Little is known concerning actual chemical changes in nerve. Carbohydrate is apparently not the main source of energy.

The metabolism of nerve cells is apparently entirely different, for the brain appears to use carbohydrate exclusively ; if glucose is absent from the blood, the brain functions are grossly disturbed.

In activity acetyl choline is released by cholinergic fibres and sympathin by adrenergic ones. Potassium ions leave the fibre and sodium ions enter. The vitamin thiamine has also been shown to leave the nerve during activity.‡ Breakdown of A.T.P. and creatine phosphate also probably occur.

Observations of heat production of nerve by A. V. Hill and his pupils also show how small are the energy exchanges. Frog's nerve at rest evolves about 4×10^{-3} cal./g./min. when in oxygen, and about one-quarter of that amount when in nitrogen.§ If returned to oxygen after being in nitrogen, the heat production is increased.

When impulses pass along the nerve, the heat production is increased, and three phases may be recognised,‖ the first being called "initial" heat and the other two "recovery" heat. Initial heat is small in amount, *e.g.* 5 to 10 micro-calories (*i.e.* $5–10 \times 10^{-6}$ cal.) per sec. per g. nerve during continuous rapid excitation. It dies away at once when stimulation ceases. The delayed heat of recovery consists of an early rapid phase, about equal to the initial heat, and a prolonged phase for 30 minutes or more, which totals about thirty times the initial heat. The heat produced by a single volley of impulses is of course much smaller, viz. about 0·067 micro-calories per g. of frog nerve at 20° C.

An explanation of these various facts is as follows : ¶ The nervous impulse is a wave of altered polarisation which rapidly moves over the polarised membranes at the surfaces of the fibres, thus also causing the action potential. The altered polarisation means that ions previously held in position on the polarised membrane are now free to wander. This change would involve but little liberation of energy and so necessitate little if any heat production. Hence it occurs equally well at first whether oxygen is present or not. But the process of *recovery* involves *repolarising* the membranes, which means that energy must be expended, oxygen used and heat set free, in order to separate the oppositely charged ions and set them in order again. This explains why these various changes are associated with the recovery of the nerve rather than with its actual functioning, and also why the excitability is lost when the nerve is stimulated repeatedly in absence of oxygen, and restored by its re-admission. At the *anode* of a constant current, the effect is the same as that of oxidative metabolism, *i.e.* the polarised state is restored.

The hypothesis also explains another phenomenon called the "retention of action current " which is well seen in cold blooded non-medullated nerves.[*] When the nerve is repeatedly stimulated, especially in absence of oxygen, the action current subsides more and more slowly, or, in other words, the depolarised state persists, as a negative after-potential. If oxygen is admitted the current subsides more quickly again, because the energy necessary to repolarise the membranes is obtainable. The more rapidly acting medullated nerves of the higher animals do not show the phenomenon so clearly, but it is demonstrable in them too. The refractory period is, indeed, due to the fact that repolarisation takes an appreciable time.

CONDITIONS AFFECTING THE CONDUCTIVITY OF NERVE

Temperature. Below a certain temperature the propagation of the excitatory process in the nerve is abolished. In the frog it is necessary to cool the nerve to − 1° C. before conduction is abolished, whereas in the mammal it is sufficient to cool the nerve to somewhere between 0° and 5° C. Since cooling the nerve does not excite it, this procedure forms a convenient method for blocking the passage of impulses along a nerve without using the irritating procedure of section. On again warming the nerve the conductivity returns. Warmth (over 32° C.) abolishes conductivity in frog nerve. The rapidity with which the excitatory process is propagated along nerve fibre depends on the temperature. Thus, the mean rate of conduction in the frog's nerve at 8° to 9° C. is only 16 metres per second. The temperature coefficient of the velocity of nerve propagation, *i.e.* $\frac{\text{velocity at T} + 10^\circ}{\text{velocity at T}^\circ}$, is about 1·58 between 12° and 26°, but below 12° is higher.[†]

Pressure. Local application of pressure above 130 mm. Hg to a nerve produces in about 40 min. a block that lasts for 2–3 hours after removal of the pressure : this differs from anæmic block which disappears when the circulation is restored.[‡]

Chemical Influences. The most important drugs with an influence on nerve fibres are the narcotics. Of these we may mention carbon dioxide, ether, chloroform, alcohol and novocaine.

These diminish, and finally abolish, the excitability and conductivity of the nerve fibres. On removing the narcotic, recovery occurs if the dose has not been too great. It has been shown that the nervous impulses (action potentials) are reduced in magnitude while passing through a lightly narcotised stretch of nerve, but regain their normal size on emerging into untreated tissue.[§] If the narcosis is severe any impulses are extinguished altogether so long as it lasts. Advantage is taken of this fact for causing a temporary loss of function in nerve trunks for clinical purposes. Thus, if novocaine is applied to a nerve trunk, all painful sensations from the part supplied by the nerve are blocked, and operations may thus be performed under " local " or " regional " anæsthesia. If applied to the spinal cord (by lumbar puncture), extensive operations on the abdomen or legs can be carried out painlessly.

Changes in hydrogen-ion concentration do not affect the spikes, but alter the excitability and the after-potentials. Increase of *c*H reduces excitability and reduction of *c*H increases it, until at *p*H 8·0 spontaneous discharges occur.[‖]

Removal of calcium produces the same effects as reduction of *c*H, which is, in fact, probably due to de-ionisation of calcium. Removal of potassium produces the opposite effects.[¶]

[¶] Lehmann. *Ibid.*, p. 613.

Asphyxia reduces the size of the response, *i.e.* of the spike and after-potentials, and also reduces excitability.[*]

Block Phenomena. When a short length of nerve is blocked, *e.g.* by cold or pressure, and an impulse started above the block, this is not entirely without effect on the nerve below the block, although no impulse has passed. For a few millimetres below the block the nerve shows for a few msec. a large increase of excitability, the threshold being often reduced by 80 per cent. Thus in an experiment arranged as in Fig. 103 a shock at S_1 sets up an impulse which is stopped at the block and so does not reach the oscillograph C. A sub-threshold shock from S_2 similarly fails to arouse an impulse. But if an adequate shock S_1 is followed 1 or 2 msec. later by a sub-threshold shock at S_2, an impulse is started and is recorded at C.

The explanation, which is of considerable theoretical interest, is that, although the impulse cannot be conducted beyond the block because of the alterations produced by the conditions, the electrical disturbance due to the impulse above the block causes currents which can be conducted perfectly well. The direction of these currents is shown in Fig. 104 from which will be seen that the current below the block is in the same direction as would be got if a cathode were applied to the nerve. Measurements at the nerve surface here do, in fact, show that an " extrinsic " potential is set up which is similar in extent and duration to one set up by applying a cathode, and it is known that the region of the cathode is one of enhanced excitability. The extrinsic potential is therefore electrotonic in nature, and resembles the non-propagated response already mentioned.

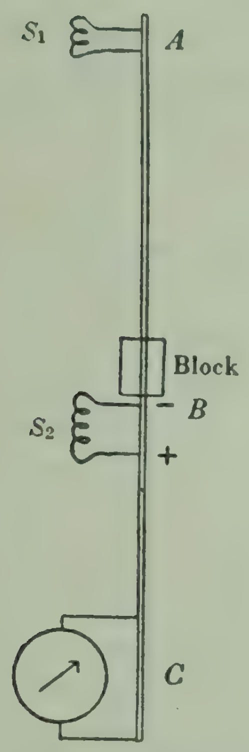

Fig. 103. Experiment to show excitability change beyond Block. (Hodgkin. *J. Physiol.*, 1937, **90**, 183.)

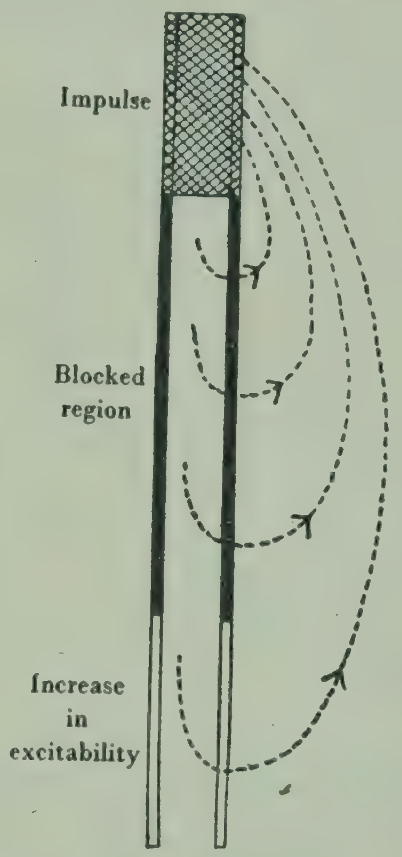

Fig. 104. Diagram of electrical circuit set up in blocked nerve by an impulse above the block. (Hodgkin. *J. Physiol.*, 1937, **90**, 184.)

The Influence of Repeated Stimulation. Medullated nerves are not at all easily fatigued, in fact they are almost indefatigable unless deprived of oxygen. This may be shown in various ways. Thus, a nerve can be isolated and repeatedly stimulated, say, at 100 per second, while its action potentials are observed on a cathode ray tube ; they will be found to continue unchanged for long periods. It may be demonstrated in mammals by poisoning the animal with curare, and then stimulating a motor nerve continuously while the animal is kept alive by means of artificial respiration. As the effect of the curare begins to wear off in consequence of its excretion, the muscles supplied by the stimulated nerve enter into tetanus. The action of the curare may be cut short at any time by the injection of eserine, when the muscles will at once begin to react to the excitation.

---

[*] Lehmann. *Ibid.*, 1937, **119**, 111.

The same fact may be shown in the frog. The gastrocnemii of the two sides, with the sciatic nerves, are dissected out, and an exciting circuit is so arranged that the interrupted secondary currents pass through the upper ends of both nerves in series (Fig. 105). A galvanic cell is connected with two non-polarisable electrodes (*np*, *np*) placed on the nerve of B, so that a current runs in the nerve in an ascending direction; this will block the passage of impulses. The exciting current is then sent through both nerves by the electrodes e_1 and e_2. The muscle A enters into tetanus, which gradually subsides owing to "fatigue."

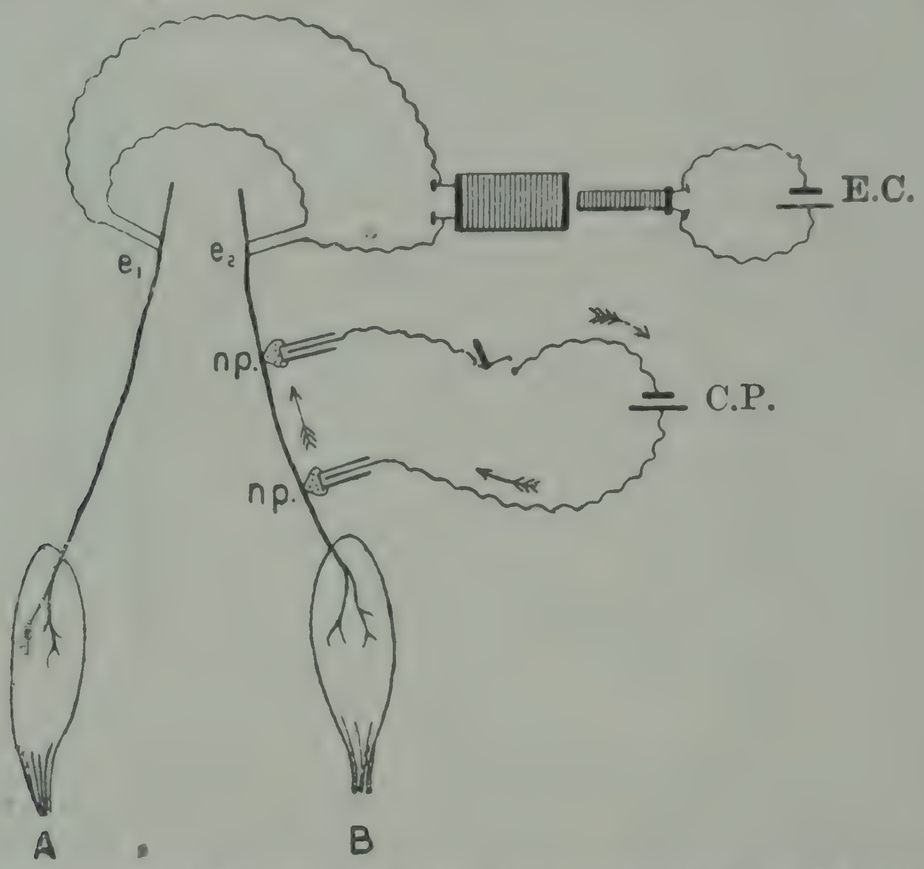

Fig. 105. Arrangement of Experiment for demonstrating the Relative Absence of Fatigue in Medullated Nerve Fibres.
E C, exciting circuit; C P, polarising circuit.

When A no longer responds to the stimulation, the constant current through the nerve of B is broken. B at once enters into tetanus. Since both nerves have been excited continuously it is evident that the fatigue does not affect the nerve trunk.

But although repeated stimulation does not reduce the nerve to an inexcitable and non-conducting state it would be wrong to suppose that it produces no change at all. The phenomena of the refractory period and the after-potentials are indications of incomplete recovery of normal membrane polarisation, and hence if stimuli follow one another with sufficient rapidity, certain consequences follow. If the intervals between stimuli are shorter than the relative refractory period, the second and subsequent stimuli produce smaller spikes than the first one (*v.* Fig. 94), and may show a progressive decline. Also as stimulation continues the negative and positive after-potentials increase (Fig. 93), and during the positive after-potential the excitability and conduction velocity are subnormal.*

ELECTROTONUS AND POLARISATION PHENOMENA

Electrotonus. When a constant current is passed along a motor nerve its direction is called *descending* when the anode is the electrode further from the muscle, and ascending when it is the nearer. Such a constant current is often called a *polarising current*, and many of the phenomena produced by it are due to changes of the state of polarisation of certain structures in the nerve. If the nerve be very excitable, the muscle may be thrown into a tetanus during the whole time that a *strong descending* current is passing ("closing tetanus"). On the other hand, if a strong *ascending* current be passed through the nerve for a considerable time, the muscle when the current is broken may go into "opening tetanus" for several seconds. Usually, however, the muscle responds with a single twitch at the make and break of a moderate current, although, on investigating the condition of the nerve *during* the passage of the current, we find that it is considerably modified. This modification in the condition of the nerve is spoken of as *electrotonus*, and includes changes in its excitability, conductivity and electrical condition.

---

* Gasser. *Amer. J. Physiol.*, 1935, **111**, 35.

To demonstrate the changes in *excitability* the apparatus shown in Fig. 106 may be used, with a nerve muscle preparation. A constant current from the battery is led through a part of the nerve by means of non-polarisable electrodes, about one inch apart. In this circuit we put a reverser and a key. This is the polarising circuit. The coil is arranged so that we may use break induction shocks, which are applied to the nerve to test its excitability, in the neighbourhood of the pole nearest to the muscle.

We employ submaximal induction shocks throughout the experiment. We now throw a descending polarising current into the nerve, *i.e.* the cathode is nearer to the muscle. At the make of this current the muscle will respond with a twitch which we may ignore. We now, with the current still flowing, test the excitability of the nerve, and we find that in the region of the cathode the stimulus, which before was submaximal, has now become maximal.

We now reverse the direction of the polarising current, and find that the stimulus when applied near the anode has little or no effect (Fig. 107).

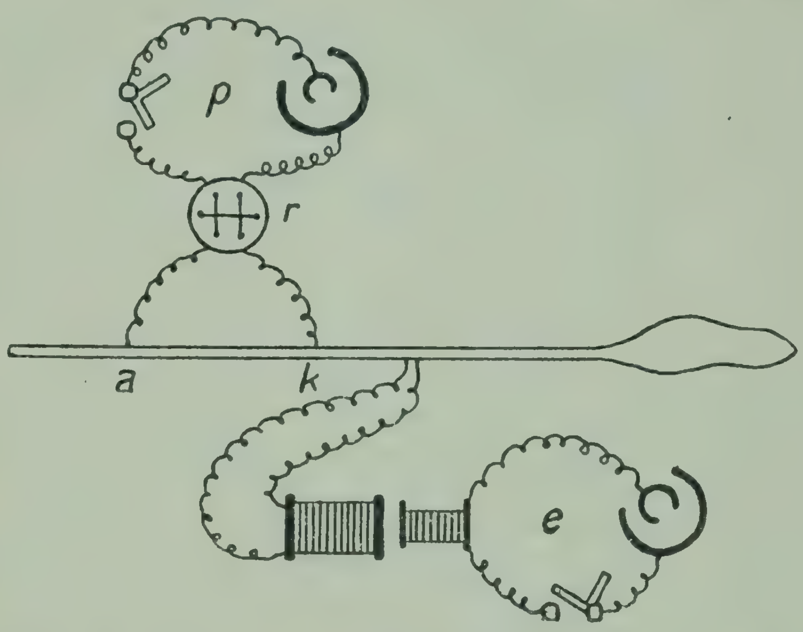

FIG. 106. Arrangement of Apparatus for showing Electrotonic Changes in Excitability. *e*, exciting current; *p*, polarising current; *r*, Pohl's reverser.

If the testing stimulus be applied between the anode and cathode, we obtain information as to the *conductivity* of the nerve as a result of electrotonus. We thus find that in anelectrotonus the impulse may be completely blocked if the polarising current is a strong one (anelectrotonic block).

On break of the polarising current the condition of the nerve returns to normal, and the stimulus is once more submaximal throughout. This return to normal is not immediate, since the first effect of breaking the current is a swing back, so to speak, past the normal, the diminished excitability at the anode giving place to an increased excitability which gradually subsides, while the neighbourhood of the cathode acquires a condition of diminished excitability, and this only gradually gives place to a normal condition.

This experiment teaches us that, during the passage of a constant current through a nerve, there is an increase in the excitability in the nerve near the cathode, and a diminution in excitability and conductivity near the anode. These conditions of increased and diminished excitability are spoken of as *catelectrotonus* and *anelectrotonus* respectively. Just after the breaking of the current there is a reversal of these states, called the *resolution of catelectrotonus* (or of anelectrotonus). Now the event that takes place at the cathode on make, and at the anode on break of a constant current is, as the last experiment shows us, a rise in excitability, in the former case from normal to above normal, in the latter from subnormal to normal. Hence we may say that the excitation by a constant current is caused by a sudden rise of excitability,* culminating in the discharge of an impulse, which may be due either to a sudden appearance of catelectrotonus or a resolution of anelectrotonus. We have said sudden because the steepness of the change is, as we have seen elsewhere, a necessary factor in causing excitation. The more excitable the tissue, *i.e.* the shorter its chronaxie, the more rapid must the change be if it is to culminate in excitation. In muscle we have seen similarly that a make contraction always starts from the cathode, and a break contraction from the anode.

---

* ROSENBERG. *Proc. Roy. Soc.* (B.), 1937, **124**, 308.

There must be, somewhere between the anode and cathode, an indifferent point—that is to say, a region where the excitability is neither increased nor diminished. This indifferent point is nearer the anode when the polarising current is weak; and approaches the cathode as the current is strengthened, so that with very strong currents nearly the whole intrapolar length is in a condition of anelectrotonus (Fig. 107).

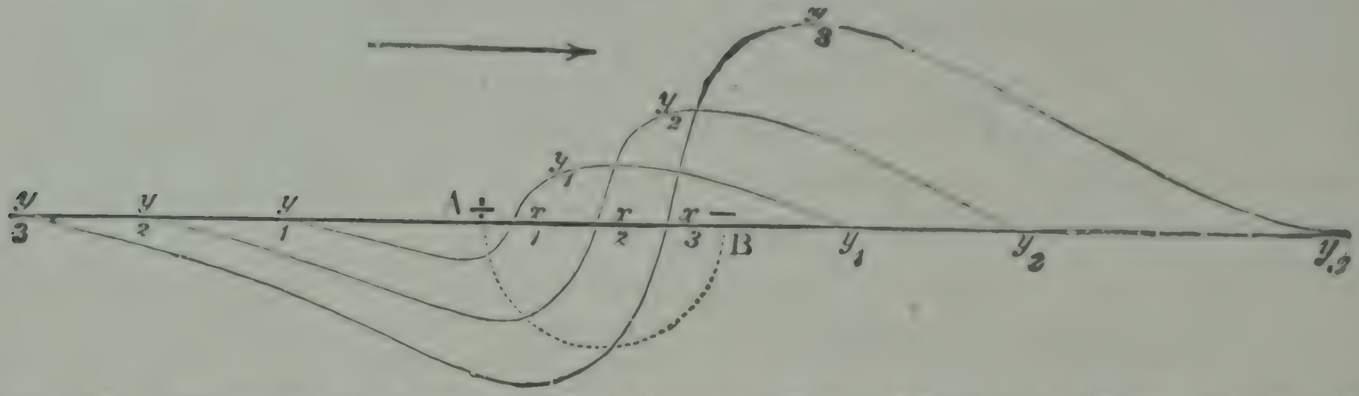

FIG. 107. Diagram to show the Variations of Excitability in a Nerve during the Passage of Polarising Currents of different Strengths. The degree of change is represented by the distance of the curves from the base line; the part of the curve below the line signifying *decrease*, that above the line *increase* of irritability.

A, anode; B, cathode; y_1, effect of weak current; y_2, medium current; y_3, strong current. It will be noticed that the indifferent point, x, where the curve crosses the horizontal line, approaches nearer and nearer the cathode as the current is increased in strength. (After PFLÜGER.)

When a strong polarising current is used, the depression of conductivity at the anode is so marked that no impulse can pass this region. Thus if we send a very strong ascending current through the nerve, there is no contraction at make. This is owing to the fact that the impulse started at the cathode on make of the current cannot reach the muscle, its passage down the nerve being blocked in the region of the anode (Fig. 108, A). Similarly at break of a strong descending current, the excitation originating at the anode is blocked by the great depression at the former cathode (Fig. 108, B).

FIG. 108. Diagram to show the Blocking Effect of a strong Constant Current passed through the Nerve of a Nerve-muscle Preparation.

With the weakest currents excitation occurs only at make, since the rise of catelectrotonus, is always more effectual than a break stimulus, *i.e.* the resolution of anelectrotonus.

These results probably hold good for all excitable tissues, and, when tabulated to indicate the results of stimulating nerve-muscle preparations by opening and closing circuits with weak, medium or strong currents, ascending or descending, are sometimes spoken of as "*Pflüger's law of contraction.*"*

If the electrodes are less than 20 mm. apart, the current necessary to excite a nerve is greater the nearer they are to one another. The threshold current leaving the cathode is the same whatever the interpolar length.† But, owing to the greater electrical conductivity of the interstitial fluid as compared with the sheaths of the axis cylinders, the nearer the electrodes are together the greater the fraction of the total currents shunted by the interstitial fluid.

ELECTROTONIC POTENTIALS. If points *e* near one of the electrodes P be tapped off during the passage of a polarising current, and their potentials compared with that of

a more distant point e_1 on the nerve (Fig. 109) by an electrometer, it is seen that the local potentials extend for some distance beyond the electrodes* (Fig. 110). These are called *electrotonic potentials*, and are confined to the outer sheaths of the structures concerned.

---

* HECHT. *Z. f. Biol.*, 1931, **91**, 252.

Electrotonic Currents. If, instead of an electrometer we use a galvanometer through which a current can pass, between extrapolar points, as illustrated by *a*, *b*, *c*, *d*, in Fig. 111 we find a steady current in the extrapolar portions of the nerve from *a* to *b*, and from *c* to *d* *i.e.* *both* currents are in the *same* direction along the fibre as the polarising current.

The currents so produced are called the "electrotonic currents." They must not be confounded with the action potential which originates at one of the poles only at make or break of the current, and is transmitted thence as a wave. The electrotonic potential, on the other hand, commences almost instantaneously,* takes a very brief time to reach its maximum, then remains nearly stationary, lasts the whole time that the current is flowing through the nerve, and does not spread far along the fibre. It is caused by the occurrence of polarisation in membranes lying between the sheath and the better conducting central part of the nerve fibre, and may be reproduced on a model made up of a glass tube filled with normal salt solution, containing a wire stretched through it (Fig. 112).† The polarisation in question occurs at the surface of the wire. On leading a current through *a* and *b*, and connecting *c* and *d* or *e* and *f* with a galvanometer, a current will be observed in the extrapolar portion of the model which, as in nerve, is in the same direction as in the intrapolar. A useful model illustrating the electrical properties of nerve may also be made with resistances and leaky condensers.*

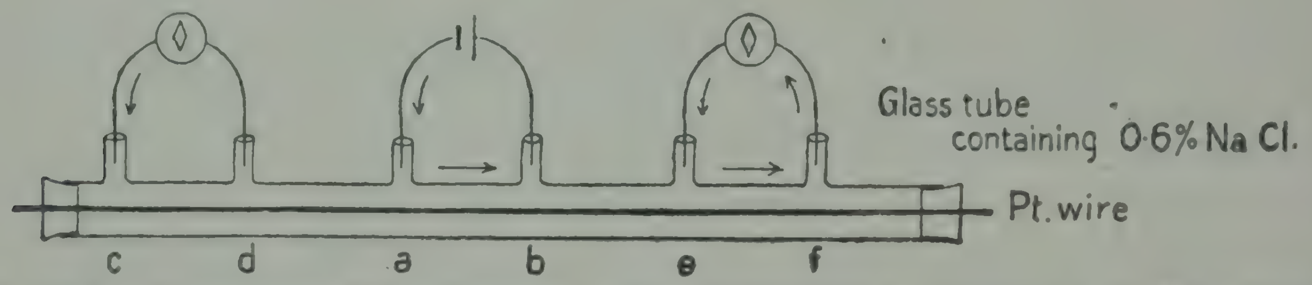

Fig. 112. Apparatus for imitating the Polarisation Phenomena in Medullated Nerve ("Core-conductor" model).

In the case of nerve, which normally has polarised membranes, the effect of the constant current is an increase of the natural polarisation beneath the anode and a decrease beneath the cathode.

This altered polarisation will not disappear at once on breaking the polarising current. On replacing the battery by a galvanometer, we shall get a current through it in the direction opposite to the previous polarising current, viz. from anode to cathode.

Relation of Electrotonic Changes to Excitation. When a constant current is led into a nerve the potential at the cathode rises very rapidly from the resting value V_0, by the establishment of an electrotonic potential, V. The rise of electrotonic cathode potential is exponential, and when it has reached a certain value, say U_0, the extent of the excitation due to polarisation change becomes sufficient to be self-propagating. With a current of rheobasic strength this is the fullest polarisation the current can produce; if of twice rheobase, excitation occurs when half the possible polarisation has occurred, and so on. In other words, for currents of short duration a constant minimal quantity of electricity is needed to produce excitation. This quantity is about 10^{-9} coulombs for medullated nerve and about 10^{-6} for non-medullated nerves.‡

The time constant *k* of the change of cathode potential from V_0 to U_0 in the expression

$$-\frac{dU_0}{dt} = \frac{(U_0 - V_0)}{k}$$

has a value for frog's nerve at 20° of about 0·35 msec., and is related to the chronaxie, which $= 0{\cdot}693\,k$.§

A second time-factor has been observed by Hill, and is called the *time-factor of accommodation.* It is well known that a slowly rising current has a higher threshold than an abruptly increasing one—the tissue seems to get accustomed to the stimulus and can disregard it until it reaches a greater strength before it responds to it. Let us call the potential at this raised threshold U_x. Then, on passing the rising current the threshold of the nerve has risen from U_0, its former threshold, to U_x at a definite rate, given by the expression:

$$-\frac{dU_x}{dt} = \frac{(U_x - U_0)}{\lambda}$$

where λ is the time-constant of accommodation. Its value is from ten to one hundred times as great as that for *k*, *i.e.* it is about 35 msec. for frog's nerve: it may vary independently of *k*, the most remarkable instance of this being produced by alteration in the concentration of Ca ions.* If the Ca ions are increased the value of λ is greatly reduced, *i.e.* the tissue accommodates itself very rapidly, or, in other words, it takes more sudden changes to excite it. Conversely, when the Ca ions are reduced, the tissue becomes hyper-excitable; this is a well-known fact in connection with the occurrence of tetany consequent on parathyroidectomy, or over-breathing, which reduce the Ca-ion concentration of the blood.

§ Hill. *J. Physiol.*, 1935, **83**, 30P.

The accommodation constant may be used to explain many facts in connection with nerve physiology. Thus, with a weak constant or slowly rising current, excitation will not occur until V reaches and passes U_X. Again, the anode cannot excite at make because the anodic V cannot catch up with U, but at break the V returns faster to V_0 than U does to U_0, so that excitation takes place.

Electrotonic changes also occur in other excitable tissues, such as muscle,† but these cannot be considered here.

ELECTRICAL STIMULI AS APPLIED TO HUMAN NERVES

When we attempt to apply the results gained on frog's nerves to man, we are met at once by the difficulty that we cannot apply stimuli to human nerves directly. So usually *unipolar* excitation is used, a small or stigmatic electrode, either anode or cathode, being applied to the skin over the nerve to be stimulated, and the other, a large one, to some indifferent area, such as the back. Under these circumstances the current is concentrated as it leaves the stigmatic electrode, and diffuses widely in the body, seeking the lines of least resistance. Thus it is impossible to get pure anodic or cathodic effects. If the anode be applied over the nerve, the current enters by a series of points (the polar zone), and leave by a second series (the peripolar zone). The polar zone will thus be in the condition of anelectrotonus, and the peripolar zone in that of catelectrotonus (Fig. 113). The currents however, will be more concentrated at the polar than at the peripolar zone, and so the former effect will predominate. These restrictions in the application of the current cause slight apparent irregularities in the "law of contraction" as tested on man.

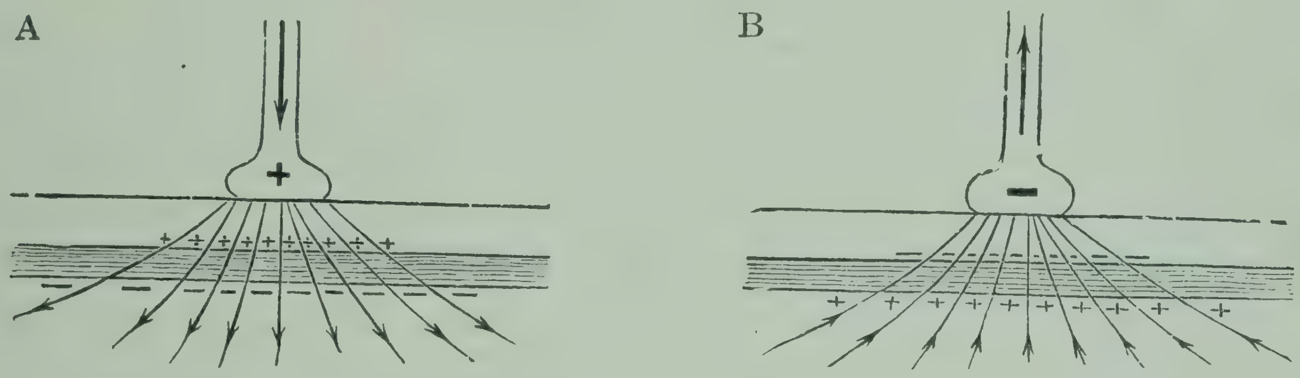

Fig. 113. Electrodes applied to the Skin over a Nerve Trunk.

In A the polar area is anelectrotonic and the peripolar catelectrotonic. The former condition preponderates, since the current here is more concentrated. In B the conditions are reversed, the polar zone corresponding in this case to the cathode. (Waller.)

In stimulating the nerves of man for the purpose of determining the conditions of the different muscles, we may use either faradic or galvanic stimulation. The electrodes are covered with chamois leather moistened with salt solution in order to diminish the resistance of the skin. When it is desired to stimulate any given muscle, the stigmatic electrode is brought as nearly as possible over the spot where the muscle receives its motor nerve. These *motor points* have been mapped out, and reference is generally made to a diagram in determining the point for any given muscle. By reversing the current the stimulating lectrode may be made either anode or cathode. It is found that stimulation occurs most asily on closure of the current with the stimulating electrode the cathode; with the greatest difficulty when the current is broken and the stimulating electrode is the cathode.* These different contractions are generally represented by capital letters, and in order of increasing difficulty of elicitation we have :—

CCC = cathodal closing contraction.
ACC = anodal closing contraction.
AOC = anodal opening contraction.
COC = cathodal opening contraction.

The problem of the determination of the chronaxies of the human nerves or muscles has been investigated by Bourguignon,† who made the important observation that different muscles (with their nerves) have different chronaxies, and further, that in the same segment of a limb, muscles of similar function have the same chronaxie. Thus when the chronaxie of flexor and extensor muscles is compared it is found that the flexors have a chronaxie only half as great as the extensors. This agrees with the relative duration of the contractions, which Baird and Fulton ‡ find to be about 30 msec. and 40 msec. respectively.

When the motor nerve to a muscle has undergone degeneration, the muscle also begins to degenerate, and we find certain alterations in its chronaxie. For some time after section of the motor nerve the chronaxie of nerve and muscle remains unaltered ; this period may be up to a week or ten days in the sciatic-gastrocnemius of the frog, and at the end of this time the nerve has ceased to function. The chronaxie of the muscle then steadily increases, and at the end of three months is up to five times its normal value. In warm-blooded animals and in man the change takes place much more rapidly.

The muscle after degeneration of its nerve gives a slow contraction and is frequently of such high chronaxie as to be inexcitable to the brief faradic shock (reaction of degeneration). In the second place, qualitative alterations in excitability may be present, so that ACC may be obtained with a smaller current than CCC. Changes in the chronaxie are, however, detectable long before this stage is reached.

THE NATURE OF THE NERVE IMPULSE

Under this heading we have two questions to discuss : (*a*) the nature of the change aroused at the stimulated spot in the fibre, and (*b*) the mode of propagation of the excitatory change away from the stimulated spot and along the fibre.

The nature of the electrical potential changes, the all-or-none character of the impulse, together with the normal absence of decrement in the excitatory process, have been taken as an indication that the plasma membrane of the axon is the seat of energy changes which may be let loose under the influence of a stimulus.

It is not known how some types of stimuli, *e.g.* mechanical, act, but in some way they alter the local state of polarisation of the plasma membrane, causing either depolarisation, or a reversal of polarisation. For this reason electrical stimulation by a cathode is far the most efficient, since in this way an immediate negative charge is imparted to the outer membrane surface. As a result of a structural change which this induces in the membrane, this now becomes freely permeable to ions to which it was previously impermeable. If the applied cathode potential is a feeble one, and small in extent, the result is merely a drop in the resistance of the membrane and a local non-propagated response : but if it is powerful and extensive enough to reverse the polarity of the membrane over a sufficient area, then a

‡ BAIRD and FULTON. *Amer. J. Physiol.*, 1927, **81,** 462.

propagated impulse is started off. Study of the excitability changes beyond a block prove that the propagation is electrical in character, current flow from resting to active membrane along the outside, and in the return direction on the inside of the membrane, as shown in Fig. 114, acting in the same sense, and producing on nearby resting membrane the same result, as an applied cathode. The process thus spreads from section to section along the nerve fibre, as originally postulated by Herman in 1879.* At the portions occupied by the impulse, the polarity is reversed and the properties of the membrane temporarily altered, and no stimulus, however strong, can produce any further effect. Hence the refractory period.

These changes do not involve any considerable chemical change or heat production, the energy for the impulse being stored up in the membrane as polarisation charges. It is probable that the surface membrane, largely composed of lipoid, separating the axis cylinder from its surroundings, is the site of the propagated disturbance. If we suppose that this is only two molecules thick,† it is evident that the amount of energy involved would be very small, as the volume concerned would be only a very small portion of that of the whole fibre. Thus the active element in a nerve fibre would be a bimolecular film maintained in a polarised state at the expense of the oxidative reactions which normally go on slowly during life. These reactions, and hence the chief energy expenditure, are concerned with restoring the state of polarisation after the impulse has passed. Hinder the oxidation and the film remains depolarised, so that the impulse can no longer be transmitted.

After the impulse has passed along the fibre, this is repolarised in the resting direction : the process takes time, during which the fibre is in a relatively refractory state.

The depolarisation during activity is accompanied, or perhaps caused, by an increase in the permeability of the nerve membranes. In consequence of this, certain substances, notably potassium, pass out of the fibre into the surroundings and Na enters it. We may suppose that it is this passage of potassium ions through membranes previously able to restrain them from wandering, which constitutes the essential cause of the depolarisation. Similar phenomena occur in muscle, and it is perhaps worthy of note that both tissues are readily rendered inexcitable when dilute solutions of potassium salts are applied to their surfaces.

Acetyl choline is released from cholinergic fibres and sympathin from adrenergic ones during the passage of an impulse ; thiamine is also said to be set free. Whether, as some suppose, these are the cause, or as others guess, the effects of the electrical depolarisation has yet to be decided.

Lillie's Model. R. Lillie has drawn attention to the striking analogy between the nerve impulse and the change which can be propagated along a "passive" iron wire. If iron wire be immersed in nitric acid of a specific gravity exceeding 1·2, it reacts only momentarily and then enters into a passive state in which no further solution occurs, a thin film of oxide being developed and maintained on its surface. Yet this seemingly stable system is highly reactive. Activation may be brought about by electrical, chemical or mechanical means. For example, if the wire is touched by a piece of zinc, a local electrical circuit is produced and it becomes activated at that spot, and turns black and effervesces ; moreover, the activation thus initiated spreads as a wave of definite velocity over the whole surface of the wire, lasts for a few seconds, and disappears, the iron becoming passive again. But now the freshly passivated iron is resistant to re-activation for a minute or so (refractory period), after which the sensitivity to activation returns again. Mechanical stimulation, summation, electrotonus, polar stimulation on electrical activation, etc., can all be imitated on this fascinating model, as can also some of the facts of the time-relations of electric currents, such as the relative inefficacy of slowly rising currents to activate as compared with currents of abrupt onset. Thus the iron wire in these particular conditions transmits a self-propagating electrochemical change, limited to its surface film and in many respects analogous to the propagated impulse in a nerve.

TRANSMISSION OF EXCITATORY STATE FROM NERVE TO EFFECTOR TISSUE

The excitatory process travelling down a motor nerve is transmitted to the muscle by the intermediation of the motor end-plate. A similar break seems to occur in the central nervous system wherever an impulse is propagated from the axon process of one nerve cell to the body or dendrites of another nerve cell, and the area of contiguity, where an impulse passes from one neuron to another, is spoken of as a *synapse*. The presence of the end-plate between muscle and nerve imposes certain new conditions on the conduction of the excitatory state. One of the most important of these lies in the fact that the conduction across the end-plate, like that across the synapse of the central nervous system, is *irreciprocal*. An excitatory process started in the nerve is transferred easily to the muscle. But an excitatory process started in the muscle does not extend back to the nerve. This fact may be shown on the frog's sartorius. If the upper (pelvic) end of the muscle be split, as in Fig. 115, a stimulus applied to the nerve-free end of one of the limbs, *e.g.* at A, causes a contraction, with accompanying electrical changes, in the corresponding half of the muscle, but no impulses, *i.e.* no electric changes, in the motor nerve.

† Danielli. *J. Physiol.*, 1941, **100**, 117.

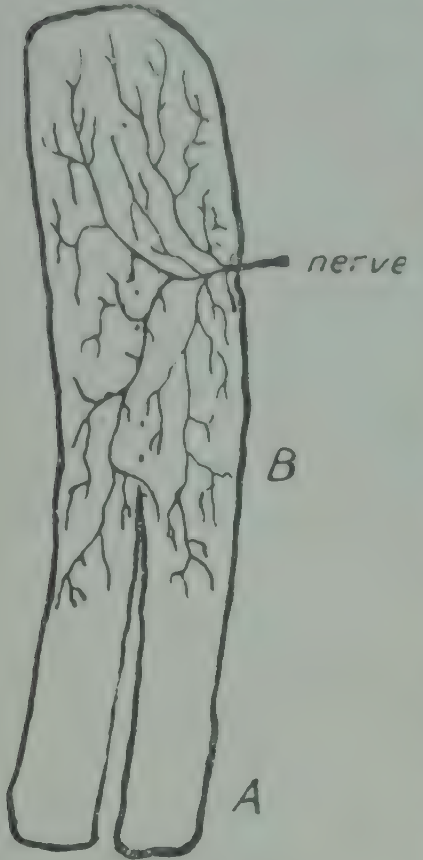

FIG. 115.

The transmission of the excitatory condition across the end-plate from nerve to muscle occupies time. If we compare the latent period of a muscle stimulated directly with its latent period when excited through the nerve, we find that there is an increased period of delay in the latter which is not wholly accounted for by the time taken for the impulse to travel from the stimulated nerve point to the muscle. The extra delay is due partly to the fact that the terminal branches of the nerve fibres supplying any motor unit are much finer than the axons from which they spring; they therefore probably conduct more slowly. But there is further delay due to processes occurring in the end-plate. The total delay in passing from the coarser fibres to the muscle is probably about 3 to 4 msec. for the frog's gastrocnemius, but for rapid mammalian (*e.g.* eye) muscles, it is only 0·7 msec.*

The spread of excitation from the end-plate seems to be the weakest point in the neuro-muscular chain. We have already seen that, when the nerve of a nerve-muscle preparation is stimulated repeatedly, the muscle very soon shows signs of fatigue, and that the seat of this fatigue is not in the nerve nor in the muscle, but at the junction between the two. Similarly, curare quenches the spread from end-plate to muscle.

The classical electrophysiological view is that the excitation of muscle through nerve depends on the electrotonic potential changes occurring at the nerve ending. The occurrence of such *end-plate potentials* (e.p.p.) can best be demonstrated in well-curarised muscle; when the motor nerve, *e.g.* to a strip of curarised cat soleus, is stimulated, a potential is set up in the part rich in end-plates.† It is due to a local depolarisation, reaches a peak in 2·5 msec., decays exponentially, and in curarised muscle (or during the refractory state) suffers a decrement of at least 50 p.c./mm., so that it never travels far. In partial curarisation a second volley falling a few msec. after a first produces a greatly increased e.p.p., followed by depression of several seconds.‡

Comparison with a Partial Block. In many respects the conduction of impulses along a partially blocked nerve resembles that across the neuromuscular junction or across a synapse. The properties of a nerve block were first studied from this standpoint by Wedensky.§ Heat, cold, galvanic polarising currents or various chemical agents, *e.g.* cocaine or alcohol have been used to cause the partial block. A partly blocked nerve will conduct impulses at low frequency, but not at high frequency—a phenomenon called Wedensky inhibition. In the blocked region there is a raised threshold of excitation, but beyond the block the threshold is lowered. This difference is accentuated if impulses at a rapid rate are sent into the region and fail to pass through it. When this happens, there is for every impulse arrested at the block a negative electrotonic potential below the block.* When the summated electrotonic potential reaches a critical value, slightly above that of a spike potential, an impulse is generated, thus " leaping " the block. It is believed that a similar state of affairs obtains at neuromuscular and synaptic junctions.†

Humoral Transmission. There is now reason to believe, however, that the excitatory state set up in the muscle is associated with, and perhaps due to, the liberation, at or near the nerve ending, of the potent chemical substance acetyl choline, which is liberated at the end-plates by the arrival of the nervous impulse, rapidly exerts its action in producing contraction, and then is rapidly destroyed. The denervated muscle, as mentioned on p. 136, responds to a dose of acetyl choline by passing into contracture. If small doses (2–20μg.) of acetyl choline are injected direct into the arteries to a normal muscle, quick contraction of the muscle results, and if the muscle is previously eserinised, the response to acetyl choline or to nerve stimulation is increased : curarine abolishes the response to acetyl choline, but atropine does not. Curarine probably acts by combining with some receptor group in the end-plate material and shielding it from combination with acetyl choline.‡

The end-plates contain the enzyme choline esterase in a concentration many thousand times as high as in muscle fibres alone. Hence the acetyl choline could be destroyed with the necessary speed during the refractory period.§ The release, and subsequent destruction, of acetyl choline at its sites of operation are estimated to take place in time intervals of the same order of magnitude as those of the electrical changes of the spike potential.

In the disease myasthenia gravis, the subject shows extreme muscular weakness and fatigability. This is believed to be due to either excessive activity of cholinesterase or failure of formation of acetyl choline at the motor end-plates. The patients are restored to muscular strength in spectacular but transitory manner by injection of prostigmine, a synthetic analogue of eserine with similar anticholinesterase activity. Other anticholinesterase agents have also been tried, but these often have general toxic effects.

It would seem, therefore, that liberation of acetyl choline at the nerve endings may be a factor in the passing on of excitation from nerve to muscle, and it will be shown later (Chapter XXIII) that the transmission of excitation at other points of junction in other tissues is probably also effected by similar chemical transmitters, and it has even been suggested that the substance is responsible for the brief and reversible increases in ionic permeability which lie at the root of the depolarisation manifesting itself as the electric potential change in nerve fibres and other tissues. Very possibly connected with this, movements of potassium and calcium ions are also concerned, either primarily or secondarily, in the process of transmission.

HISTORICAL NOTE

Scholarly curiosity has unearthed many early philosophic speculations regarding the functions of the nervous system, but space will not allow of their being mentioned here. It is true that DESCARTES (1596–1650), one of the later of these philosophers, evolved speculations (publ. 1662) in which considerable foresight was subsequently discerned, or supposed ; but the lack of experimental, or even of anatomical, basis for these theories, robbed them of much of their scientific value, as STENSEN, indeed, pointed out.

The essential anatomical foundations began to be laid by THOMAS WILLIS (1659) and by STENSEN (1662), and have been continued by many since ; the preliminary hardening of tissue (REIL, c. 1800) ; the method of serial sections (STILLING), and of staining (GERLACH, 1858), of dissociation by forceps (MEYNERT), and the introduction of the WEIGERT method (1884) all played an important part in these increasingly detailed anatomical studies. It is more difficult to say at what date instructive and well-directed experiments were initiated, but, apart from those of GALEN, which for centuries were unique and disregarded pointers, perhaps some observations on decapitate frogs by Johann BOHN in 1686, and the ablation of the cerebrum and cerebellum by du VERNEY in 1697 may be accepted as early beginnings.

HALLER (1757) recognised that nerves were essential to both feeling and movement ; and conveyed messages to and from the brain, which he thought could also feel.

The first outline of the principle of reflex action, and the demonstration of the dependence of each reflex on the integrity of a particular part of the central nervous system, was given by ROBERT WHYTT (1768) : the conception of a reflex *arc*, however, had to wait until a clear distinction had been made between afferent and efferent nerves. This emerged with the demonstration of the functions of the ventral and dorsal spinal nerves by BELL (1811) and MAGENDIE (1822). The logical sequel, the conception of the reflex arc, was introduced by MARSHALL HALL (1833 ; 1850), who also showed the reflex nature of sphincter action, and the actions of chloroform and strychnine on spinal reflexes.

Although GALEN, in the 2nd Century had demonstrated that the paths for both movement and sensation passed along the spinal cord, it was not until the fifth to the seventh decades of the 19th Century that the approximate functions of the dorsal, ventral and lateral columns of the cord were discovered by the methods of section and stimulation (LONGET, TÜRCK, VULPIAN, SCHIFF, BROWN-SEQUARD, WOROSCHILOFF and others). The important fact that the fibres of the dorsal roots do not arise from cells of the grey matter was discovered by GERLACH (1871). The method of nerve degeneration discovered by WALLER (1850) not only allowed of the following out of nerve tracts, but supplied the important theoretical conception of the dependence of the axon, discovered by WAGNER (1851), upon the cell. Out of the realisation of this, and as a result of histological work by MARCHI, HIS and others, there grew the neurone theory (WALDEYER, 1891), which was supported and confirmed by the work of Golgi, Cajal and others, and which, together with the conception of the synapse by Foster (1897), has contributed so largely to the establishment of present-day views of the nervous system.

Not long after the promulgation of the idea of reflex action there appeared indications that conduction in the C.N.S. differed in many respects from that along nerves. Helmholtz (1854) showed that reflex time might be 12 times as slow as nerve conduction, and Exner (1873) that the transmission through the centres was generally slow: also Du Bois Reymond (1859) gave reasons for supposing that the rate of emission of the messages along motor nerves from the centres differed from their frequency when the motor nerves were stimulated directly.

Early speculators had often suggested that the different parts of the C.N.S. had different functions, but their enquiries were largely concerned with the search for the seat of the soul, which was variously located, *e.g.*, in the pineal body, the medulla, or even diffused over the whole body: Willis supposed that the corpora striata were the seat of sensation and movement. It was not until the early decades of the 19th Century that experimental ablations were practised with noteworthy results. Rolando (1809) showed that voluntary movement was lost after removal of the cerebral hemispheres, and Desmoulins (1825), Flourens (1842) and Goltz (1868) studied the various effects of removal of parts of the cerebral cortex, but without any definite ideas of localisation of function emerging. In the meantime there had been introduced, by Gall and Spurzheim (1812), the views on localisation of cerebral function which subsequently became known as Phrenology, and were soon quite discredited. The discovery, however, by Broca (1861) of an area in the brain the integrity of which was definitely essential for speech, was the first clear indication that there might be some localisation of function in the cerebrum, and this was further supported by the anatomical investigations of Meynert, the clinical observations on epileptiform convulsions by Hughlings Jackson (1868), and especially by the experiments of Fritsch and Hitzig in 1871, who showed that galvanic excitation of certain areas of the cortex resulted in precise movements of the limbs. The substitution of faradic for galvanic excitation by Ferrier, and his extensive exploration of the cortex of the ape (1874) firmly established the notion. Of sensory areas, the visual was studied by Ferrier, and its approximate location was fixed by Munk (1878). The motor areas in man were forecast in 1873 by Hitzig, the characteristic large cells of the area being discovered by Betz in 1874, and further confirmation of the functions of this area provided by Ferrier in 1879, and by Sherrington (1895–1917). Following the observations of Baillarger (1840), v. Kölliker (1885) and Meynert (1868) that lamination varied from place to place in the cortex, the mapping of the cortex into areas of characteristic structure and lamination was actively pursued (Bolton, Brodman, Campbell and others) until early in the present century. The fact remained, however, and still remains, that, apart from certain special areas to which specific functions can be attributed, large areas of cortex can be removed without any very serious effects, as was evidenced by a series of clinical cases ranging from that of Berenger de Carpi (1715) to the famous "American crowbar accident" of Bigelow (1850). The idea of a functional integration of the cerebral cortex, adumbrated by Foster (1897) is not necessarily in opposition to the view that there is localisation of certain executive zones of the cortex. The experiments of Pavlov (1898–1935) on the conditioned reflexes have perhaps provided reasons for such a compromise in outlook.

The analysis of the phenomena of reflex action, as exemplified by the spinal reflexes, forms the hard core of our knowledge of the physiology of the central nervous system. Apart from observations on irradiation of reflexes (Pflüger, 1853), on the fact of the possibility of central inhibition (Setschenov, 1863) and of facilitation (Exner, 1882), little real progress was made in the study of the spinal reflexes until the closing decades of the 19th Century, when the work of Sherrington began: he introduced the method of myographic analysis for the quantitative study of motor reflexes, and his work, outlined in "The Integrative Action of the Nervous System" (1906), forms the basis of our present-day knowledge of the reflex as an integrating mechanism of high precision, and threw a flood of light on the working of the entire central nervous system. The elegant studies of Magnus on postural reflexes provided a valuable complement to that work.

The location of various "centres" in the brain stem was sporadic throughout the 19th Century. The medullary respiratory centre was identified by Legallois in 1812; the corpora quadrigemina as a centre for light reflexes by Flourens in 1847; the medullary vasomotor centre by Ousjannikov in 1871, and so on. Views on the levels of integration of nervous functions took shape about 1884 largely under the influence of Hughlings Jackson.

Much labour has been expended in investigations on the cerebellum; the effects of its ablation were studied by Flourens (1822), Magendie (1824), and many others since, some of the most profitable studies being those of Luciani about 1890. It was first regarded as the seat of muscle sense by Lussana and Morganti in 1853.

The discovery of the autonomic system has been of slow growth. Galen described the vago-sympathetic trunk, the sympathetic chain, ganglia, rami, and splanchnics as branches of his sixth pair of nerves, and it was not until 1552 that Eustachio recognised the separate nature of the vagus. He described the sympathetic, however, as arising from the cranium. Willis, in 1644, gave the name of "intercostal nerve" to the sympathetic chain, and regarded it and the vagus as responsible for involuntary actions, and for "sympathetic" relations between various parts of the body, a conception which was widened considerably by Whytt (1751–1756).

It was Pourfour de Petit (1727) who first showed that the sympathetic did not arise from the cerebrum. The ganglia of the sympathetic were considered by Winslow (1732) and by Johnston (1764) to be independent centres, and it was not until the 19th Century that their real nature was understood. The independence of the ganglia was further stressed by Bichat (1801); he saw that the sympathetic was not as other nerves, but was a chain of ganglia, and he separated the nervous control of somatic from that of visceral functions, which were involuntary, and controlled such things as digestion, circulation, etc.

The cell bodies of the ganglia, and the white and grey fibres were distinguished by Ehrenberg (1833), and Valentin (1836) first recognised the white and grey rami, and their relation to the cord, while the first accurate description of the characteristic non-medullated fibres was given by Remak in 1838.

The vaso-motor functions of the sympathetic were simultaneously recognised by Claude Bernard and by Brown Sequard in 1852, and the ventral roots recognised as the origin of the sympathetic.

Embryological proof that the sympathetic arises from the spinal cord was given by Schenk and Birdsall in 1878, and in 1885 the important work of Gaskell began. He showed the relation between the white and grey rami, mapped out their anatomical distribution, and gave to the system the name of the involuntary nervous system: he divided this into bulbar, thoracicolumbar and sacral outflows, and noted an underlying antagonism between those nerves of the anabolic type, *e.g.* the vagus, and the katabolic sympathetic. The further understanding of the anatomical arrangement, and the distinction between pre- and post-ganglionic fibres (1893) was based on the nicotine method introduced by Langley and Dickinson in 1889. The name "autonomic" was introduced by Langley in 1898, and the "parasympathetic" and sympathetic were separately designated by him in 1905. This distinction was largely based on the action of drugs, especially of that of adrenaline, which Langley showed in 1901 closely resembled sympathetic stimulation in its effects. Later, the humoral theory of nervous action was introduced, chiefly as the result of the work of Loewi, Dale, Cannon, Magnus and others, and the distinction of cholinergic from adrenergic nerves introduced by Dale in 1934.

Modern work, employing as powerful tools the micro-electrode, valve amplification and the cathode ray oscillograph, is rapidly developing research in the C.N.S. in a variety of directions, and many important discoveries have already been achieved by these means.

CHAPTER XIII

GENERAL FEATURES OF A CENTRAL NERVOUS SYSTEM

THE central nervous system enables the individual to respond in a co-ordinated manner to changes in its environment. In the course of its evolutionary development the cells and their processes, the nerve fibres, of which it is essentially composed, have been endowed in an exaggerated form with the properties of excitability and conductivity inherent to lesser degrees in all living protoplasm. Being thus highly excitable and able to conduct the excitatory state with speed and precision for considerable distances, and often to distribute it over wide areas, it is able under appropriate conditions to put remote parts of the body in temporary functional connection with one another and by means of these connections to give close correlation between the actions of such parts.

A nervous system is functionally divisible into three series of parts, the *afferent*, the *central* and the *efferent*. The afferent portions consist of those nervous structures which normally originate and conduct nervous impulses towards the centres, and the efferent portions of those conducting outwards from the centres.

The afferent portions are connected with appropriate sensory receptors and serve to convey nerve impulses aroused by stimuli, *e.g.* visual, touch, etc., from the outer world (exteroceptive stimuli), or stimuli arising in the body itself, *e.g.* in viscera or muscles (interoceptive stimuli), to the nerve centres.

The most important stimuli which reach us from the outer world are those of light and sound and to a lesser degree (in man) of smell, since by these we obtain knowledge and warning of things at a distance from us. Taste, by enabling us to make judgments as to edibility is next in importance. These stimuli are all received by organs placed in the head, which therefore has the prior position in the body. Touch is more generalised and requires actual contact with the sensory surface. It is confined to the surface of the body, the deeper structures of which are totally insensitive to touch.

Of the interoceptive stimuli, important are those (proprioceptors) that arise in the muscles, joints, tendons, etc., which give us information as to the position of our limbs, etc., those from the labyrinth which tell us of the position of the head in space, or of its movement, and those from the various internal organs. Many of the interoceptive stimuli arouse no conscious sensations.

The nerve centres receive these impulses, some of which enter consciousness and produce an awareness of the world around us, and of the position and state of our own bodies. It is obvious that our knowledge of the universe, including that of our own bodies, is solely dependent upon, and limited by, these impressions. Many nervous impulses arriving at the centres do not enter consciousness at all, but nevertheless they play an important part in maintaining or regulating the many processes which are constantly proceeding, unknown to us, in the body.

The efferent parts of the system conduct impulses outwards from the centres, and these impulses represent the responses of the centres to the afferent impulses which they have received. When the efferent impulses so generated in, or reflected outwards by, the central portions arrive at their destinations in the so-called *effector organs*, *e.g.* muscle, gland, etc., these are thrown into action and this action represents the response mediated by the central portions as appropriate to meet the particular situation indicated by the afferent stimulus.

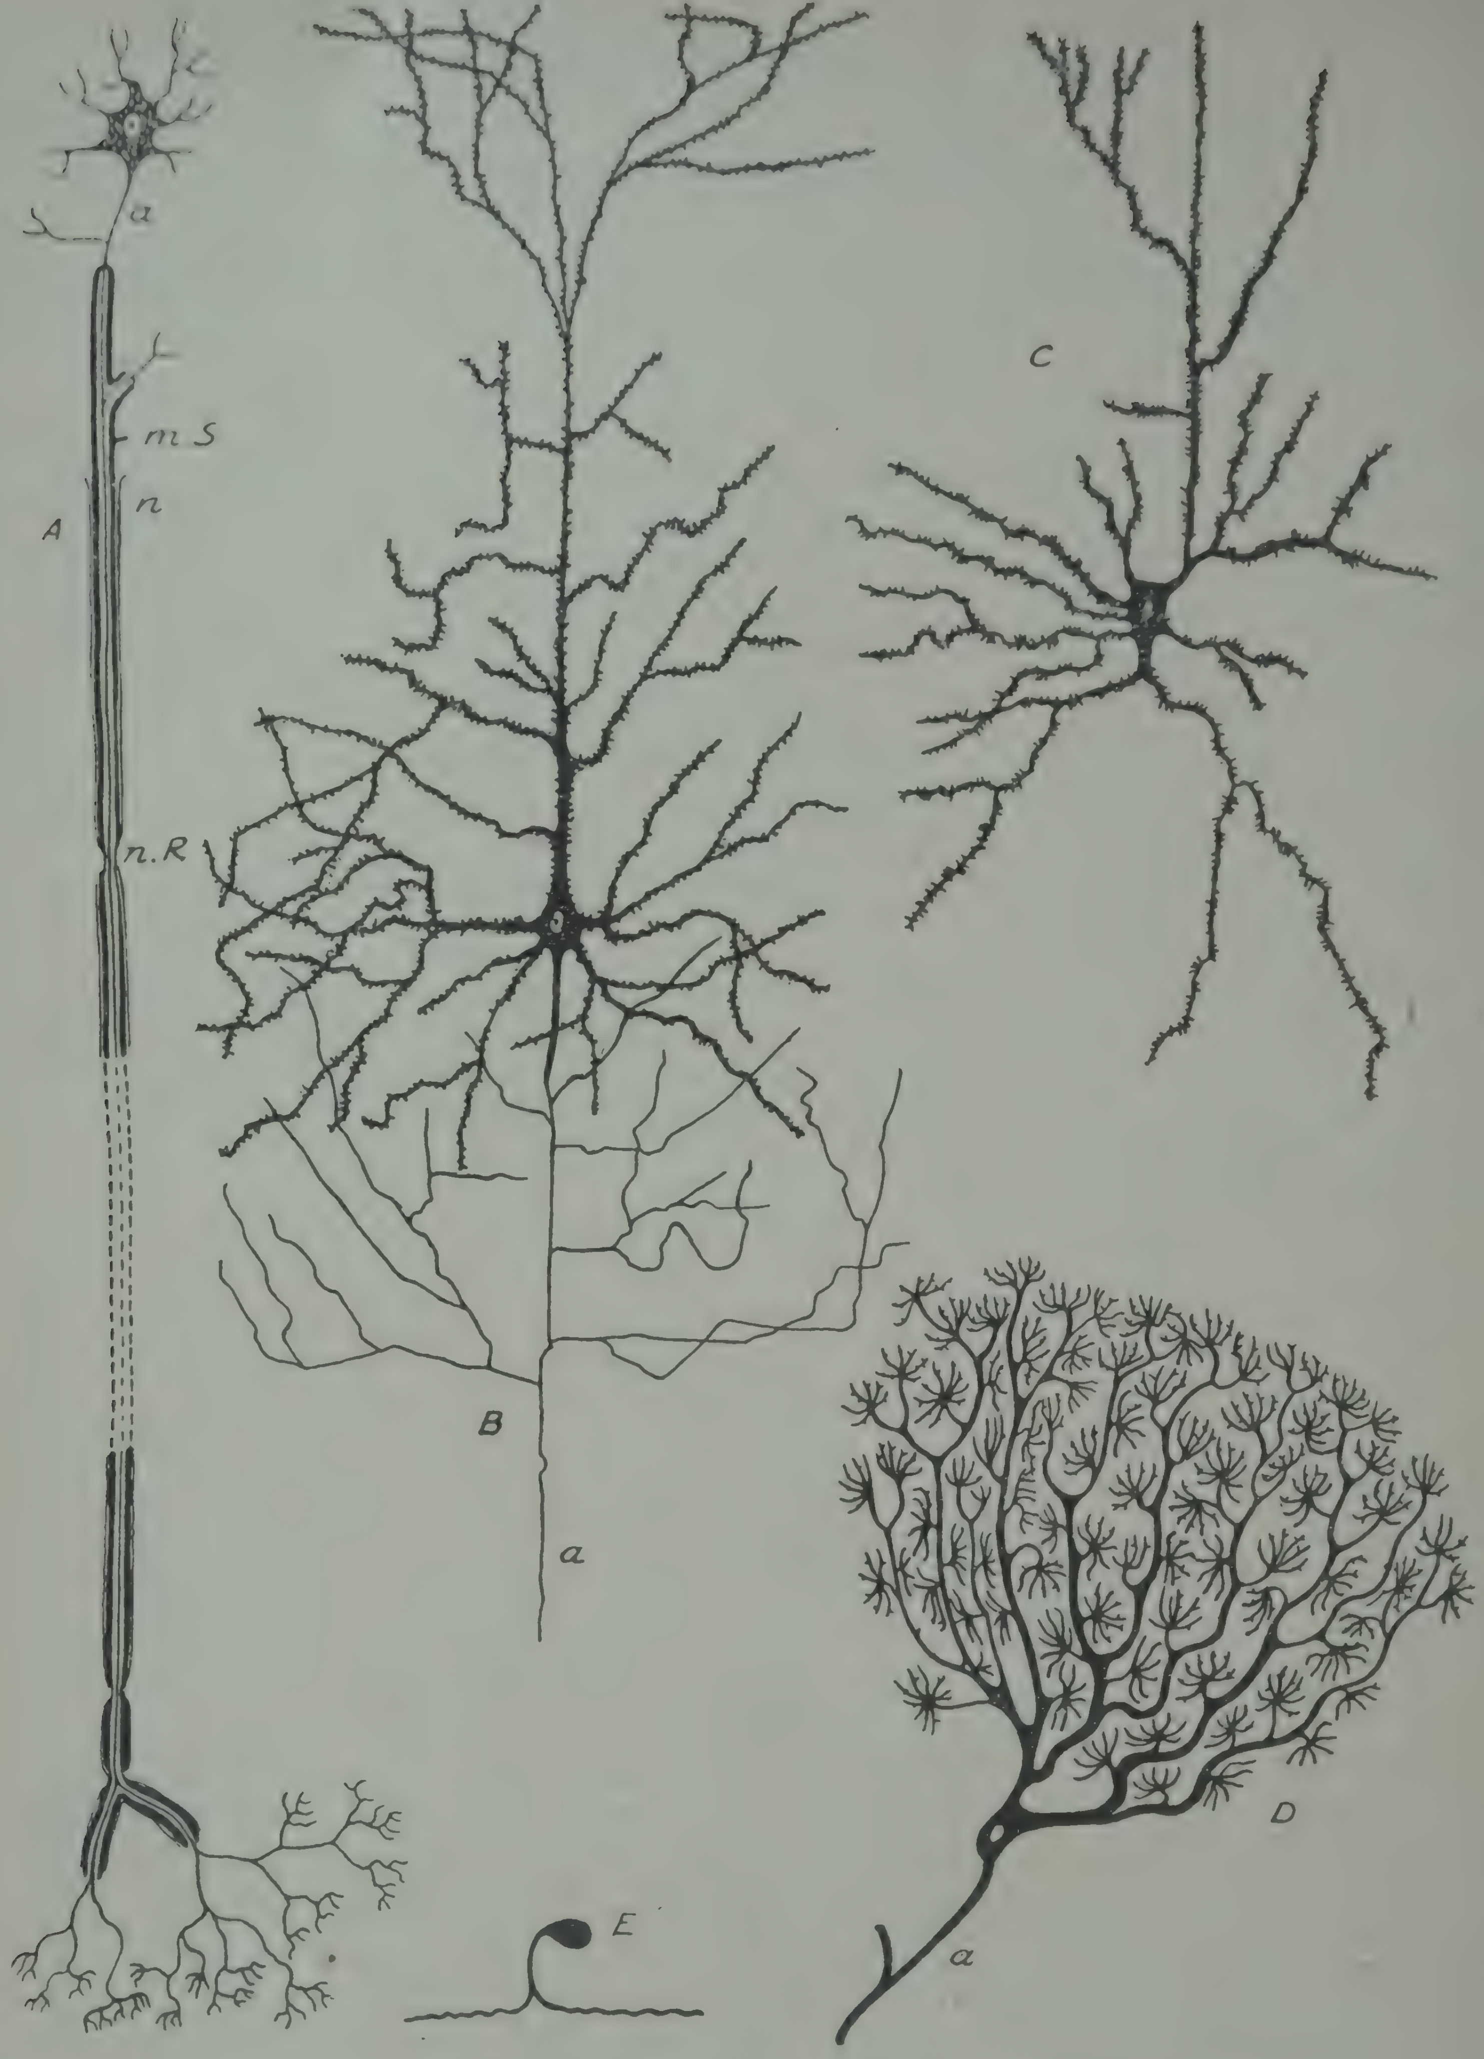

FIG. 116. Characteristic Types of Neurones (diagrammatic).

A Multipolar motor neurone of spinal cord.
B Pyramidal cell of cerebral cortex.
C Golgi Type II cell of cerebral cortex.
D Purkinje cell of cerebellum.
E Bipolar cell of spinal ganglion.
a The axon, is indicated in *A*, *B* and *D*.
n Neurolemma ; *m.S.* medullary sheath ; *n.R.* node of Ranvier.

Two main types of cells go to build up the nervous system, viz. *neurones* and *neuroglia* cells. The latter are supporting cells and are of no immediate physiological interest.

THE NEURONE is the name given to a nerve cell with all its branches. According to the neurone theory, now generally accepted, the neurone is the functional unit of the central nervous system. There are many kinds of neurones, classified variously according to situation, shape, size, number and length of branches, etc., but every neurone consists of two essential parts, viz. the *soma*, neurocyton or nerve-cell body, and second, its branches, which are nerve fibres (Fig. 116).

The branches of each neurone may vary from one to several in number, but one, and only one, of them is distinguished as the axis cylinder process or *axon*, the others being called dendrites or *dendrons*. The axon carries nerve impulses away from the soma, and the dendrons convey them towards the soma.

The neurocytons, or nerve cell-bodies, are found in the grey matter of the central nervous axis and in the various ganglia which lie outside it, but not in the white matter, which consists of nerve fibres only. Every nerve fibre, however, is a branch, either an axon or a dendron, of a nerve cell.

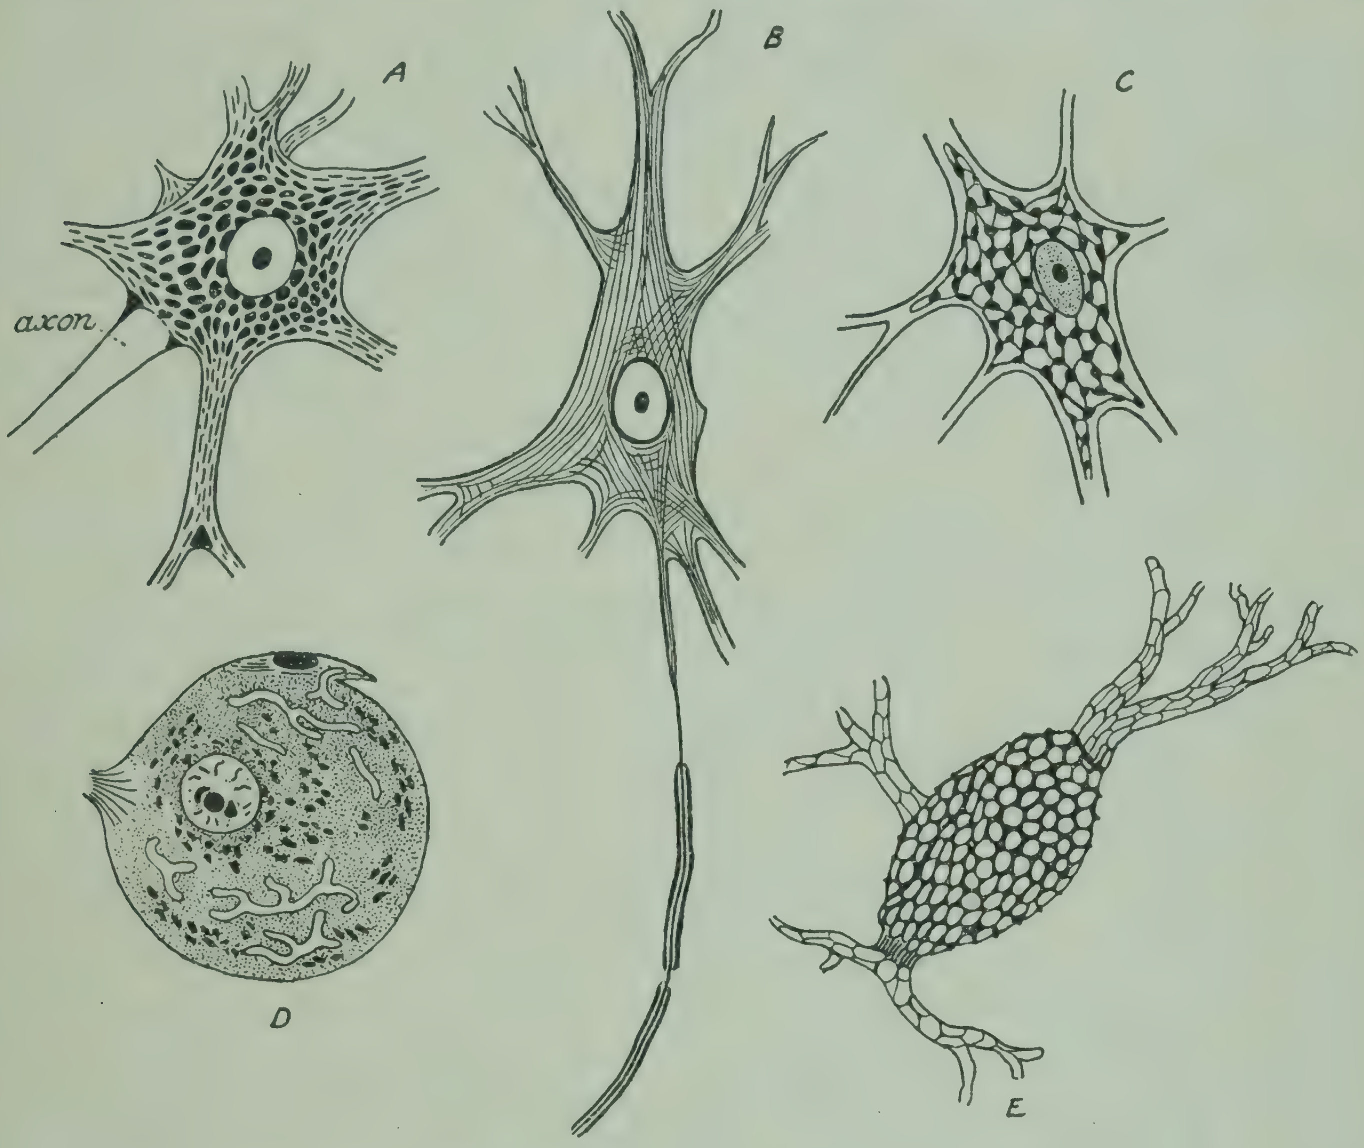

FIG. 117. Illustrating Structure of the Neurocyton.

A, Nissl granules in multipolar cell; *B*, neurofibrils in multipolar cell, and addition of medullary sheath to axon; *C*, Golgi endo-reticulum in multipolar cell; *D*, Holmgren's canaliculi, in ganglion cell; *E*, Golgi superficial network in multipolar cell.

The neurocyton, whatever its type, always exhibits certain characteristics of structure on examination by special histological fixing and staining methods.* Although these characters have often been claimed to be produced by the methods employed for fixation and staining, their invariable presence in cells under certain physiological conditions, and their absence or modification in other circumstances, give them an interest and a claim to further study (Fig. 117). There are, for instance, the Nissl's bodies,† and the Golgi networks, neither of which are visible on ordinary inspection in the living cell-bodies. The Nissl granules are, however, easily seen by photography with ultraviolet light.‡

The Nissl bodies are spindle-shaped masses of basophile material, apparently consisting of a nucleoprotein containing iron. They are of a size, and are arranged in a manner, characteristic for each type of neurone, and are disintegrated in fatigue, by certain poisons, and after section of the axon of the neurone, this process being called *chromatolysis*. Nissl bodies are present in all the hillocks from which dendrites arise, but are absent from the axon-hillock for some unknown reason.

* GREENFIELD, *J. Neurol. & Psych.*, 1938, **1**, 306.

† MOTT. *B.M.J.*, 1912, *ii*, 780.

‡ WEIMANN. *Z. ges. Neurol. Psych.*, 1925, **98**, 347.

The Golgi networks are of two kinds, an endocellular and a superficial. Their functions are unknown, but following section of the axon the endocellular reticulum is displaced to the periphery of the cell and often fragmented. The fine channels called Holmgren canaliculi are of doubtful significance, and are probably artefacts.

The neurofibrils seen in the cell-body on special fixation and staining form intricate networks continuous with the neurofibrils demonstrable in the axon and dendrons; their properties vary with the physiological state of the cells, and although some consider them to be artefacts, others claim to have demonstrated them in the living cells and fibres.

Each neurocyton has its nucleus, but no centrosome, and it is perhaps for this reason that adult nerve cells are incapable of division. Mitochondria are present in the cytoplasm, where they are visible in the living state.

Many neurones are entirely confined to the grey matter of the central nervous system, and these as a rule have only short axons. They are called Golgi type II. cells (Fig. 116, C). Those neurones that send their axons into the white matter, or into peripheral nerves are called Golgi type I. cells.

The dendrons of a nerve cell, and those parts of its axon which lie within the grey matter of the central nervous system, are composed of neuroplasm and neurofibrils, with no demonstrable cell wall or sheath, but on emerging into the white matter a covering is usually added to the axon, viz. the medullary sheath. To those axons that lie outside the central nervous system a second covering, the neurolemma is added.

Terminations of Nerve Fibres. The medullary sheath and the neurolemma are present throughout the peripheral nerves until near their terminations (in efferent fibres) or their origins (in afferent fibres). As these terminations (or origins) are approached the axons branch freely, at nodes of Ranvier, so that several, or many, terminal structures are connected with one axon (Fig. 116, A). Motor fibres for instance usually form about 100 branches, each one supplying one muscle fibre. The name *motor unit* is given to the complete structure consisting of motor neurone, with all its branches and all the muscle fibres supplied by them. It functions as a unit of motor activity. In all probability similar arrangements hold good for secretory and other types of neurone. Whatever the mode of termination, it is usual for the medullary sheath to disappear when it is reached. The neurolemma also sometimes disappears, leaving the terminal nerve fibre as a freely branching net of bare axis cylinder substance. In other instances the neurolemma may fuse with the wall of the cell in which the fibre terminates, as in skeletal muscle, in which the neurolemma and sarcolemma fuse together. The terminal nerve filaments thus come to lie directly in contact with, or may even penetrate into the cytoplasm of the cells at which they terminate, so that the relation between them is of the most intimate nature.

Nature of the Connection Between Neurones. The study of the development of the central nervous system in higher animals showed that from the embryonic cells, the neuroblasts, of the neural groove and crest there are formed by cell division the definite units in the construction of the nervous system which we now know as neurones. These retain their individuality from birth onwards and undergo no further divisions. It is now generally held, at all events for higher animals, that each neurone is a morphologically separate structure having no cytoplasmic continuity with other neurones, and being nutritionally distinct from them.

This conception of the neurone as a discrete structure is largely owing to the Golgi staining method, by which certain neurones are stained throughout all their branches, while adjacent neurones are quite untouched. Also, the facts of mammalian physiology seem mainly to be in favour of the neurone hypothesis. It is implicit in the present-day conception of the functioning of the nervous system that impulses can, under certain conditions, pass from one neurone to another, across some intervening junctional material. This junction is called the *synapse*. At the motor nerve endings in muscle there is also an apparent break of structure at the termination of the nerve in the muscle fibre, any continuity between nerve-ending and contractile substance being subserved by undifferentiated protoplasm. There is thus no difficulty in postulating a similar propagation across a synapse, from the axon of one neurone to the cell body or dendrites of another neurone.

If, however, the conception of the evolution of a nervous system from a continuous conducting protoplasmic network be correct, we should expect to find in the fully developed brain and spinal cord some traces of continuity throughout the whole system of neurones. The question as to the existence of anatomical continuity from neurone to neurone has been hotly discussed both for vertebrates and invertebrates. In some of the latter, evidence in favour of the continuity of neuro-fibrillæ from sensory surface to reacting tissue is strong. If we examine a mammalian nerve cell, such as a cell of Purkinje of the cerebellum, or of Clarke's column in the cord, we find that it is surrounded by a thick basketwork of fibres which are the arborisations and synaptic terminations of the axons which pass to the cell to enter into functional relationships with it (Fig. 118). It is probably not really a network, but a felt-work in which the fine fibres intertwine among each other without becoming actually continuous at any point. On the periphery of the cell itself another network has been described and is known as the Golgi network. According to Bethe the Golgi network on the one hand receives fibres from the encircling pericellular basketwork of axons, and on the other hand gives off towards the interior of the cell fine fibrils, which are continuous with the neurofibrillæ of the cell and pass out in its axon. There are physiological difficulties in the acceptance of this doctrine of continuity through the central nervous system. Thus, in the central nervous system, injury to an axon causes degeneration of the portion of the axon below the point of section, but the degeneration usually stops short at the synapse and does not spread into the next neurone. Exceptions to this rule occur, and the degeneration may affect several successive neurones—"trans-neuronal degeneration." A still more serious difficulty in the acceptance of this theory is the "Law of Forward Direction." It is possible that we may have to distinguish two types of nervous systems, viz.: (*a*) A neurofibrillar type, specially developed in invertebrata, with conduction in all directions; and (*b*) a synaptic type, which the Law of Forward Direction holds, of later evolution and forming the greater part of the nervous system of vertebrata.

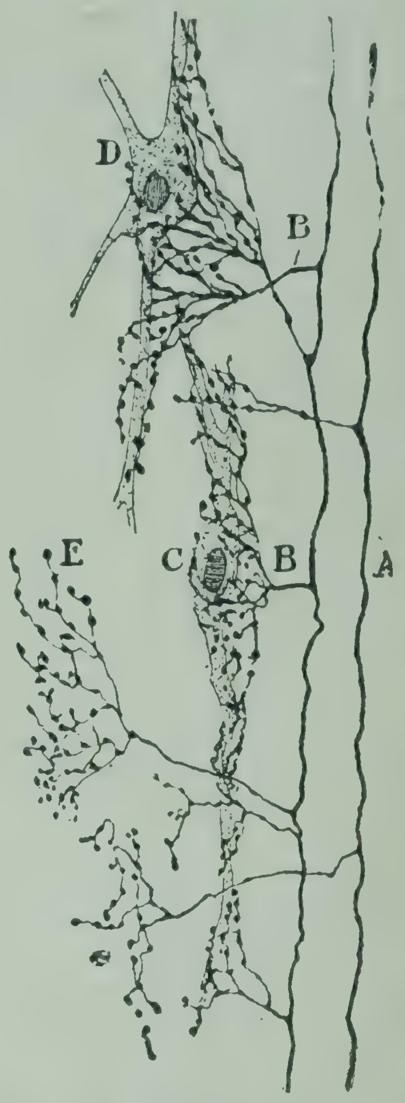

FIG. 118. Arborisation of Collaterals from the Posterior Root Fibres round the Cells of the Posterior Horn. (RAMÓN Y CAJAL.)

THE SYNAPSE. The synaptic arrangement by which communication can be established between contiguous neurones varies considerably in detail in different situations. In some cases the axon of one neurone and the dendrons of the next both break up into a finely interlaced mass of separate branches, comparable with the interlacing of fine branches of trees growing close together. More usually there is a plexus or basket of fine axon branches surrounding the body of the cell of the second neurone (Fig. 119) and terminating in small buttons or feet (*end-feet* or better, *synaptic knobs*) applied closely to the cell body or its dendrons (Fig. 120), or even to its axon-hillock. Although, in mammals, these synaptic knobs are generally minute (down to $0{\cdot}5\ \mu$), they may be very numerous (several thousand to a large soma), and cover an appreciable fraction (*e.g.* one-third) of the cell surface, to which they seem to adhere as if sticky. Typically, we may suppose, the knobs clustered upon a soma are derived from several—perhaps many—different axons, the fields of termination of the separate axons overlapping: but instances are known in which different axons terminate on separate areas, and sometimes by different shapes or sizes of terminal. Between the terminal knobs and the soma cytoplasm is a clearly stainable membrane, the synaptic membrane or synaptolemma, on the afferent side of which an aggregation of mitochondria is to be seen. Despite the variability of these anatomical arrangements there is no reason to suppose that the function of the

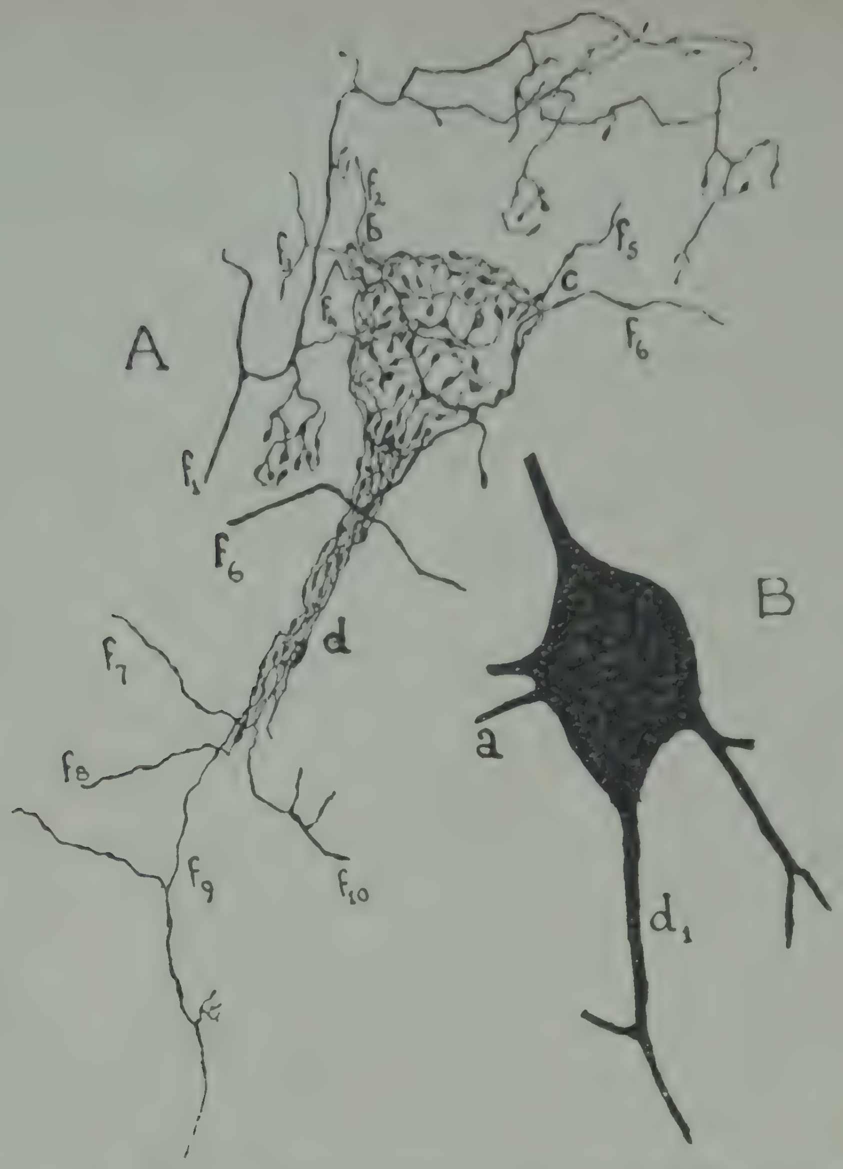

FIG. 119. A, synapses on a small internuncial neurone of the ventral ganglion of the acoustic nerve of a 20-day-old cat. B, a cell of the same type. *a*, axon; b.c.d,d_1, dendrites; f_1 to f_6, fibres having synaptic junctions with cell A. (LORENTE DE NÓ. *J. Neurophysiol.*, 1938, **1**, 195.)

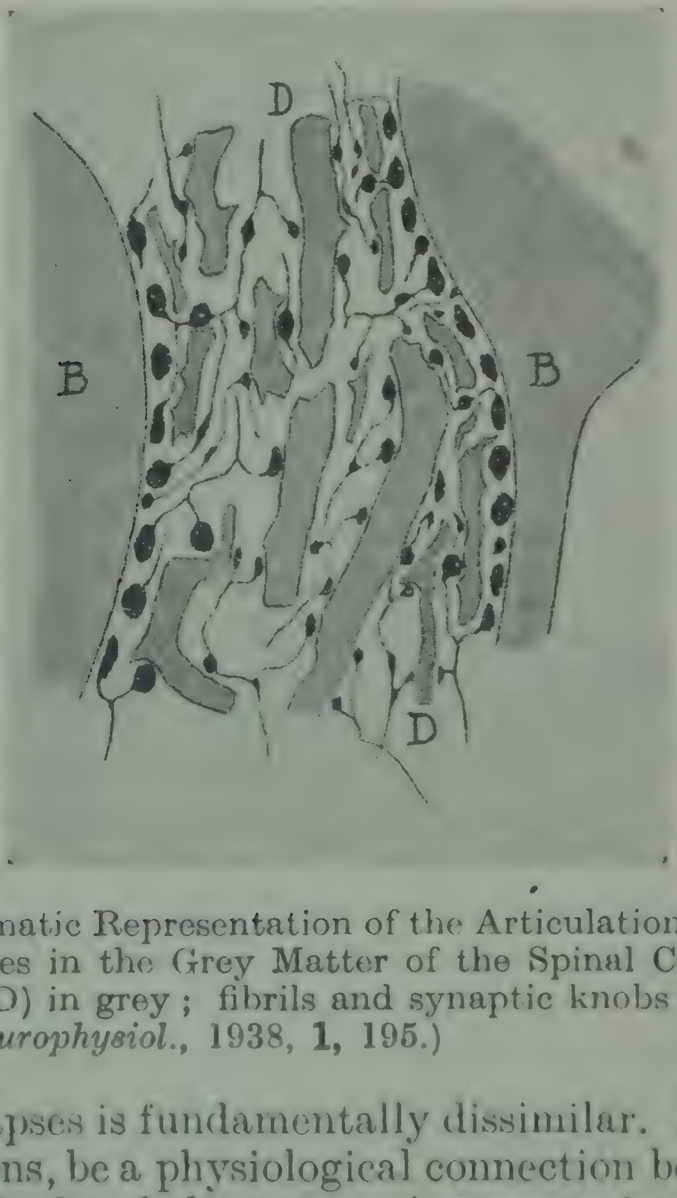

FIG. 120. Diagrammatic Representation of the Articulation of the Dendritic and Fibrillar Plexuses in the Grey Matter of the Spinal Cord. Cell bodies (B) and dendrites (D) in grey; fibrils and synaptic knobs in black. (LORENTE DE NÓ. *J. Neurophysiol.*, 1938, **1**, 195.)

different types of synapses is fundamentally dissimilar. In each case there can, under certain conditions, be a physiological connection between the axon of one neurone and the cell-body of the next. A nervous impulse can only pass in that direction, from axon to cell body, and so on to the axon of the second neurone. At the synapse there is usually a retardation of the nervous impulse called *synaptic delay*, which we may compare with the end-plate delay occurring on the passage of excitation from nerve to muscle Not infrequently a synapse is temporarily incapable of transmitting the excitatory state, a condition called *synaptic block*. But under no circumstances is the synapse capable of passing an impulse (or at least, does pass one, so far as we know) in the reverse direction from cell or dendron of one neurone to axon of the next, a rule which was called by Sherrington "*the law of forward direction*." In virtue of this the synapses act like valves allowing impulses to pass in one direction only. The probable reason for this is that the excitation time and intensity relations of soma and terminal are such that the soma surface is extremely unlikely ever to develop potential differences of such duration and intensity as to excite the knob around it.

It is an interesting subject of speculation as to the effects upon the cell of the arrival of impulses at synaptic knobs at different points in time and space, but as yet there is only a beginning of experiment in this field. Another interesting field for experiment and speculation is the enquiry into the fundamental nature of synaptic transmission.

When a stimulus is applied to any part of a neurone, *e.g.* at *x* in Fig. 121, A, it spreads throughout all its parts, and since the normal place for receipt of a stimulus is the synaptic area on the cell body, the normal direction taken by an impulse will be away from the soma and towards the axon, and along this centrifugally from its origin in the cell body to its terminal branchings *e.g.* from *a* to *b*, whence it will either reach an effector cell or another synapse, which latter, if patent, will be duly traversed, *e.g.* from *b* to *c*, so as to pass the excitation on to the next neurone.

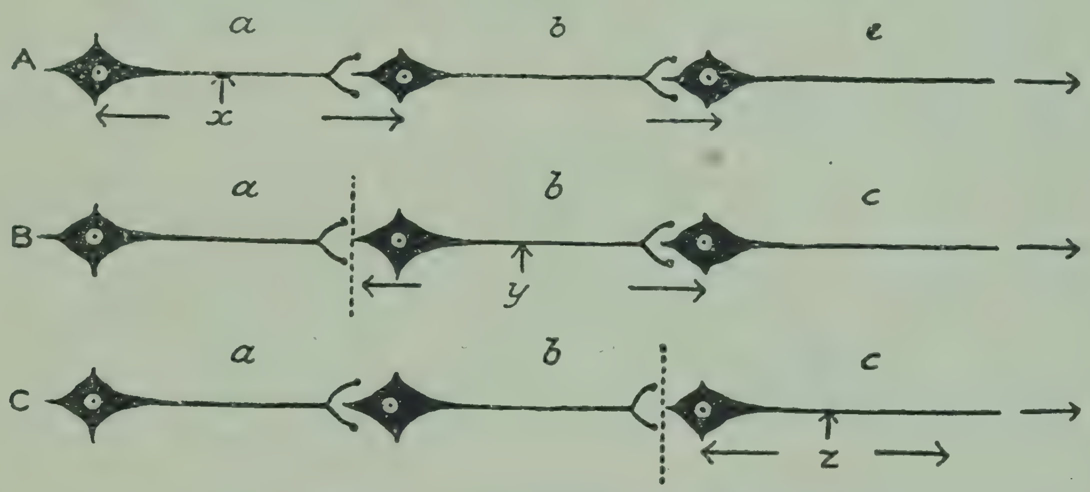

FIG. 121. Diagram to illustrate Forward Conduction.

If by any exceptional means an excitatory state be generated at an abnormal place, *e.g.* in the axon, as at *x*, *y* or *z* in Fig. 121, A, B, C, impulses will travel in both directions from the site of excitation, but only the forward or centrifugal one, *i.e.* which passes in the direction away from the cell body, will succeed in passing the synapse. The centripetal impulse will traverse the cell and dendrons but will be blocked " up-stream " at the synapse (Fig. 121, B, C).

Distributing, Commutator and Focussing Action of Neurones. From what has been said of the structure of the neurone and of the functions of the synapses, it is evident that the neurones play an essential part in distributing widely the impulses which they receive. This will be readily understood from Fig. 122, A, which shows that impulses received at a single neurone can be dispersed so as to reach many other neurones. This is called the *principle of divergence*. It is well illustrated in the optic nerve, each fibre of which sends branches to five or six cells of the lateral geniculate body.

A modification of this dispersing action is that seen in associative connection between neurones, as illustrated in Fig. 122, B. This is frequently of a reciprocative type, *e.g.* an excitation of neurone *a* may pass on an excitation through neurones *a′* and *b* to neurone *a″*, but the intercalated neurone *b* may now cause a block at the synapses leading to *c″*, with the result that as *a″*

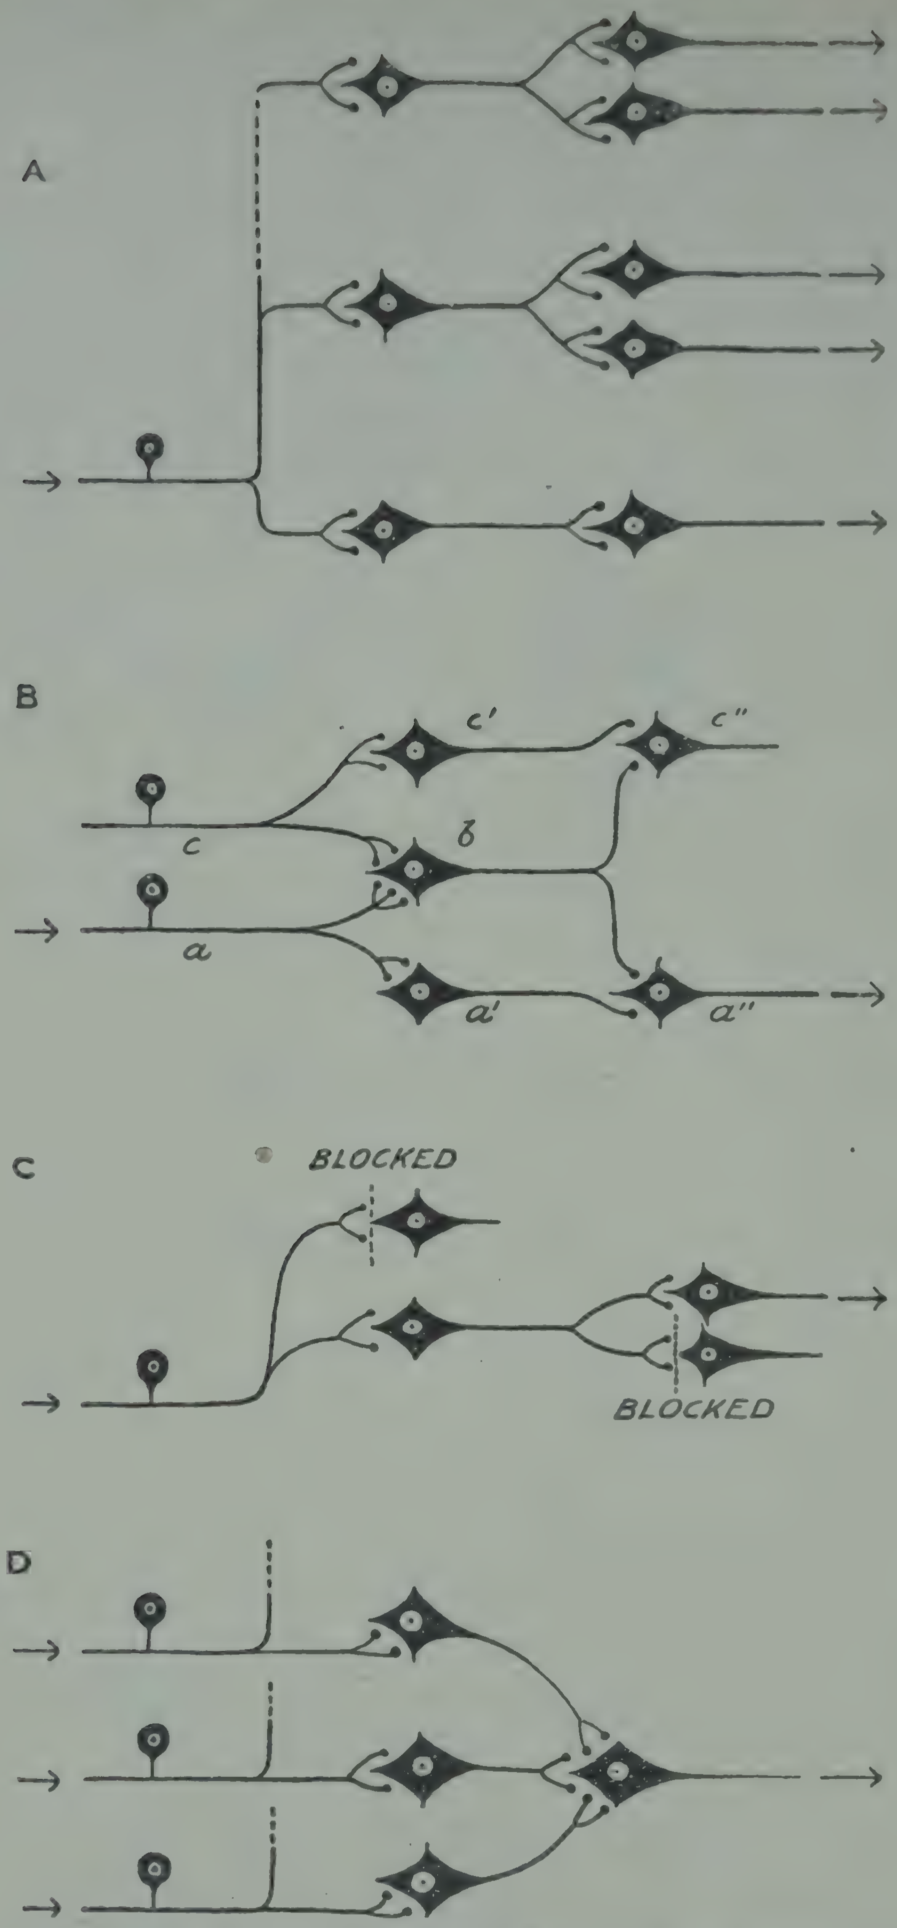

Fig. 122. Diagram to illustrate different connections of neurones.

enters into action, any activity in c'' is suppressed. The reverse would hold good for excitations applied to c, the synapse leading to a'' then being in a state of block owing to the action of neurone b.

A further function closely connected with the last is dependent on the fact that not all the synapses may be permeable to impulses, a result of which is that a number of alternative paths are open to impulses passing through a neurone, which thus acts like a commutator or railway junction (Fig. 122, C).

Lastly, owing to the multiple interconnections between neurones it is evident that a neurone may function in the opposite way to a distributor and may emit by its axon impulses collected or focussed from widely different sources (Fig. 122, D) to a "*final common path*." This is the *principle of convergence*. Instances of these three types of action are frequently met with in the central nervous system.

THE MAMMALIAN NERVOUS SYSTEM

It is impossible to give here an account of the anatomy of the central nervous system, for which the reader should consult works on Anatomy and Neurology. All that can be attempted is to recall such outlines as are indispensable to our purpose.

Anatomically, the mammalian central nervous system is a modified tube consisting of the brain, which gives rise to the 12 pairs of cranial nerves, and the spinal cord, from which there emerge 31 pairs of spinal nerves. The hollow portions are modified to form the ventricles and the central canal of the cord.

The brain, or encephalon, is divided, largely on embryological grounds, into the rhombencephalon and the cerebrum, which are united by an isthmus. Of these the rhombencephalon comprises the myelencephalon, or medulla, and the metencephalon, or cerebellum and pons. The cerebrum includes the mid-brain or mesencephalon, the between-brain or diencephalon, and the cerebral hemispheres or telencephalon.

(1) **RHOMBENCEPHALON** (*IVth ventricle*)
  (*a*) *Myelencephalon* = Medulla.
  (*b*) *Metencephalon* = Cerebellum and Pons.
  Isthmus = Superior cerebellar peduncles and superior medullary velum.

(2) **CEREBRUM**
  (*a*) *Mesencephalon* = Mid-brain and cerebral peduncles (*Aqueduct of Sylvius*).
(*b*) *Diencephalon* = Hypothalamus, Thalamus, etc. (*Third ventricle*).
(*c*) *Telencephalon* = Basal ganglia (Corpus striatum), Amygdaloid nucleus and Claustrum Cerebral Hemispheres (*Lateral ventricles*).
Fore-brain.

The structures remaining after removal of cerebral cortex and cerebellar cortex are sometimes called the Brain Stem (Fig. 123).

The spinal cord, and the brain stem and cerebellum, *i.e.* the greater part of the brain apart from the cerebral cortex, are chiefly concerned with reflex functions of an instinctive type, and with conduction to and from the cerebral cortex. The cerebral cortex with its appendages is sometimes called the "new brain" (Neëncephalon), and is concerned with the highest functions of association, memory, etc. All its connections with the rest of the body and with the outer world are affected solely through the intermediation of the lower parts, the brain stem, cerebellum and spinal cord.

The details of the anatomical structure of the central nervous system are of little direct interest to the physiologist except in so far as they throw light on function. His attention is directed rather to the attempt to understand the different modes of neural activity, either as studies in themselves, or, more especially, in their effects as subserving the co-ordination of functions of the various organs of the body.

The functions performed by each of the parts of the central nervous system will be considered in the chapters which follow. Briefly, we may say that the function of the cord is to act both as a series of reflex centres and also as a conductor to and from higher parts of the nervous system. Histologically, it consists of a column of cells (the grey matter), which is H-shaped in cross-section, surrounded by bundles of medullated axons (the white matter). Of the nerve cells, some give rise to motor axons which leave the cord and go to muscles, some are connected with afferent nerves, to long sensory axons which convey impulses up the cord towards the cerebrum, or to structures below it, *e.g.* to the cerebellum, while some give origin to short-distance axons which correlate the action of neighbouring groups of muscles or subserve reflex acts.

The medulla contains the long path axons which are passing through it on their way to and from the cord, and also various accessory structures. In addition it contains important involuntary "centres" (control stations) for the heart, blood vessels, and for respiratory movements, as well as the nuclei (relay stations) of many of the cranial nerves. The mid-brain likewise lies on the main track; and also contains the relay stations of several cranial nerves. The ganglia at the base of the cerebrum act as sorting and relaying stations for impulses which are on their way to the cerebrum. They also have certain specific functions assigned to them which will be described later. The cerebellum lies off the main track and receives impulses both from the cord and medulla below and from the cerebrum above. It presides over the co-operation of muscles for the performance of skilled acts.

The Brain Stem. It is usual in treating of the structure of the brain stem to consider it as a prolongation forwards of the spinal cord and as consisting, like this, of a central tube of grey matter surrounded by a tube of white matter. But at the fore end of the body have been developed the organs of special senses, which are the most important in determining the reactions of the animal in response to present or approaching changes in its environment. Hence we cannot expect to find in the brain stem the regularity of arrangement of grey and white matter which is met with in the cord, and the typical division of the grey matter into cornua becomes altogether lost. While some nerves take their origin from or terminate in the central tube of grey matter, in other cases the collections of nerve cells and fibres forming the nuclei of the cranial nerves have become more or less separated from it. Moreover, the central grey matter is by itself quite inadequate to deal with the flood of ingoing impressions entering the central nervous system through the organs of special senses, or to co-ordinate these with one another, or with those arriving from the skin and lower part of the body. In consequence, masses of grey matter, which have no representatives in the cord, make their appearance, and may be regarded as additional sorting or relay stations for the various kinds of impulses which determine the nervous activities of the animal.

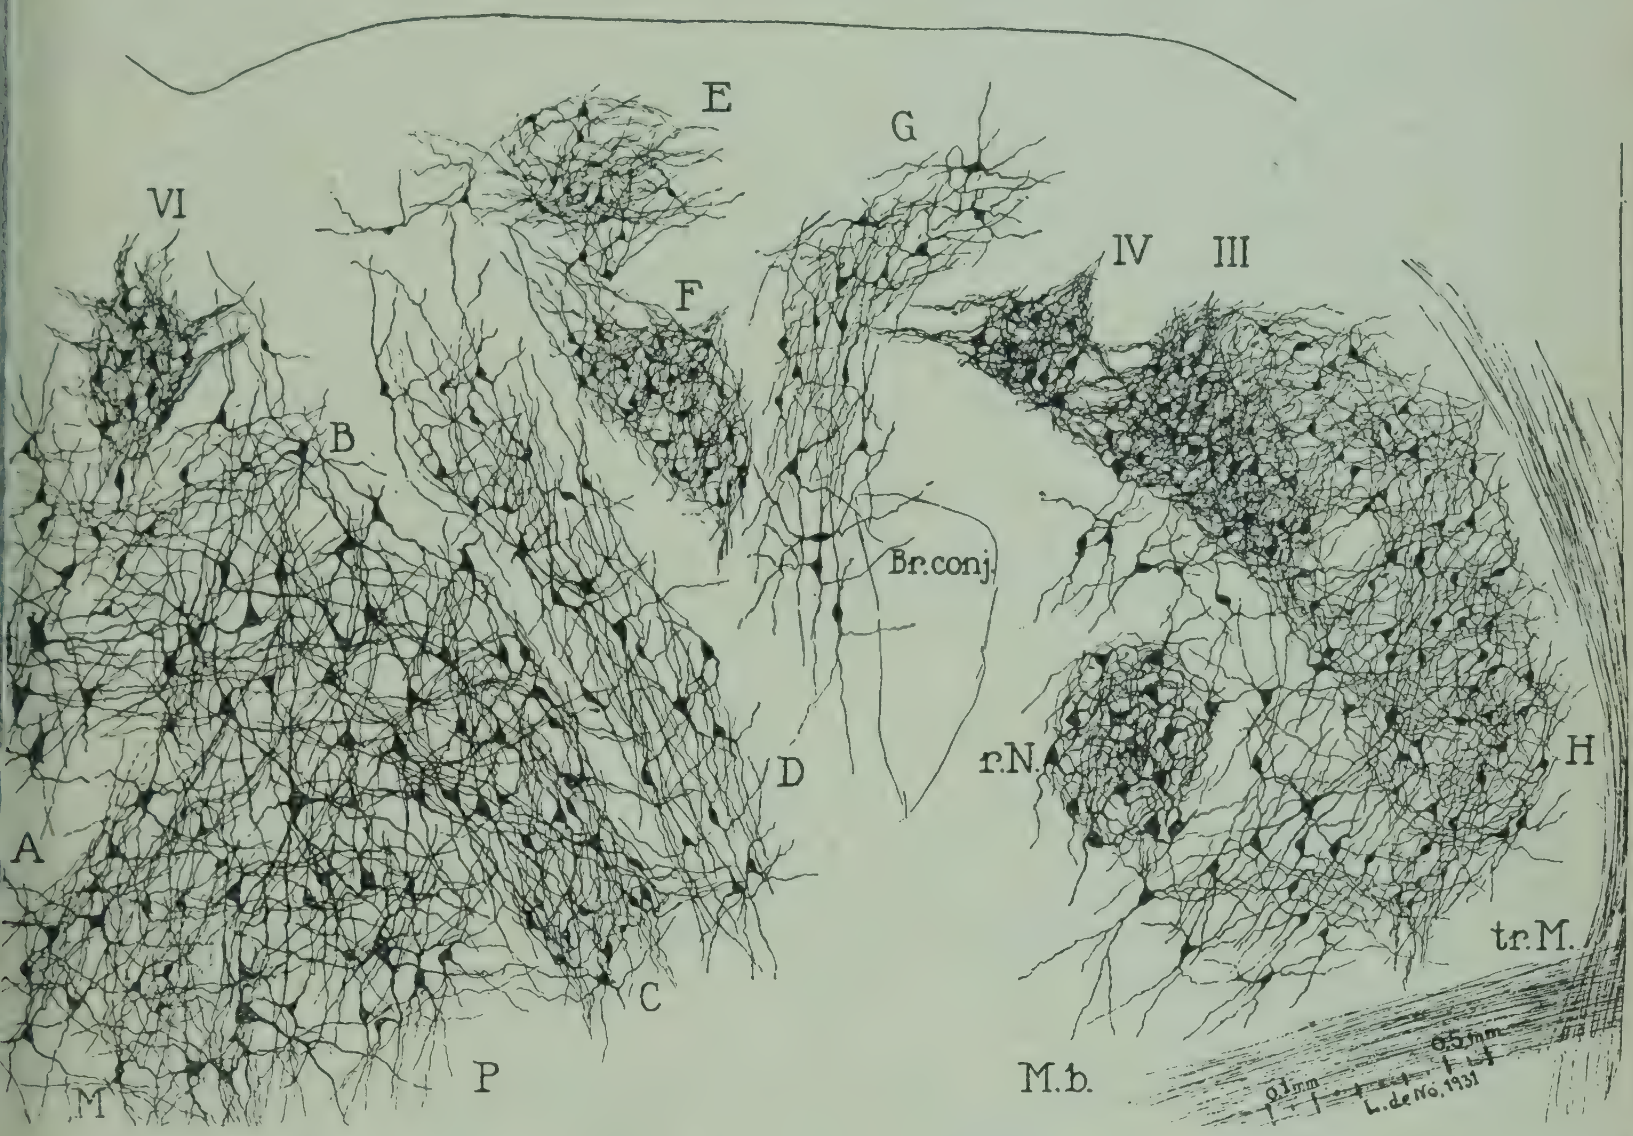

Fig. 124. Longitudinal Section through Medulla (M), pons (P), and Mid-brain (M.b.) of Mouse. E, F and G are neurone pools belonging to the autonomic system; tr.M., tract of Meynert. (Lorente De Nó. *J. Neurophysiol.*, 1938, **1**, 207.)

The anatomical relationship between the parts of the central nervous system just mentioned may be gathered from a careful study of Fig. 123. The greater part of the diagram is occupied by the thick, much-convoluted cerebrum, the right and left halves of which are associated by the large mass of axons forming the corpus callosum. Below this will be seen a hollow funnel-shaped mass of tissue, which is narrowing as it passes downwards from cerebrum to mid-brain. In this mass the ganglia at the base of the cerebrum are situated. Past them the long path axons travel through the internal capsule, connecting cerebrum with mid-brain. The narrow neck of the mid-brain is well shown. Below this comes the pons which contains the long paths and which by its transverse fibres also associates the two halves of the cerebellum. Below the pons is the medulla, while the laminated cerebellum is seen lying behind.

Centres. Often the cells of the grey matter are arranged in groups of cells, of similar size and common functions, called *neurone pools*, and when such groups are sufficiently conspicuous, either anatomically by their size, or physiologically by their functions, they are usually spoken of as centres. Thus we can distinguish anatomically such groups as the oculo-motor nucleus, the red nucleus, etc., or physiologically a functional group such as the respiratory centre, micturition centre, etc. Those aggregations into physiological groups such as these latter are not necessarily anatomically definable, since they often consist of several closely co-ordinated groups of cells, which may be at considerable distances from one another: the unity is one of function rather than of position. Frequently, however, one group is of predominant importance and of precise location and is more clearly entitled to the name of centre, *e.g.* the cardio-inhibitory centre. Fig. 124 will give an idea of the actual anatomical relationship of different neurone pools.

The Autonomic Nervous System. In connection with the central nervous system is an important system called the autonomic nervous system. This, which subserves the control of most of the involuntary functions of a vegetative type, *i.e.* those concerned with the routine reflex adjustments of most of the principal systems of the body, is divisible into the sympathetic and parasympathetic systems. The *sympathetic system* is connected with efferent fibres from the thoracic region of the spinal cord, the *parasympathetic* with certain cranial and sacral nerves. The two systems have in common the possession of synaptic connections situated in pools called *ganglia* which lie *outside* the central nervous system.

The work of many of the medullary, and other " centres " which control important bodily functions is largely carried out through the mediation of the autonomic nervous system, which therefore is of much greater physiological significance than its modest anatomical build would lead us to expect.

REFLEX ACTION

The conception of the reflex arc was evolved early in the nineteenth century, though it is chiefly to Sherrington that we owe the initiation of researches which have made it a corner-stone of physiological neurology.

It is common knowledge that the application of many kinds of stimuli to different parts of the body produces an involuntary movement (Fig. 125).

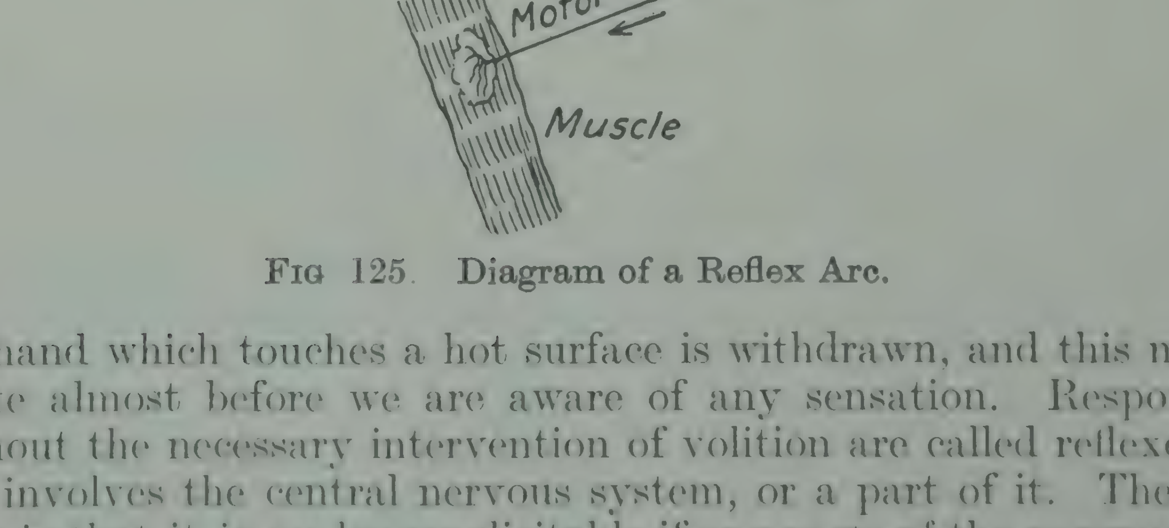

Fig 125. Diagram of a Reflex Arc.

Thus the hand which touches a hot surface is withdrawn, and this movement is complete almost before we are aware of any sensation. Responses that occur without the necessary intervention of volition are called reflexes if their execution involves the central nervous system, or a part of it. The criterion of a reflex is that it is no longer elicitable if any parts of the nervous path involved is destroyed. Sensation may accompany or follow a reflex action, but many important reflexes occur without the obtrusion of sensation into consciousness, as *e.g.* in the normal blinking of the eyelids at frequent intervals.

These automatic responses are of great variety, involving every system and organ of the body, and in a majority of cases they serve to protect, or otherwise further the interests of, the organism as a whole, or of the species. By their agency the various involuntary actions of the body under innumerable changes of conditions are properly effected and suitably co-ordinated, and its voluntary actions rendered more smooth and efficient. The secretions of glands and the movements of the viscera, the responses of the heart and blood vessels, and indeed all those bodily functions of which we are nearly always unaware, are largely controlled by delicately co-ordinated reflex actions.

Most of our detailed knowledge of reflex action, however, has been gained by the study of muscular responses, for the reason that they are the most objective and easily measured. As an example of a motor reflex in man we may take the knee-jerk. If one sits with, say, the right thigh crossed loosely over the left knee in such a way as slightly to stretch the quadriceps extensor, and then taps the right patellar tendon, a sharp extension of that leg at the knee-joint results. For this, as for all other reflexes, certain component structures are indispensable, and these components when reduced to their simplest terms of a one-fibre track form what is known as a reflex arc.

THE REFLEX ARC

A reflex arc comprises an afferent " limb," a centre, and an efferent " limb " (Fig. 126).

(1) The *afferent limb* of the arc consists of the receptors, and the afferent neurone. In the case of the knee-jerk, the receptors in the quadriceps muscle are stimulated by the tap. As a result of this they originate nervous impulses which enter the spinal cord by the dorsal roots of, say, the 4th lumbar nerve.

(2) In *the centre* (in our example in the 4th lumbar segment of the spinal cord) the impulses pass by a collateral fibre, *e.g.* from fibre B, direct to the ventral horn, and there, at a synapse (synapse 2 of Fig. 126) excites a large motoneurone. This is the simplest type, or *two-neurone arc*. In other less simple reflexes, *e.g.* some flexor reflexes, the collateral from a fibre such as A in Fig. 126, passes into the dorsal horn of grey matter, and so by synapse to a nerve cell, known as an *internuncial* cell (or interneurone, or relay cell) which is in turn excited ; the nervous impulse thus relayed passes by a short axon to the ventral horn and there, at a second synapse, excites a large multipolar motor cell. This is an example of a *multi-neurone arc*.

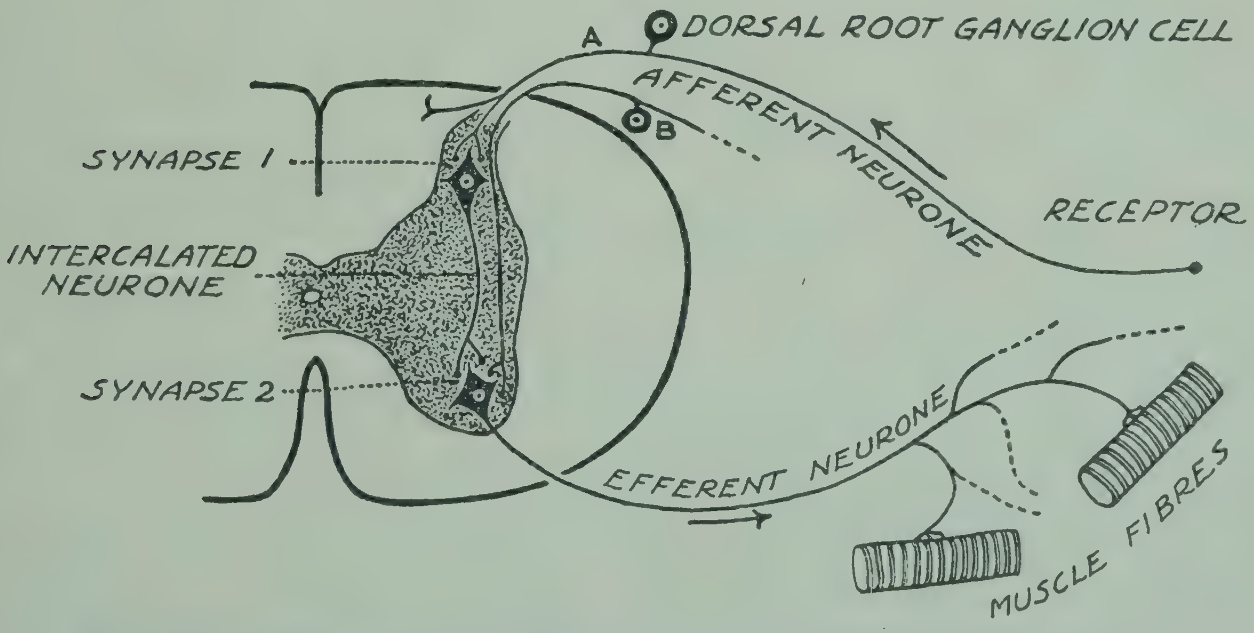

Fig. 126. Diagram illustrating the Reflex Arc in the Knee-jerk.

(3) *The Efferent Limb.* This consists of the motor nerve cell, its axon or motor nerve fibre, and the *effector organ* which effects the response (Fig. 126). The excited motor cell discharges a fresh relay of impulses along the motor

fibres which leave by the ventral root (4th lumbar) and so the excitation is ultimately conveyed to the muscle (quadriceps). The whole process for the knee-jerk occupies about 10 msec., most of which is taken up by the passage of the impulses along the nerve fibres.

We may substitute any other receptor organs, paths, centres and effector organs, but the general principle remains the same as that illustrated above. For example, we may consider the reflex secretion of saliva which follows when an acid is introduced into the mouth, as shown in Fig. 127. Here the afferent nerve is the VIIth cranial, the centre is in the medulla, the efferent path is by the chorda tympani (with another cell station peripherally) and the effector organ is a salivary gland. No doubt internuncial neurones are also placed in the arc.

Since the arc for a particular reflex only involves a limited amount of the central nervous system, it is possible, and often convenient, when studying reflexes in the laboratory, to remove parts of the central nervous system not involved. This is well illustrated in the "spinal frog" in which the brain has been destroyed, and in which spinal reflexes are easily studied. For example, if the frog is hung up by the head, and a toe of a hind leg is pinched, the leg is promptly drawn up in a co-ordinated flexor movement; if it is held so that it cannot move, the opposite limb moves vigorously instead. Again, if a scrap of filter paper soaked in dilute acetic acid is placed on one flank, the hind leg of the same side performs accurate movements to remove it; if that leg is held firmly, the opposite leg is brought into action.

FIG. 127. Illustrating the Reflex Secretion of Saliva.

The spread, or *irradiation* of a reflex, as shown by this passage to the opposite side, illustrates the fact that alternative paths are available in the central nervous system, and a further spread is seen if both legs are restrained, when the fore legs enter into action.

Integrity of Reflex Arc. The necessity for the integrity of the reflex arc can also be illustrated with the spinal frog. If all the nerves of a limb are divided and the foot of that limb then stimulated, there is no response on either side, because of interruption of the afferent path. If the foot of the opposite side is stimulated that leg will be moved, but if its movement is prevented the denervated limb will not now be affected by irradiation because the efferent path is interrupted by division of its motor nerves. Lastly, if the spinal cord is destroyed with a wire, all reflexes are permanently lost, because the centres are absent. More elaborate experiments which have been performed on higher animals illustrate the same facts in more precise fashion. Thus if in a cat or dog all the dorsal roots or all the ventral roots are divided, no spinal reflexes can be elicited.

Integrity of Reflex Arcs in Man. In the human subject, the existence of certain reflexes supplies evidence for the integrity of the reflex arcs concerned, and is therefore of clinical importance. Thus the presence of knee-jerks shows that the 4th lumbar segment of the cord, with its afferent and efferent nerves, is intact, and in similar ways the following reflexes illustrate the integrity of the spinal segments indicated.

Segment.	Reflex.
C 5 and 6	Biceps-jerk
C 6	Supinator jerk
C 6, 7, 8	Triceps-jerk
Th 7–12	Abdominal reflex
L 1	Cremasteric reflex
L 2 to 4	Knee-jerk
L 4–5	Gluteal reflex
S 1 and 2	Ankle-jerk
S 2	Plantar reflex
S 4–5	Anal reflex

Other reflexes indicate the integrity of various higher parts of the central nervous system, *e.g.*, the contraction of the pupil of the eye to light shows that the IIIrd cranial nerve nucleus and the essential optic and efferent paths are intact.

In disease these reflex arcs may be interfered with in a variety of ways, some of which closely resemble the conditions introduced in laboratory experiments. Thus in tabes dorsalis, knee-jerks and other reflexes are lost because the dorsal spinal nerve roots suffer destruction, throwing the reflex arc out of action by loss of its afferent limb. In anterior poliomyelitis (infantile paralysis) the motor cells of the ventral horn degenerate, which causes paralysis of the affected segments by loss of the efferent limb of the arc. In syringomyelia the grey matter of the cord is generally affected, so that the whole central mechanism of the arc is lost.

CHAPTER XIV

THE RECEPTORS

THE receptors are the structures at which afferent nerve impulses are normally originated in response to appropriate, or adequate, stimuli. They are conveniently subdivided into exteroceptors and interoceptors. The *exteroceptors* convey impressions of the outer world, and are again divisible into telereceptors, chemical receptors and cutaneous receptors. The telereceptors are the end organs for vision and hearing, and will be specially considered under special senses, as also will the chemical receptors of taste and smell.

The *interoceptors* fall into the three groups of *proprioceptors*, *visceroceptors* and *chemical interoceptors*. The proprioceptors are end organs stimulated by the position or activity of the body itself, and visceroceptors similarly are situated in and give impulses arising from the viscera. Chemical interoceptors are present in the carotid sinus and certain other situations.

CUTANEOUS RECEPTORS

(For details, text-books of Histology should be consulted.)

The cutaneous receptors are of two types; viz. the free terminal ramifications and the specialised cutaneous end organs. Some of the principal types are shown in Fig. 128, but there are many others.

Free Ramifications. These are widespread and are usually non-myelinated at their terminations, or even throughout their course. Such terminal ramifications often form unmyelinated plexuses just beneath the epidermis,* and fine branches from this penetrate between or even into the epidermal cells. These free endings almost certainly subserve the pain sense and perhaps in some cases also touch.

Special Cutaneous Receptors. There are varieties of these, according to the various kinds or *modalities* of sensation, viz. touch, heat, cold and pain, *e.g.*,

Receptors for Touch. The chief varieties are: the hair follicle, the Meissner's corpuscle, and the Pacinian corpuscle (Fig. 128).

The hair follicles are supplied with a fine plexus of non-medullated terminal filaments, and these are stimulated whenever the hair is moved. *Meissner's corpuscles* are placed in certain of the papillæ of the skin. The fine non-medullated terminal fibres form a spiral imbedded in connective tissue. *Pacinian* corpuscles lie deep in the subcutaneous tissue of the hands and feet, but also in the joints and mesentery. The nerve fibre enters, loses its medullary sheath and becomes surrounded by an oval laminated structure of considerable size.

Receptors for Temperature Change. These are the Krause end-bulbs for cold (Fig. 128) and the Ruffini organs for warmth. In both of these there is a basket-like network of nerve fibres enclosed in an oval connective tissue capsule.

THE INTEROCEPTORS

Proprioceptors. The impulses from these receptors, often termed *kinæsthetic*, depend upon the movements or position of the body itself. They comprise the labyrinth of the internal ear, and the receptors of muscles, tendons and joints, and upon the impulses they furnish to the central nervous system the accurate pose and movement of the body largely depends.

Fig. 128. Skin End Organs. It has been supposed that corpuscles of the type of Meissner's corpuscle subserve touch sense, and that nerve plexuses, such as that illustrated for the cornea, are for pain.

The labyrinth consists of the *utricle* and *saccule* and the three *semicircular canals,* and will be considered in further detail in a later chapter. The receptors of the utricle and saccule are variously stimulated according to the *position of* the head in space, *i.e.* it is a static register, while the receptors of the three semicircular canals are differentially excited according to the *movement* of the head in the planes of space, and hence its impressions are kinetic in nature. The impulses aroused are conveyed from the labyrinth to the medulla by the vestibular division of the VIIIth cranial nerve.

Muscle Afferents. If the ventral roots supplying a so-called motor nerve are divided, and time allowed for degeneration to occur, it is found that as many as one-third of the fibres in the nerve remain undegenerated, *i.e.* are afferent fibres. The *muscle proprioceptors* are represented by the muscle spindles. In these structures a specialised type of muscle fibre, often split into several finer fibres, receives three nerve fibres. One is an afferent nerve fibre which, after penetrating the sarcolemma and losing its own neurolemma and medullary sheath, is spirally wrapped round the muscle fibres, the whole structure being enclosed within a capsule (Figs. 129 and 130).

Usually a second afferent fibre enters the capsule and forms dendritic branchings on the surface of the modified muscle fibres (Fig. 130). That these two types are both afferent is shown by the fact that their specialised endings disappear after removal of the dorsal spinal root-ganglia that supply the muscle in question. The third fibre is an efferent fibre with the usual motor end-plates. They degenerate on section of the ventral nerve roots concerned.

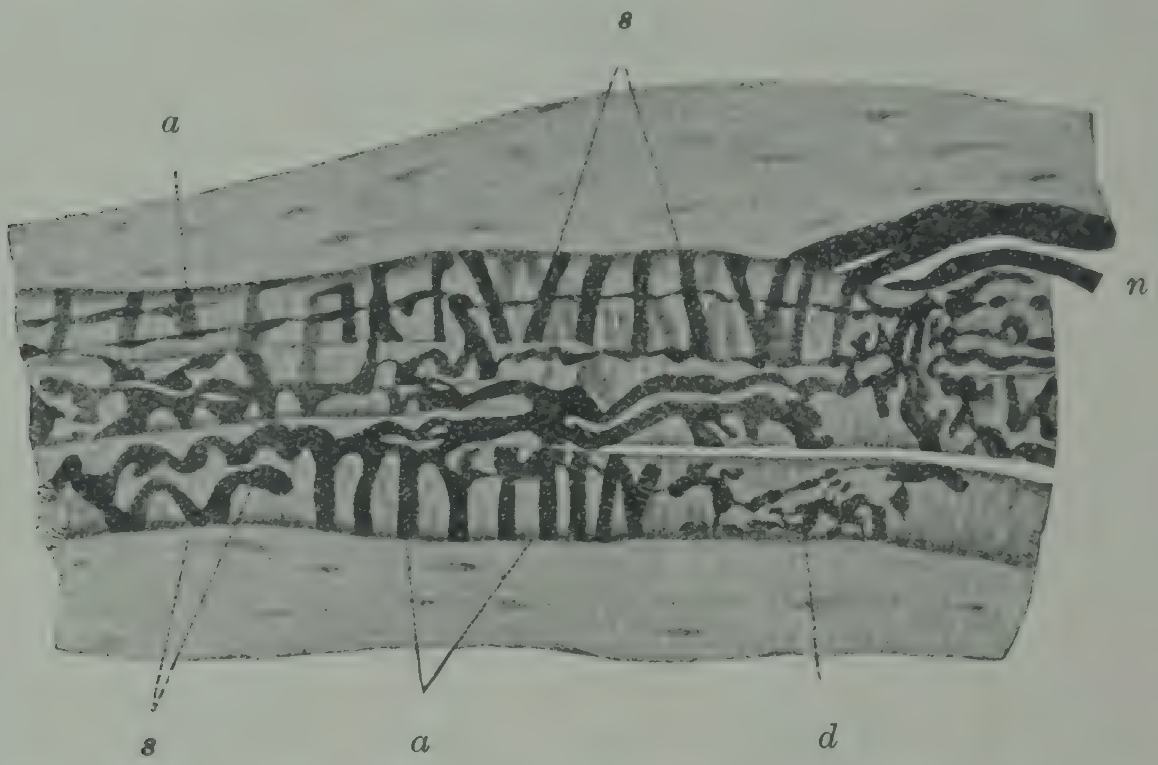

FIG. 130. Part of a Muscle Spindle more highly magnified. (RUFFINI.)

n. Nerve fibres passing to spindle.
a. Annular endings of axon.
s. Spiral endings.
d. Dendritic endings.

The muscle spindles are regarded as *stretch receptors*, *i.e.* they are excited when the muscle is elongated passively. When the muscle is contracting, any tension on the spindle fibres would be relieved by the support provided by surrounding fibres in a state of contraction.

The *tendon receptors* are represented by the Golgi tendon nerve-endings, which are found in the tendon near to its attachment to the muscle fibre. They are sensitive to tension, but since they are placed beyond the end of the muscle fibre, they will respond to a pull of any kind on the tendon, whether due to passive stretch or to actual contraction of the muscle. We therefore speak of them as *tension receptors.*

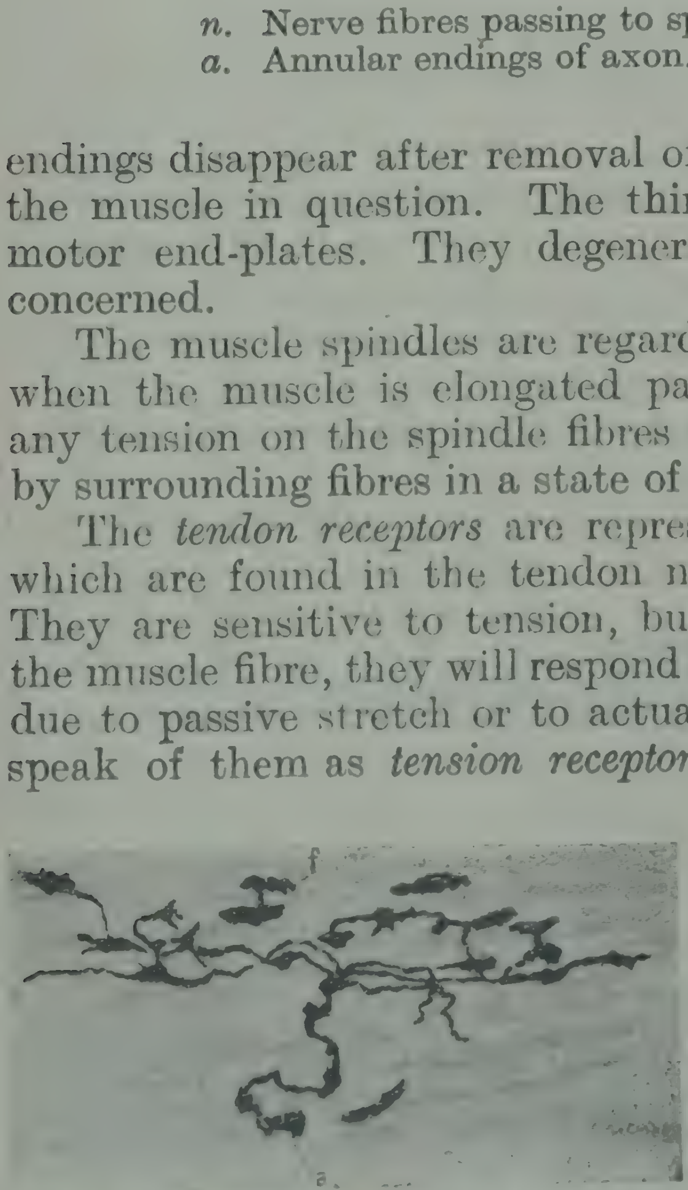

FIG. 131. Sensory endings in the adventitia of the carotid sinus in man: (*a*) arborising nerve fibres; (*f*) end organs. (C. Heymans, *after* de Castro.)

In addition to the above, receptors of other kinds will also be brought into play whenever movement occurs or posture is modified. Thus *Pacinian corpuscles* are found not only in the dermis but in tendon sheaths, joints, etc., and free nerve networks are also abundantly distributed to muscles, joints, tendons, etc.

Visceroceptors. The viscera and other internal parts of the body are not endowed with sensation in the ordinary acceptance of the term, but can be the seats of origin of a great variety of afferent impulses, including in some cases those capable of producing pain. Most of the hollow organs are provided with *stretch receptors* of some kind. These and other visceroceptors are often of the nature of dendritic branchings of non-medullated terminal nerve twigs. A remarkable instance of such a stretch receptor is in the carotid sinuses (Fig. 131), and aortic arch, from which afferent impulses arise when the pressure in the arteries is increased.

In addition to the stretch receptors, the carotid and aortic bodies in particular, are provided with *chemical receptors* which are affected by certain chemical changes in the blood passing through them.

Other important visceroceptors are the Pacinian corpuscles which are widely distributed over the peritoneal cavity.

THE EXCITATION OF RECEPTORS

Since it is the function of the receptors on suitable excitation to originate nervous impulses, we must enquire into the conditions and result of this stimulation. These differ in several important respects from those of nerve fibres. One difference lies in their specificity, *i.e.* they are so constructed as to respond only, or most easily, to one kind of stimulus, those of the retina to light, those of muscle to stretch, and so on.

Another difference is that the application of a stimulus to a receptor very readily leads to the origination of a *series or train of excitations*, which are duly passed on to the nerve fibre. This property is only feebly developed in nerve fibres themselves, so that stimuli applied directly to them do not, unless very strong, produce more than one nerve impulse per stimulus, even if this be a prolonged one. When a *prolonged steady stimulus* is applied to a receptor, however, a prolonged train of impulses is set up, and passed on to the nerve fibre, since each impulse in the receptor acts as a new stimulus to its nerve fibre.

Strength of Stimulus. Since the nerve impulse is an all-or-none phenomenon, the only effect of increasing the *strength of the stimulus* to a given receptor can be to produce a larger number of impulses along its nerve fibre. This results in the impulses following one another at shorter intervals, and also in the train continuing to be generated for a time after the stimulus has ceased. But another effect enters into the picture under most conditions in which a stimulus is applied to a tissue endowed with receptors, viz. as the stimulus is increased, an increasing number of receptors is excited. Hence an augmenting stimulus normally leads to an increasing rate of discharge along an increasing number of nerve fibres.

On account of this fact, the detection of the impulses initiated by a given stimulus requires, in practice, a special technique, which we owe to Adrian and Zotterman,* and to Adrian and Bronk,† by which the nerve impulses traversing a single nerve fibre are recorded. Adrian and Zotterman achieved this by isolating one receptor (spindle of sterno-cutaneous muscle of the frog) by cutting away the others; Bronk ‡ by dividing all except one of the afferent nerve fibres that led away from the sensory tissue (muscle or skin); Matthews § by using a tiny muscle (of a frog's toe), which had only one spindle.

In each case the spike potentials along the single nerve fibre were recorded, after amplification, and the complication due to the recording of impulses along many nerve fibres was avoided. By similar methods it has been possible to obtain records of the nervous impulses (spike potentials) which pass along many kinds of afferent fibres on appropriate stimulation of their receptors, and in all cases the results are essentially similar (Fig. 132).

‡ BRONK. *J. Physiol.*, 1929, **67**, 17.
§ MATTHEWS. *J. Physiol.*, 1931, **71**, 64.

When the strength of the stimulus applied to the receptors is raised, the frequency at which they respond is increased up to a certain maximum, which

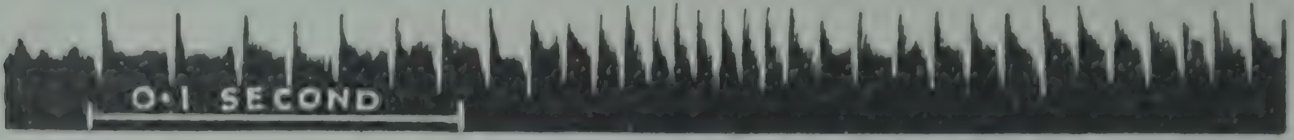

Fig. 132. Action potentials (*i.e.* nerve impulses) in a single nerve fibre from a frog's muscle spindle, caused by stretching muscle. The waves are all similar in size, but increase in frequency as the tension increases and then decline slowly when the tension is constant. (Tsai.)

in some receptors may reach as much as 300 per second ; this is about the limit at which a nerve fibre can fully respond to direct stimuli, since the absolute and relative refractory periods of the fibre are about 3·5 msec. It follows that the refractory periods of the receptors themselves must at most be of this order.

Adaptation. All nervous structures exhibit the phenomenon of adaptation, *i.e.* the responses to a stimulus become less and less frequent with time. Nerve fibres have this property so strongly developed that each application of a stimulus usually only produces a single nerve impulse. With receptors more than one excitation usually results from each stimulus, and they are capable of responding to a continuous stimulation by firing off a long train of responses which pass on to the nerve fibre. Thus the stretch receptors of muscle, or the touch receptors of the skin, when subjected to appropriate mechanical stimulation fire off a series of nerve impulses into their respective nerve fibres. The receptors, however, do show adaptation, as a result of which the train of impulses, at first in quick succession, soon shows a slowing down in frequency. In this respect the different receptors show considerable differences. In muscle receptors the rate at which impulses are generated falls off at first and then reaches a fairly steady rate of discharge (Fig. 133) ; whereas skin receptors adapt much more rapidly and may in spite of continued stimulation, ultimately only discharge very slowly. This corresponds to our own subjective experience. When the skin is lightly touched, as, *e.g.* by clothing, the sensation is much

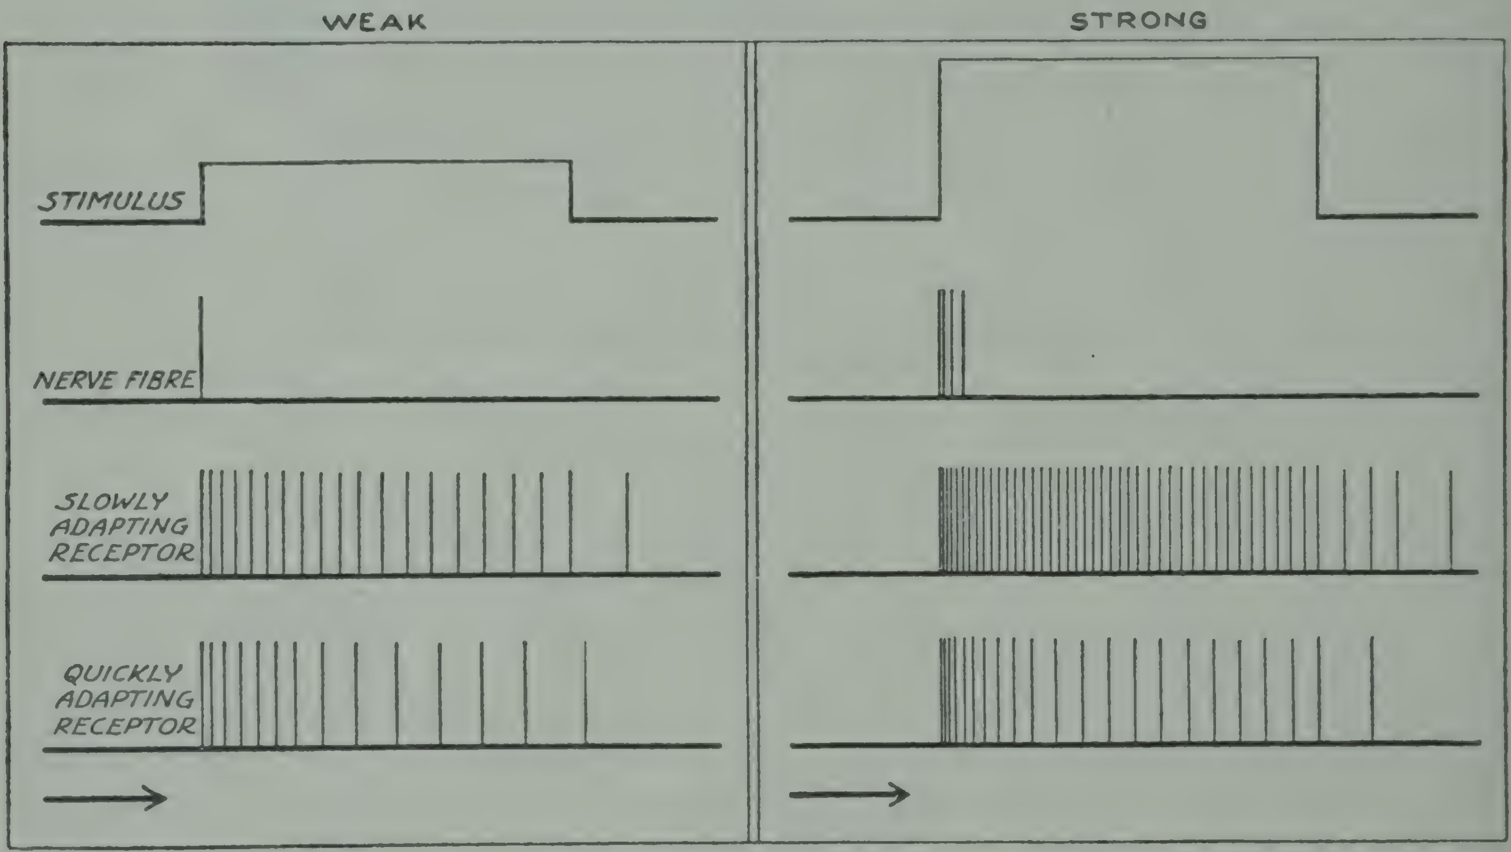

Fig. 133. Diagram illustrating the effects of continuous Stimulation, Weak and Strong, on Nerve Fibre and on Receptors. The vertical lines represent nerve impulses. Nerve fibres give only one impulse for weak stimuli or two or three for very strong ones. Receptors discharge trains.

more intense at first than it subsequently becomes—otherwise the wearing of clothes would be intolerable.

NATURE OF ACTION OF RECEPTORS. Why and how the various receptors respond to their appropriate stimuli, and to those alone, is an interesting question, but one to which no definite answer can at present be given. Whatever the manner in which the state of excitation is brought about, the ultimate result is the same, viz. the generation of trains of nerve impulses along the fibres whose endings they form. It is not improbable, therefore, that the effect on any end-organ of its appropriate stimulus is in all cases the same physico-chemical process. Observations on the retinal terminations suggest that this change is a surface *depolarisation*,* and this view would be acceptable, since it brings the process of excitation of nerve-receptors into line with that of other structures, and particularly with that of nerve cells, which, like the receptors, also generate impulses. Two facts are in accord with this view: artificial depolarisation by an electric current causes excitation; and an impulse sent backwards (antidromically) into the receptor by artificial stimulation of its nerve fibre causes the receptor to enter for a short time into a refractory state,† and so interrupts its normal rhythm of discharge.

CHAPTER XV

THE SPINAL CORD

AND ITS RELATIONSHIP TO THE HIGHER PARTS OF THE CENTRAL NERVOUS SYSTEM

It is not strictly possible to consider the central nervous system as a series of separate parts, the functions of which when added together make up the functions of the whole. Rather we should aim at understanding how the entire system functions. Keeping this end always in view, however, much that is of value can be learned by considering the separate functions of the parts. We shall therefore in the first place study the functions of the spinal cord in brief fashion, because it is simpler in structure, and because on that account much can be learned about neural physiology that can subsequently be applied to the understanding of the functions of the higher parts.

In man the spinal cord gives off, symmetrically on either side, thirty-one pairs of nerves. Each nerve has two roots, an anterior, or ventral, root and a posterior, or dorsal, root. The ventral roots are efferent (*e.g.* motor) in function, and the dorsal ones afferent (sensory). Both types of root contain fibres of widely differing diameters. A mixed nerve consists of fibres which are connected to both these roots. The anterior root fibres emerge from the cord in a series of rootlets; the posterior root fibres, on their way into the cord, pass first to the posterior root ganglion and then enter the cord as a compact bundle. On section the cord is seen to consist of an H-shaped core of grey matter surrounded on all sides by white matter. The former contains the nerve cells, the latter is made up of nerve fibres which are devoid of neurolemma and are connected into bundles held together by neuroglia.

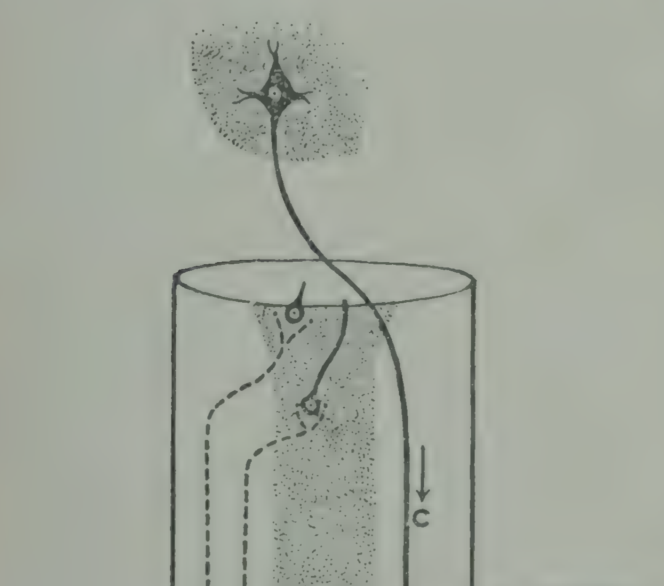

Fig. 134. Diagram to illustrate Method of tracing Tracts by Degeneration. A, fibre of an exogenous ascending tract; B, fibre of an endogenous ascending tract; C, a descending fibre. Degenerated tracts shown by broken lines.

THE NERVE CELLS OF THE CORD

The nerve cells of the grey matter of the spinal cord are all multipolar cells; they are not uniform in size or distribution, but tend to be aggregated in pools or columns, the cells of each column having approximate similarity of function. The cells are of Golgi types I. and II. The type II., with short axons, are found only in the dorsal horn, and chiefly in its lateral basal group. Their short axons pass towards the ventral horn of the same or the opposite side. The type I. cells usually send out their axons into the tracts of the white matter. Important groups of the posterior horn are the cells of the *substantia gelatinosa Rolandi*, and at the base of the posterior horn is the *Clarke-Stilling column* (or mesial basal group). The cells of the substantia gelatinosa Rolandi send out axons mainly into the spinothalamic tracts of the opposite side. The axons of the cells of the Clarke-Stilling column pass out into the dorsal and ventral spino-cerebellar tracts and so reach the cerebellum, mainly of the same side (Fig. 137).

In the lateral portions of grey matter, in the thoracic and sacral regions, are cells forming the *lateral splanchnic column* which give origin to axons that pass out *viâ* the ventral roots and white rami communicantes, to the sympathetic chain (Fig. 137).

In the ventral horn of grey matter are three or four groups of cells forming the *motor cell columns.* Their axons pass out into the ventral spinal nerve roots, and so to the spinal nerves.

THE WHITE MATTER

The white matter of the spinal cord represents the conducting matter of the cord, and contains fibres of four types: (i.) long path afferent axons, such as those of Goll and Burdach in the posterior columns, forming the main tracts to higher parts, (ii.) long path efferent axons, leading down from higher parts, *e.g.* the pyramidal tracts, (iii.) association or intrinsic axons, which connect neighbouring segments of the cord, (iv.) commissural fibres which connect opposite halves of the same segments of the cord. The fibres are of varying size, and some are non-myelinated.

Much of the white matter is divisible into *tracts,* consisting of long fibres of similar function and destination, and these again are distinguished as *afferent and efferent tracts.* The tracts are mapped out mainly by the degeneration method. If a tract is divided, the parts of the axons cut off from their cells will degenerate, *i.e.* right up to the next synapse, and after some days may be distinguished by appropriate staining methods. The same thing happens if the whole spinal cord, or other part of the central nervous system, is cut across; the axons from cells below the lesion (ascending tracts) will be degenerated in the part above the section, and those with cells of origin above the lesion (descending tracts) will be degenerated only below the section (Fig. 134). If the dorsal nerve root be divided proximal to the ganglion, *i.e.* between the ganglion and the cord, it will be clear that the whole of the course of the axon within the cord will degenerate, and this method provides a way of differentiating those afferent tracts which are directly derived from the dorsal root fibres (A in Fig. 134) from those of secondary origin in the grey matter of the cord (B in Fig. 134).

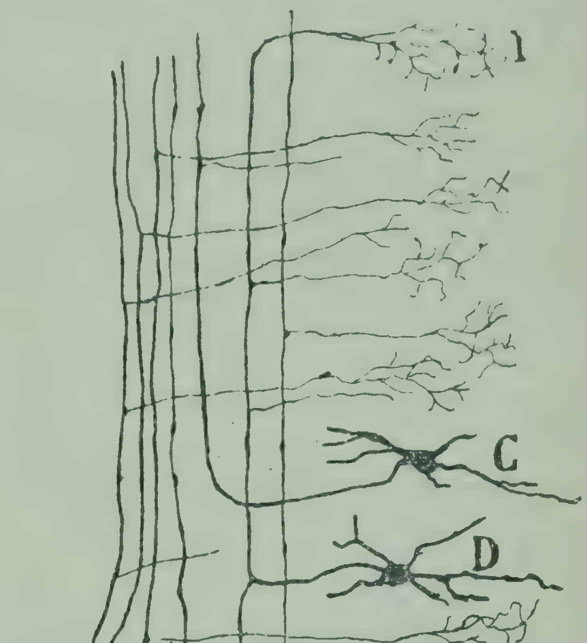

Fig. 135. Longitudinal Section of Spinal Cord of Chick, showing bifurcation of Dorsal Root Fibres and the passage of their Collaterals into the Grey Matter. Three cells of the Dorsal Horn are also seen sending their axons into the dorsal columns of white matter (short intraspinal neurones). (Cajal.)

Degenerating myelinated fibres are picked out by the Marchi method. In studying fibre degenerations in the C.N.S. the non-myelinated fibres must also be taken into account: these are stained by a silver method if undegenerated.

In some instances the divided fibres still connected to the cell also degenerate (retrograde degeneration); usually the cells of origin of divided tracts undergo chromatolysis. Hence the pool of cells from which a tract arises (*e.g.*, tract B in Fig. 134) can often be identified. Cell and fibre counts will indicate the extent to which a given neurone pool contributes to a given fibre tract.

Another method of following the course of impulses in the central nervous system is by the use of microelectrodes and amplifiers. With sufficiently small electrodes the passage of impulses can be followed along separate fibres, using the natural stimuli applied to skin, muscle, etc., and the velocity of the impulses, which is related to the fibre diameter, can be estimated. Stimuli can also be applied direct to selected tracts in the C.N.S., and the resultant impulses traced. This method, sometimes called *electroneuronography*, has opened up new fields of study.

In some parts of the central nervous system the connection between one set of neurones and the next can be determined by what is called *transneuronal degeneration*; *i.e.* when one neurone is removed the next one degenerates. Thus if a part of the retina is excised, the cells which connect with it in the lateral geniculate body degenerate.

The chief paths of physiological importance are briefly as follows :—

I. Afferent Paths. Each dorsal root fibre, on entering the cord, gives off a short descending branch and an ascending branch (Fig. 135), each of which has numerous small collaterals which enter the grey matter of the dorsal horn and there form synaptic connections with cells in one of the pools. The ascending branch may, (*a*) after a short course, similarly terminate in the grey matter, by synapse with a cell from which an axon arises, to pass out again into the white matter as a fibre of a secondary tract; or (*b*) pass directly as an "exogenous" tract into the white matter of the posterior columns (Fig. 137). On entering the spinal cord the fibres become grouped into tracts according to their origin, destination and functions.

As regards origin, the fibres are arranged within their tracts in an order corresponding to the dermatomal sequence. As regards destination and function, fibres of like function and destination travel in the same tract: thus, broadly, the posterior columns convey fibres dealing with proprioception and fine conscious discriminations, while the anterolateral columns are concerned with pain, temperature and sex sensations, and with unconscious afferents.

It has been argued by Stopford * that the afferent nerve fibres fall naturally into two groups. One group is connected with defensive functions, is phylogenetically the older, gives sensory responses of an all-or-nothing character as regards their affective qualities, and has important central connections with the thalamus. This group of fibres (spino-thalamic) crosses in its path in the cord. It includes sensations of pain, of extremes of temperature, and of pressure. The other group (posterior columns), less old, uncrossed in the cord, is essentially cortical in its terminations, and is concerned with finer discriminations of localisation, discrimination of position and passive movements, fine differences of temperature, and appreciation of lightest forms of touch.

Fig. 136 shows the main tracts of the spinal cord and Fig. 137 illustrates the mode of formation of the chief afferent paths, which is as follows :—

(1) FINE SKIN SENSATIONS, *e.g.* light touch, light or heavy pressure, fine localisation and discrimination, stereognosis, pass up at first in the *dorsal columns*, and continue there to reach the nuclei gracilis and cuneatus. The arrangement of the fibres is according to the order of dermatomes, the sacral fibres nearest the mid-line, the cervical ones furthest from it. Some of them, however, of cruder function, end synaptically at cells of the posterior horn, from which axons pass out to the *ventral spino-thalamic* tract of the opposite side. [This joins the spinal lemniscus and ends in the thalamus.]

(2) AFFERENT IMPULSES RELATED TO MOVEMENTS. These may be conscious, *i.e.* give rise to sensations, or unconscious; most of the latter are related to the maintenance of posture.

(*a*) The impulses subserving *conscious sensations of movement* enter at the posterior root, ascend in the columns of *Goll and Burdach* until they reach the *nuclei gracilis* and *cuneatus* in the medulla. [The cells in these nuclei give off second order relay fibres which, crossing in the sensory decussation, ascend in the mesial lemniscus (fillet) to the thalamus. Third order fibres originating in this convey the impulses to the cerebral cortex.]

(*b*) The *unconscious kinæsthetic impulses*; (i.) those from the skin enter the posterior root, and ascend in the columns of *Goll and Burdach* to the *nuclei gracilis* and *cuneatus*. [Second order fibres originate from the cells in these nuclei to travel as superficial or deep arcuate fibres to the inferior cerebellar peduncle by which they reach the vermis. Third order fibres may then convey the impulses to the cerebellar cortex.] The impulses along the dorsal columns travel rather slowly (70 m. p. sec.).

(ii.) The *spino-cerebellar tracts* also convey kinæsthetic impulses that do not enter consciousness. Impulses are set up by stimulation of muscle afferents (as by stretch) but not by stimulation of skin. They travel at high speed along large fibres, and most of them reach the cerebellum of the same side, where the arrival of impulses can be detected. They enter the posterior root and go to Clarke's column; from the cells in this column second order fibres ascend in both the spino-cerebellar tracts, chiefly of the same side. [Those of the *dorsal* tract entering by the inferior cerebellar peduncle, go to the vermis, from which third order fibres convey the impulses to the cerebellar cortex; some of the axons from the Clarke's column cells cross to the spino-cerebellar tracts of the opposite side. The *ventral* spino-cerebellar tract may arise from cells in Clarke's column, or (the crossed fibres) from cells scattered along the margin of the ventral horn.* At the level of the mid-brain the tract turns back abruptly to enter the superior cerebellar peduncle, where the fibres reach the vermis on the same side as that on which they started. From this, third order fibres travel to the cerebellar cortex.]

(3) PAIN AND THERMAL SENSE. The sensory fibres for pain and temperature enter by the *lateral* divisions of the dorsal nerve roots. Many of the fibres are non-myelinated.† They ascend a short distance in Lissauer's tract and relay in the cells of the *substantia gelatinosa Rolandi*. Second order fibres originating in these cells cross near the central canal to form the *lateral spino-thalamic* tract where they are dermatomally arranged, cervical nearer mid-line, sacral most lateral. [In this they ascend by the spinal lemniscus to the optic thalamus, where those concerned with the cruder sensations end. Some others for less crude forms relay round third order cells in the thalamus, which convey the impulses to the cortex.]

(4) SHORT PATH DESCENDING fibres derived from the descending axon branches include: a triangular bundle found in the lower lumbar region; the oval bundle of Flechsig, found in the lumbar region; and the comma tract, found in the thoracic region.

(5) AUTONOMIC afferent paths.

II. **Efferent Paths.** The chief projections from the cortex can be divided into the pyramidal or cortico-spinal tracts, and the extrapyramidal. The fibres of the former run *via* the medullary pyramids and end in the cord: those of the latter have a different course and destination.

(1) *The cortico-spinal tracts* arise from various sources, perhaps not all of them cortical, but at least 50 per cent. are, and this includes the large fibres which make up about 3 per cent. of the whole, and which originate in the Betz cells of area 4γ of the precentral cortex. This area also contributes many small fibres, as also does area 6 and parts of the parietal lobe (areas 3, 1, 2, 5 and in monkey 7).‡ Some fibres may be of subcortical origin. The tract is motor, and concerned with co-ordinated movements. The fibres, many of which are unmedullated, pass down through internal capsule, crura and pons to reach the medulla. Here the majority of the fibres cross, forming the *motor decussation*; part descend uncrossed. The crossed fibres form the *lateral cortico-spinal* or crossed pyramidal tract; they do not usually end at ventral horn cells directly but indirectly, by first synapsing with a cell in the dorsal horn and then perhaps again with one in the intermediate column; from here the impulse passes to the ventral horn cells; the axons of the ventral horn cells convey the impulses to the muscles. Those which do not cross travel in the *anterior cortico-spinal* or direct pyramidal tract, but most of them cross near their terminations to

---

* COOPER and SHERRINGTON. *Brain*, 1940, **63**, 123.

† RANSON. *Arch. Neurol. Psych.*, 1931, **26**, 1122.

‡ WOOLSEY and CHANG. *Fed. Proc.*, 1947, **6**, 230.

reach dorsal horn cells of the opposite side, from which fibres convey the impulses to ventral horn cells and so to the muscles. Thus, nearly all fibres from the right motor cortex are distributed to the left side of the body. The cortical cell and its axon leading to the spinal neurones is called the "*upper motor neurone*." It is of slow conduction rate (18–60 m. in cat), and its primary action is on flexor-reflex arcs, operated through interneurones in the dorsal horn.

In the lower mammals, impulses for posture and group movements probably travel largely in the *rubro-spinal* tract. This arises in the large-celled portion of the red nucleus. The fibres cross to the opposite side, and descend till they finish at anterior horn cells. These give off motor fibres to the muscles.

By means of the rubro-spinal tract the final common motor path is put into communication with the cerebellum of the *same* side (because this cerebellar path crosses twice, once in the superior cerebellar peduncles, and once in the rubro-spinal tract decussation). It also establishes connection between the corpus striatum and the final common paths of the opposite side. The cerebellum and corpus striatum also exert an influence on the final common path through the reticulo-spinal tract.

(2) BULBOSPINAL CORRELATION SYSTEM. The tracts of this system are ventrolateral in position, and represent a spinal continuation of the dorsal longitudinal bundle, with important contributions from the reticular and vestibular nuclei. The reticulo-spinal and vestibulo-spinal tracts play an important part in the control of posture.

(i.) The *reticulo-spinal tract.* This arises from the reticular formation of the brain stem and ends at the ventral horn interneurones.

The conduction is rapid, and the fibres synapse with interneurones from which the motoneurones are affected (or run direct to the latter). The reticulo-spinal tract is also directly activated on stimulation of the motor cortex, and as conduction is rapid, impulses reach the muscles earlier than those arriving *via* the pyramidal tracts, and so, perhaps, prepare the way for voluntary movement.

(ii.) The *vestibulo-spinal tract.* Impulses travel from the hair cells of the vestibular organs, and from other sources, to *Deiter's nucleus.* The cells in this nucleus give off fibres which descend by the *vestibulo-spinal* tract to the ventral horn interneurones in the cord and so to the motoneurones.

(iii.) The *tecto-spinal tract.* As the result of light falling on the retina, impulses are transmitted to the *superior corpora quadrigemina* (*colliculus superior*). Thence, fibres proceed downwards and cross at Meynert's tegmental decussation, forming the *tecto-spinal tract* by which they reach the anterior horn cells, and so reach the muscles. The connections, through the dorsal longitudinal bundle, facilitate co-ordination between the nuclei of the IIIrd, IVth, VIth and VIIth cranial nerves, and the eye and neck movements are harmonised.

(3) SYMPATHETIC EFFERENTS, *e.g.* (*a*) the pupil-dilating fibres. These fibres probably originate in or near to the superior corpora quadrigemina. They descend as far as the eighth cervical or first dorsal nerve roots. Here they probably relay at lateral horn cells, from which white rami proceed out by the ventral roots to the sympathetic chain. In this they pass up the cervical sympathetic to the superior cervical ganglion, where they synapse with cells from which postganglionic fibres proceed to the eyeballs, and so to the dilator muscle of the pupil.

(*b*) The vaso-motor fibres. These travel down the cord from the vaso-motor centre in the medulla by an unknown route. They relay in the lateral horn cells. Fibres from these cells pass out at the ventral roots of Th 1 to L 2, forming part of the white rami communicantes to the sympathetic.

There are many other sympathetic efferents (*v.* Chapter XXIII.)

EFFECTS OF SECTION OF CORD AND ROOTS

Complete Section of the Cord. Complete section of the cord results in permanent loss of voluntary movement of all muscles below the lesion. Thus, a monkey which has suffered a section of its lower cervical region will have paralysis of the lower limbs and part of the trunk, while parts above the section are apparently quite normal. The animal may contentedly direct its gaze through the window or may amuse itself by catching flies on the pane. There is also complete loss of all true sensations in parts of the body below the lesion ; reflexes such as micturition and defæcation become automatic, after a period of paralysis; and there is temporary vaso-dilatation below the lesion. These effects will be described later.

Hemi-Section of the Cord. The symptoms that follow division of the right or left side of the cord were first described by Brown-Séquard, and, after a preliminary period of spinal shock, are: (1) complete paralysis of muscles below the lesion on the same side; (2) increased postural tone and reflexes in muscles below the lesion on the same side; (3) pain, temperature, and some sensibility to touch is lost on the *opposite* side below the lesion; (4) kinæsthetic sensations are lost on the same side below the lesion; (5) temporary vaso-motor paralysis, and therefore a higher temperature below the lesion on the same side. In addition, as a result of irritation to the cut sensory fibres, there may be pain referred to parts of the body below the section. It is referred to the *opposite* side of the body to that on which the lesion of the cord has occurred. If the lesion has destroyed a length of the spinal cord, then in addition to the above we shall have the symptoms of damage to the ventral and dorsal nerve roots.

Section of the Dorsal Roots causes (most clearly when several consecutive roots are cut): (1) loss of all sensations from the limbs or other parts supplied; (2) weakness and inco-ordinated movements of the muscles owing to inability to receive kinæsthetic sensations from them; (3) injuries to the skin of the limbs supplied, owing to the absence of protective sensory impulses; (4) complete loss of tone in muscles of limbs supplied, since the kinæsthetic impulses which are responsible for them do not reach the anterior horn cells. If the section has been between the posterior root ganglion and the spinal cord, the degenerative changes affect the fibres entering the cord. These results are found in the disease tabes dorsalis. If, on the other hand, the lesion has affected the fibres between the posterior nerve roots and the sensory end organs, the fibres degenerate between the cut and the sensory end organs (see Fig. 138).

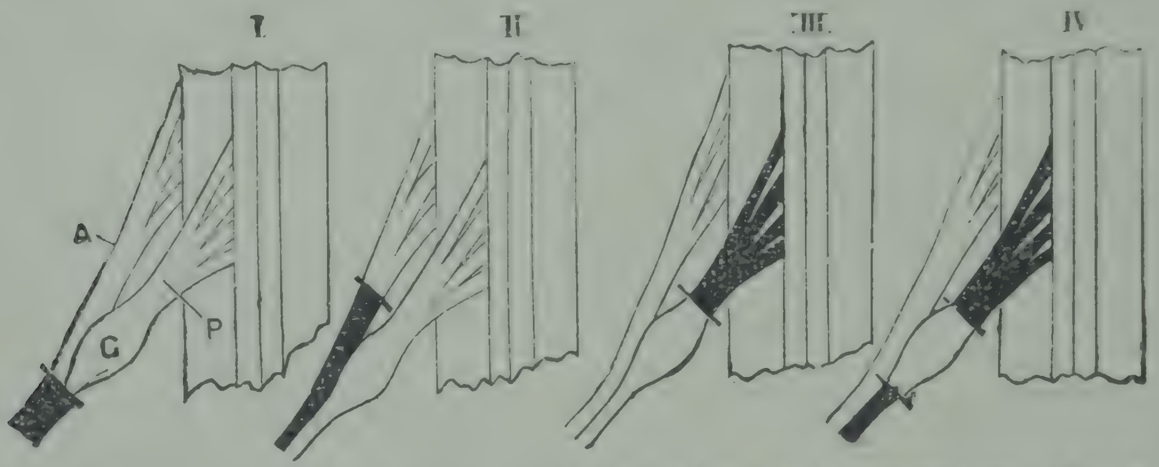

Fig. 138. To illustrate the extent and direction of degeneration (shown black) as a result of Section of the Spinal Roots. (From Yeo.)

Division of: I, Whole nerve trunk, below ganglion; II, anterior root; III, posterior root above ganglion; IV, posterior root above and below ganglion.

The above statement regarding the direction of degeneration of fibres after section of the dorsal roots is only an approximate one. Actually, many fibres remain undegenerated in the central stump, after section proximal to the ganglion,* and it has also been shown that efferent impulses, detectable electrically, pass outwards along the dorsal roots.† One among several explanations is that given by Barron and Matthews,‡ viz. that fibres enter the cord by one rootlet, and, after passing a short distance up the dorsal columns, a branch emerges by another rootlet, and passes to a second receptor at the periphery: there is the usual ganglion cell on the course of the normal afferent fibre, but none on the recurrent collateral.

Section of the Ventral Roots (several consecutive ones) causes in the part supplied: (1) complete loss of tone in muscles; (2) complete paralysis of muscles; (3) temporary vaso-dilatation owing to cutting of fibres which emerge as the white rami communicates to the sympathetic system; (4) nutritional disturbances, *e.g.* disuse atrophy of muscles, etc., unless measures be taken to prevent this: (5) changes in excitability and in chronaxie,

(v. p. 194); (6) degenerative changes in the nerve fibres between the cut and the periphery.

FUNCTIONAL LEVELS IN THE CENTRAL NERVOUS SYSTEM

Much of the investigation of the functions of the central nervous system involves the operative cross-section of the nervous axis at particular levels, or the removal of portions of the central nervous system. Thus a section may be made at any required level of the spinal cord, medulla or mid-brain; or part or the whole of the cerebral hemispheres, the cerebral cortex, the cerebellum, etc., may be extirpated. Animals so treated represent fundamental preparations for the study in simplified form of central nervous functions.

When the spinal cord is cut in the cervical region we have the *spinal preparation* *; when the section is made at the mid-brain we have the so-called *decerebrate preparation*; if only cerebral cortex is removed, a *decorticate preparation*, and so on.

An important principle of neurology was first enunciated by Hughlings Jackson; "increasing differentiation is attended or followed by more complete integration," and the means by which this integration is effected is a problem of fundamental interest. When a lower part of the central nervous system is separated by section from a higher part, two consequences ensue. First there is *loss of certain functions* of a higher order by reason of interruption of the paths by which the lower centres are controlled from the higher ones. So, for instance, on section at the mid-brain, there is loss of voluntary movement in the trunk and limbs. Secondly, certain new properties may appear as a result of what is known as "*release of function.*" For instance, after mid-brain section there is an exaggeration of the tonus of muscles, particularly extensor muscles, normally employed in the maintenance of posture. This result appears to be due to the removal of a restraint, normally exercised by the higher centres on centres in the medulla, thus revealing or releasing a reflex exaggeration of tone in the extensor muscles (decerebrate rigidity). When the higher centres are removed, the lower ones are released from their control, as first suggested by Hughlings Jackson in 1884. It is probable that primitive behaviour responses of the lower and phylogenetically older parts of the central nervous system are normally largely dominated and repressed by the higher levels of the nervous system.

The Spinal Animal. In the spinal animal proper, section is made at the junction between the spinal cord and the medulla, and often the entire head is removed, the body and limbs then being known as a "*decapitate*" *or* "*spinal*" *preparation* (Fig. 186, p. 275). Since breathing ceases, artificial respiration by means of a pump is carried out, and the preparation then remains alive for many hours, and provides a valuable object for acute laboratory experiments.

When section is made at lower levels, we speak of an animal with *spinal transection*; if section is above the fifth cervical segment, however, artificial respiration will have to be maintained if the animal is to survive for more than a few minutes, and this is inconvenient. It is customary, therefore, where possible, for spinal transections to be made at lower levels, so that the cervical cord, which gives origin to the phrenic nerves, will remain in connection with the higher parts of the nervous system from which respiration is controlled. Such animals, or human subjects with lesions, *e.g.* by bullet wounds, etc., in the dorsal or lumbar cord, may survive for months or years, and provide objects in which the reactions of the spinal cord may be studied without the interfering influences from higher parts.

For a variable length of time after the transection of the cord, a condition of depression prevails at levels supplied by the cord below the section. This state of depression is called *spinal shock*. In lower vertebrates such as the frog, it may pass off in a few minutes, but in higher animals it may last for hours, days, or, in man, weeks. During spinal shock there is paralysis of many reflexes, the limbs are flaccid, the blood pressure low, and the bladder fails to empty. All extensor reflexes are depressed.* The flexor reflex and the knee-jerk, however, are usually retained in lower mammals, though in man the knee-jerk returns late and is then feeble.

---

* The term "preparation" in physiology means a surviving portion of an animal.

Cause of Spinal Shock. Spinal shock was formerly thought to be a result of the irritation due to the section, but is now recognised as a release phenomenon, due to the cessation of a stream of impulses from above, which normally have a facilitating action.† The reasons for this belief are (1) that if, after the shock has passed off a second section is made lower down, no shock results, (2) that if a ring of the upper spinal cord be cooled, so that conductivity is abolished at that level, shock develops although no irritation is caused by the cooling, and when the cooling agency is removed the shock vanishes again,‡ (3) that, if the cord is only partly divided, evidence of shock only appears when the vestibulo-spinal and reticulo-spinal tracts (in cats) § or the cortico-spinal tracts (in man) are sectioned.

Alteration in the reflex excitability of the spinal cord is not entirely confined to the parts of the cord below the section, since the parts above the section often show an increased excitability of reflexes (the Schiff-Sherrington phenomenon). This may be attributed to release from an inhibitory influence of the lower segments of the cord on the upper segments.

Spinal Reflexes. The *flexor reflex* is obtained when a *nociceptive stimulus* (*i.e.* a stimulus which in a conscious animal would cause pain) is applied to a hind foot or leg, and consists of a flexion of the same (or ipsilateral) limb at all joints (Fig. 139). The *knee-jerk* is obtained by tapping the patellar tendon while the quadriceps extensors are put slightly on the stretch by the

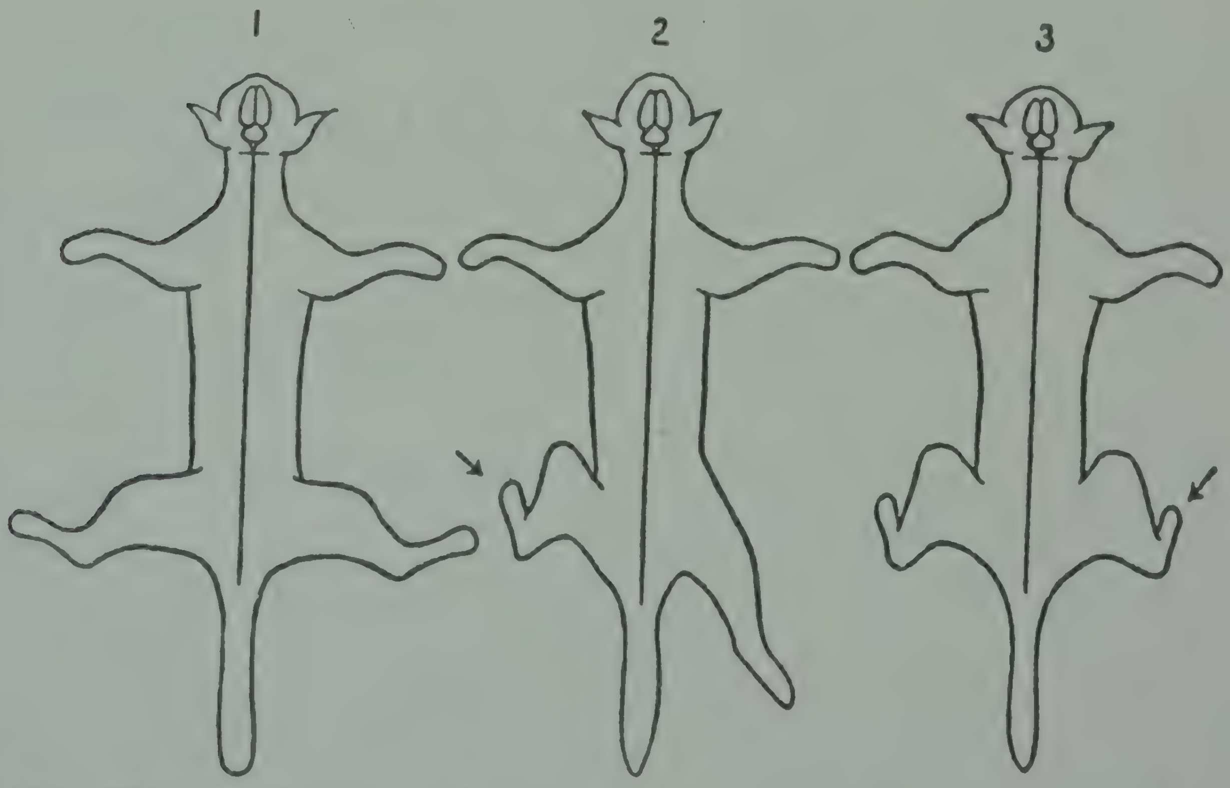

FIG. 139. Diagram illustrating Reflexes in the Spinal Cat. (1) The initial pose of the spinal animal. (2) Stimulation of left hind foot causes ipsilateral flexion and contralateral extension in the hind limbs. (3) On simultaneous stimulation of both feet there is flexion of both legs, since flexion reflex is prepotent. (SHERRINGTON. "Integrative Action of the Nervous System." Constable, 1906.)

---

* In acute experiments the extensor reflexes emerge earlier if an intravenous injection of ephedrine (1 mg./kg. for dogs) is given. HINSEY, RANSON and ZEISS. *J. Comp. Neurol.*, 1931, **53**, 401.

† LIDDELL. *Brain*, 1934, **57**, 386.

§ FULTON, LIDDELL and RIOCH. *Brain*, 1930, **53**, 311, 327.

weight of the leg, and consists of a strong extension of the leg at the knee joint.

As the condition of shock wears off, other reflexes make their appearance. Among these are the extensor reflexes. The *crossed extensor reflex*, *i.e.* extension in the opposite (contralateral) hind limb is obtained, together with the ipsilateral flexion reflex, when a nociceptive stimulus is applied to the foot or to any afferent nerve from the leg (Fig. 139 (2)). This is clearly a co-ordinated response, enabling the animal to throw more weight on one leg when the other is injured and therefore flexed out of the way. Various *stretch reflexes* also return, but these will be discussed later.

The *extensor thrust reflex* in spinal animals is only seen after recovery has made considerable progress. It consists in a sharp extensor push of the leg when firm pressure is applied to the pad of the foot. Flexion of the opposite leg accompanies it, and the two actions represent a compound reflex which forms the basis of galloping.

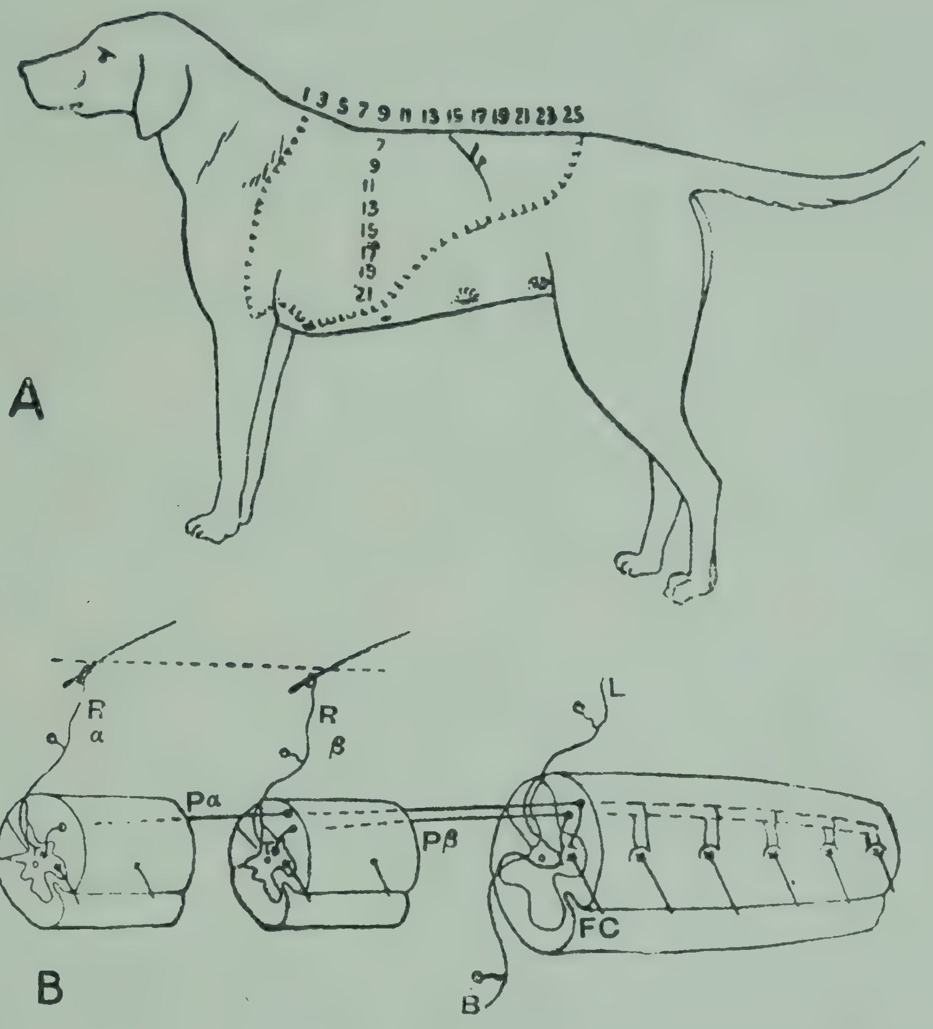

FIG. 140. A, the area from which the scratch-reflex can be evoked. B, the reflex arcs involved. (SHERRINGTON. "Integrative Action of the Nervous System." Constable, 1906.)

Another still more complex reflex late in returning is the *scratch reflex*, well seen in the spinal dog. If an appropriate stimulus is applied to a certain area (Fig. 140) of skin over the flank and shoulders, the ipsilateral hind limb executes rapid scratching movements, while the contralateral limb is rigidly extended. The appropriate stimulus should be a continuous one, slowly moved along among the hairs, in order to offset the rapid adaptation of the skin receptors, and the significance of the reflex is self-evident

Isolated Segments. For some investigations it has been found possible to isolate short portions of cord consisting of one or two segments only, by making sections above and below. In portions consisting of only two or three segments, quite normal reflex responses can be obtained.*

The Decerebrate Preparation. Division of the nervous axis at the level of the mid-brain (and destruction of the parts above the section) gives a very valuable preparation. In this, the body is left under the management of the spinal cord, medulla, cerebellum and pons, with variable parts of the mid-brain, according to the level of the section. It is sometimes called a "bulbo-spinal" preparation. As with the decapitate preparation, after the operation is completed no further anæsthetic is required, because the higher centres are all removed; unlike the decapitate preparation, various complex automatic and reflex acts are preserved. Thus respiration continues, swallowing and vomiting can take place, the arterial blood pressure remains high, and various cardiac, vascular and respiratory reflexes are retained. Temperature regulation and righting reflexes are lost, however, as in the spinal animal, but, on the other hand, there is nothing corresponding to spinal shock. It is clear, therefore, that the nervous mechanism of temperature regulation is situated higher than the level of the mid-brain, but that the cells of origin of those tracts, division of which causes spinal shock, must be somewhere between the upper spinal cord and the mid-brain. Not only does the decerebrate animal *not* show the transitory extinction of extensor reflexes characteristic of spinal shock, but instead, it shows such great exaggeration of all extensor reflexes that many of the extensor muscles are aroused to a state of permanent hypertonus. The flexor responses seen in the spinal preparation can all be elicited, however, though not so easily.

---

* TEN CATE. *Arch. néerl. Physiol.*, 1932, **17**, 331, 525.

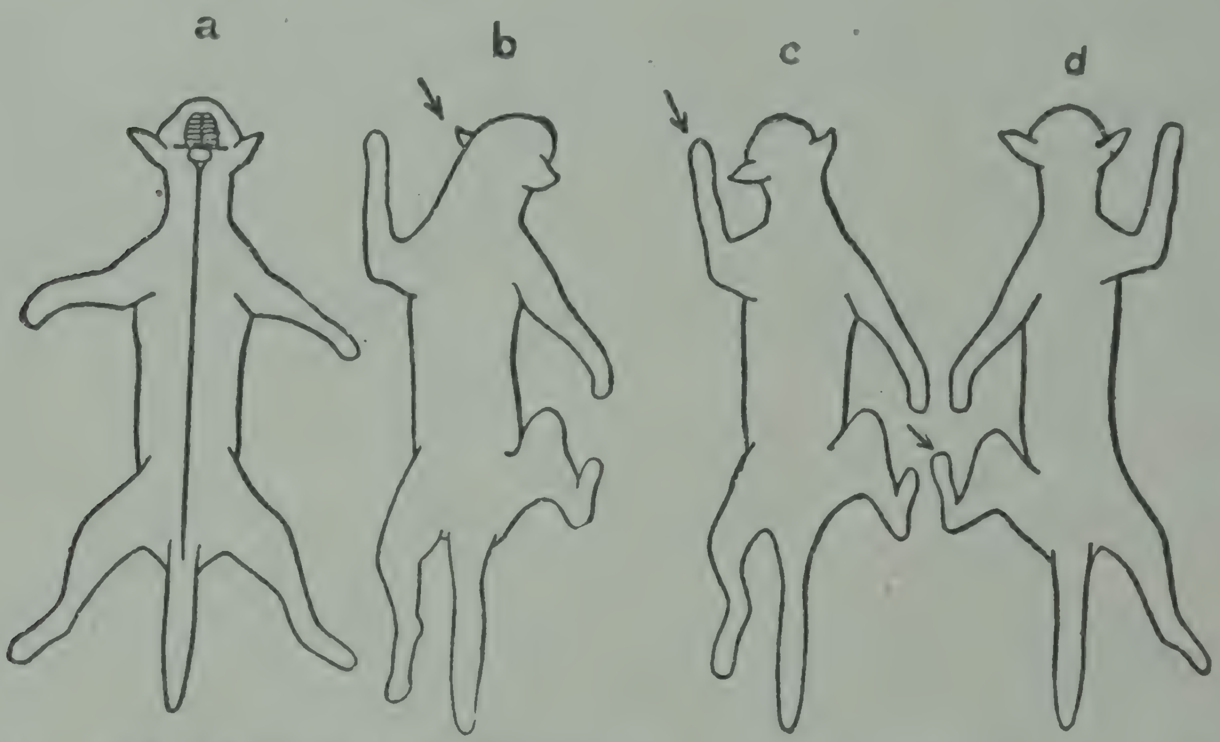

FIG. 141. Reflex Figures in Decerebrate Cat. (a) Normal decerebrate rigidity—extension of all limbs. (b) Stimulation of left pinna—flexion of left fore and right hind limbs, increased extension of others. (c), (d) Stimulation of left fore and left hind limbs respectively. (SHERRINGTON.)

The extensor tonus is evident as a rigidity of the limbs,* spoken of as *decerebrate rigidity* (Figs. 141, and 186, p. 275). It affects the anti-gravity muscles, *i.e.* those muscles involved in keeping the animal in a normal standing posture, which in most quadrupeds are the extensors at all joints of the four limbs, and the muscles that keep the head and tail from falling forwards.

If we accept spinal shock as a release phenomenon, due to the removal of an influence from above, which augments the extensor reflex responses, then we must recognise decerebrate rigidity as due to the retention of that influence. It is thus a release phenomenon of another type. We may suppose that the influence of centres in the medulla, or other higher parts that are present in the preparation, in exaggerating extensor responses is now left in undisputed possession of the field, whereas in the intact central nervous system the effects of these centres are subordinated to still higher centres. Hence a grossly exaggerated picture of reflex standing results, which under the influence of higher centres would be modified to give the normal stance.

The decerebrate preparation is accordingly very useful for the investiga-

---

* SHERRINGTON. *J. Physiol.*, 1897, **22**, 319.

tion of phenomena of extensor reflexes and their inhibition. It also shows many instances of complex reflexes involving co-operation between different segments of the cord. For instance, there is the phenomenon of *reflex figures*, *i.e.* if a pinna or one limb is stimulated characteristic flexion and extensions of limbs as shown in Fig. 141 (b).

It will be clear that these various reflex figures play their parts in the normal movements of the animal.

The Decorticate Preparation. Removal of the entire cerebral cortex gives a preparation that in many respects resembles a normal animal.* In dogs and cats, most bodily functions and also temperature regulation, locomotion and posture are normal, and *righting reflexes* are present, *i.e.* if the animal is put into an abnormal position, it rights itself. There is no extensor rigidity so long as a normal position is maintained, though if held up by the neck an extensor hypertonus resembling decerebrate rigidity makes its appearance. If sections of the brain are made coronally from before backwards, no sign of decerebrate rigidity appears until section reaches a plane passing through or just behind the posterior part of the thalamus,† thus indicating that decerebrate rigidity is due to release of lower postural centres (Deiter's nucleus), from the control of centres lying anterior to the pons. Posture and righting reflexes are, in fact, retained almost normally if section passes anywhere anterior to the mid-brain, so that righting reflexes are probably controlled from the mid-brain.

If only the cerebral *cortex* is removed, leaving behind the basal ganglia, the animal may retain many reflexes connected with special senses ; thus it will make attempts to eat articles that smell like food, moves to sounds, shows constriction of the pupil of the eye to light, etc. All of these reactions, however normal in appearance, are reflexes mediated by subcortical centres and have no connection with any actual sensation, since the animal is totally deaf, blind and unconscious.

Still more remarkable are the appearances of the expression of primitive emotions, such as rage and fear. A decorticate dog or cat, if disturbed or stimulated in almost any way, however slightly, will exhibit all the signs of violent and exaggerated rage, biting, struggling, lashing of tail, erection of hairs, high pulse-rate and blood pressure, etc. These reactions, though complex and apparently purposive, are also reflex in nature, and are not associated with any state of consciousness on the part of the animal. They are accompanied by intense outbursts of sympathetic activity. These subconscious manifestations are probably due to activity in the posterior part of the hypothalamus,‡ and are release phenomena, due to the removal of that cortical control which regulates and rationalises the behaviour of the whole animal. It is probable that unreasoning fear or rage, and emotional instability, in man, are often associated with release of the hypothalamic mechanisms from normal cortical control.

In the higher apes (and we may suppose that it would be similar in man), decortication leads to more profound and evident losses of function than is the case with lower mammals. Normal locomotion is lost and the animal lies on its side in an abnormal posture, with the undermost limbs extended and rigid and the uppermost ones flexed.§

SPINAL TRANSECTION IN MAN

The consequences of spinal transection in man were studied in great detail by Head and Riddoch ‖ on men wounded in the World War I. At the moment of injury, if the transection is complete, the subject feels that the lower part of his body has vanished. The patient will never recover, though his condition alters as time goes on. (I.) There is first a prolonged *stage of shock*, with complete loss of movement and sensation in the parts below the lesion, and a feeling of a tight or painful girdle round the body is often present just above it. The muscles are flaccid, the limbs flushed but cold, and there is no sweating below the lesion. Blood pressure is low. Nearly all the muscular reflexes vanish. The anal and bladder sphincters are tightly contracted, the detrusor flaccid, and urine and fæces tend to be retained. This stage lasts for two or three weeks.

---

* Goltz. *Pflüger's Arch.*, 1892, **51**, 570.
† Thiele. *J. Physiol.*, 1905, **32**, 358.
‡ Bard. *Amer. J. Physiol.*, 1928, **84**, 490.
§ Bieber and Fulton. *Arch. Neurol. Psychiat.*, 1938, **39**, 435.
‖ Head and Riddoch. *Brain*, 1917, **40**, 188.

(II.) In the second stage there is a *return of reflex activity*. The bladder sphincters become less tonic, and later the bladder is reflexly emptied. The arterial pressure returns to normal and there is some improvement in circulation in the legs. Tone begins to return a little in the flexor muscles, and flexor reflexes appear, the first hint of this usually being the occurrence of slight upward movement (" dorsiflexion ") of the big toe (the Babinski reflex),* when the sole of the foot is scratched. Later, the complete flexor reflex (dorsiflexion of toes and of foot, flexion of knee and hip with abduction of thigh), slowly emerges, and tone in flexor muscles is back to normal.

The Babinski reflex is a primitive one, seen in infants, which is absent from normal adults : in these the response of the toes is plantar-flexion. This is converted to the dorsiflexor response in any circumstances in which the cortico-spinal tract is severed. It is unfortunate that the name " extensor response " has been attached to the Babinski reflex. Dorsiflexion of the big toe as seen in the Babinski response, is part of a generalised nociceptive *flexor* reflex,† since the extensor longus hallucis shortens the limb ; when the response is powerful it can be elicited from a large area of the limb, and is accompanied by a crossed extensor response.

The abdominal reflex, a contraction of the recti on scratching the surface of the abdomen, is another conspicuous flexor reflex.

Extensor tone never shows much recovery, and extensor reflexes, such as the knee-jerk are weak, but sharp and brief. A weak crossed extensor response may accompany a flexor reflex. Owing to the preponderance of flexor over extensor tonus, the lower limbs usually remain semiflexed, and hence this condition is often called *paraplegia in flexion*. Flexor response to even a slight stimulus almost anywhere in the paralysed region may ultimately become very widespread and powerful, and becomes the *mass reflex*. This is due to irradiation, and is accompanied by sweating in the paralysed regions and by evacuation of the bladder owing to the rise of intra-abdominal pressure.

During this second stage, reflex micturition and defæcation make their appearance. Gradually also, there appear, at intervals, " spontaneous " reflex flexor movements of the lower limbs, which ultimately become almost continual. Hence the muscles do not waste so much as in cases of destruction of the lower motor neurone, *e.g.* that on section of the motor nerves.

In a third, and much later, stage, reflex activity may gradually fail again and then the muscles do waste. Trophic changes such as the formation of ulcers and bed-sores further complicate the patient's existence.

Incomplete transection of various degrees, of course, also occurs in man and is frequently distinguished by the fact that extensor tone and extensor reflexes may be enhanced instead of being lost. Flexor reflexes, including the abdominal reflex, on the other hand, are depressed or absent. Hence the condition is often called " *paraplegia in extension*." The difference is attributed to the section of the cortico-spinal with retention of the vestibulo-spinal and reticulo-spinal tracts, so that the state of reflex activity in the cord more resembles that of the decerebrate than of the spinal animal.

Trophic Functions of the Cord. The reflexes which are excited by nocuous stimuli must be regarded as *prepotent*, in that their inhibitory effect on other reflexes is more marked than that produced by any other quality of stimulus. In the struggle for existence, the reaction to nocuous stimuli must predominate over those due to any other kind, since it is essential for the survival of the animal that these stimuli should be removed or avoided.

---

* FULTON and KELLER. The Sign of Babinski. 1932 (Thomas, Springfield).

† WALSHE. *Brain*, 1914, **37**, 269.

It is natural, therefore, that after complete section of the spinal cord, or of the afferent nerves from any part of the surface of the body, there should be a tendency to trophic disturbances such as the formation of ulcers, etc. A spinal patient may easily be burnt by a hot-water bottle. After section of the first division of the Vth nerve, ulceration of the cornea is often produced. These effects are due to the absence of the normal protective reactions of the part, and can be prevented by scrupulous cleanliness and protection of the anæsthetic part from all possible injuries.

There are other trophic effects caused by nerve lesions which cannot be ascribed to the mere absence of protective reflexes. Thus, inflammation of the posterior root ganglia often sets up "herpes zoster," or "shingles," in the region of cutaneous distribution of the corresponding sensory nerve. Changes in the skin ("glossy skin"), nails and hair are often seen after irritative injuries of nerves to the part. Section of a motor nerve causes rapid changes in the skeletal muscles supplied, which become smaller, and after months or years may disappear altogether, being replaced by connective tissue.

It seems that the nutrition of a tissue is determined by its activity, and this in turn is under the control of some nerve path. Section of the nerve path, by cutting away the impulses which normally maintain the activity of the part, must at the same time seriously affect its nutrition. Thus, muscles such as the sphincter ani, which, though striated, are only under the reflex control of the central nervous system, only slowly undergo degeneration after section of their nerves, or after extirpation of the lower part of the spinal cord.

The Brown-Séquard Syndrome. One of the most impressive of neurological states is that in which, as a result of injury, or of pressure from a tumour, there is unilateral interruption of the spinal pathways. There follows a loss of movement on the same side as the injury, together with a qualitatively differentiated loss, or impairment, of sensation on one or other side. Proprioceptive sensations are lost on the same side as the lesion, because their fibres, in the posterior columns, do not cross until the medulla is reached. Pain and thermal sensations are lost on the opposite side, because their fibres cross (into the lateral spino-thalamic tract) soon after entry into the cord. Fine skin sensation is not lost because some fibres remain uncrossed, though most cross over.

Section of the spino-thalamic tracts has been effected surgically for relief of intolerable pain.

CHAPTER XVI

THE EXCITABILITY OF NEURONES AND THE PROPERTIES OF CONDUCTION AT SYNAPSES

Conduction in a reflex arc differs from that in peripheral nerves, in that part of it takes place through grey matter, and hence we must look to the properties of the bodies of the nerve cell (soma) or to properties of the synapse for an explanation of the differences between nerve fibre conduction and reflex arc conduction.

It is implicit in the neurone hypothesis that the impulse which emerges by the efferent fibre of a reflex arc is not the same impulse as that which enters the spinal cord by the afferent fibre : it is a new impulse generated by the cell of which the efferent fibre is the axon. Apart from the important evidences of histology, we believe that this is so because (*a*) the time that elapses between the entry of the afferent impulse and the emergence of the efferent response is longer than would be needed for direct transmission, and (*b*) the emergent impulses in response to a given train of afferent impulses, though they may, and often do, tally impulse for impulse, with the number of ingoing impulses, do not necessarily do so ; either more or fewer may emerge.

Present-day conceptions of the mechanism of reflex action are indebted chiefly to the investigations of Sherrington and his pupils, and most of their explanations, derived from the study of spinal reflexes, have received general acceptance. It is also generally agreed that an isolated and simple reflex, as diagrammatically represented in Fig. 126, is nothing more than a convenient fiction. When we come to study actual reflexes, we find them to be less simple, and hence interpretation is a matter for detailed analysis. The essential correctness of the conclusions reached by the Sherrington school is shown by the fact that their conceptions have received important confirmation and extension from recent work, which, being more definitely directed to the study of the properties of synapses and neurones, will be outlined first.

Nature of Synaptic Conduction. When we speak of the "passage" of an impulse through a synapse, we mean that the incoming impulse is extinguished and a new impulse started in the cyton of the succeeding neurone. There are two views as to the way in which this transmission is brought about, and these may be called the *electrical* theory and the *chemical*, or humoral, theory respectively.

According to the electrical theory, the action potential in the synaptic terminals of the afferent fibres excites the body or dendrites of the second neurone, acting, in fact, as an electrical stimulus. According to the humoral transmission theory, the action potential at the synaptic endings causes, in or near those endings, a liberation of a highly active substance, the transmitter substance, which chemically excites the next neurone. We have already considered such a case for neuromuscular transmission.

For the present we shall consider the matter from the electrical standpoint, because, as a first approximation, it is simpler to do so, and later, in Chapter XXIII, shall return to the consideration of the chemical theory. Probably each of these theories represents a partial view of what occurs, and the electrical and chemical changes are only different aspects of a complex event of many concomitants.

The main requirements in electrical synaptic transmission are * : (i) that the action potentials at the synaptic knobs of the pre-synaptic endings set up local electrotonic potentials at the surface of the post-synaptic cell. These resemble the local non-propagated responses in nerve fibres (p. 180) and beyond a nerve block (p. 187); (ii) these potentials can summate, and, when the threshold is reached, start off an impulse in the post-synaptic cell and so on to its axon.

---

* Eccles. *Ann. N.Y. Acad. Sci.*, 1946, **47**, 429.

The rapid build-up of synaptic potentials is helped by the fact that many synaptic endings converge on to each nerve cell. As the action potential in the pre-synaptic fibre approaches the synaptic knob, the post-synaptic membrane would become first an anodic and then a cathodic region, as shown in Fig. 142 (*a*) and (*b*). The former would locally depress excitability, and the latter would set up a locally increased excitability due to the catelectrotonic state; when this has reached a sufficient intensity and occupied a large enough area, an impulse would be started which would then pass to the post-synaptic axon.

That there is nothing inherently improbable in this hypothesis has been shown by experiments on artificial synapses or *ephapses*.* These consist of two giant non-medullated fibres touching one another, the orientation of one fibre to the other being varied in different ways. The results of such experiments have been described on p. 184. Under the conditions of the experiment the resting fibre is not sufficiently excited to start a propagated impulse, but this result can be attained if the excitability of the fibre is raised by lack of calcium, and it could well be that in the actual synapse, the number of end-knobs, and their nearness to the post-synaptic membrane, would readily allow of the catelectrotonic state of the latter reaching the requisite threshold.

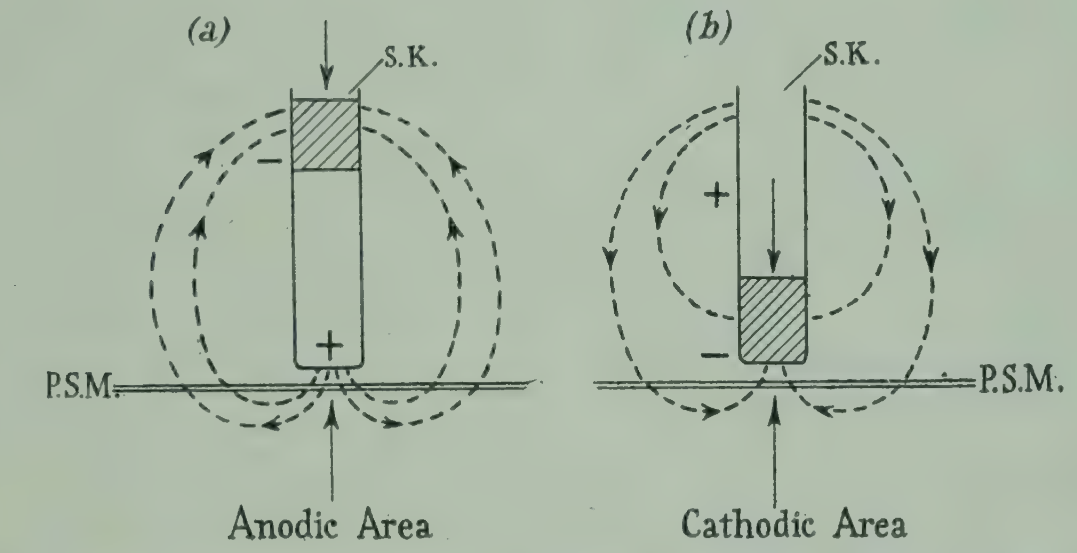

FIG. 142. Development of Synaptic Potential. S.K., Synaptic knob; P.S.M., Post-synaptic membrane. (*a*) Action potential approaching; area of anelectrotonic potential beneath knob. (*b*) Action potential arrived: area of catelectrotonic potential beneath knob. (After Eccles.)

Transmission in Sympathetic Ganglia. Synaptic transmission is reduced to its simplest terms in the sympathetic ganglia, *e.g.* the superior cervical ganglion, when stimulated by a synchronous pre-synaptic volley. The fibres which enter from below (pre-ganglionic fibres) have synapses in the ganglion, from the cells of which axons pass up (post-ganglionic fibres) in the neck and are distributed to various structures in the head. One of these structures in the cat is the plain muscle of the nictitating membrane (Fig. 143) and it is the neurones supplying this which have been especially studied. There are at least three other types of neurones in the ganglion, but for the sake of simplicity we shall only consider this one.

When a volley of impulses is started in the pre-ganglionic fibres, by stimulation at *A* (Fig. 143), a volley emerges along the post-ganglionic fibres and can be recorded from electrodes one of which is placed at *E*.† Also the response

can be registered by recording the contraction of the nictitating membrane.* The neurones respond to each afferent impulse with one efferent nerve impulse, and one only.† In conduction across these synapses about 3 msec. is lost (= synaptic delay). If the post-ganglionic nerve be stimulated, *e.g.* at B (anti-dromic stimulation), no impulse can be detected in the pre-ganglionic fibre, *e.g.* at electrode *C*, *i.e.* the synapse will not conduct backwards; but a disturbance is detected at the ganglion itself, showing that the antidromic impulse extends back as far as the nerve cell, and probably into any dendrites it may have. The backfiring of an anti-dromic impulse does not leave the nerve cells unaffected, but is followed by a refractory period during which a normally arriving pre-ganglionic volley produces no effect.

When the pre-ganglionic fibres are stimulated, and the action potentials thereby produced are studied in the ganglion and in the adjacent post-ganglionic fibres, these are found to be unlike those which pass along the pre-ganglionic fibre. The changes in the ganglion show three waves, viz. a spike (*S*), a negative after-

† BRONK, TOWER, SOLANDT and LARRABEE. *Amer. J. Physiol.*, 1938, **122**, 1.

potential (N), and a positive after-potential (P) (Fig. 144), and it was shown by Eccles * that these are related to the excitatory process in the nerve cells, in much the same manner as the spike and after-potentials of nerve fibres are related to its excitatory condition.

Immediately following the arrival of the pre-ganglionic nerve impulses at their synapses is a *synaptic delay* of about 3 msec. The spike potential of the soma then occurs if the nerve cell is to discharge an impulse along its axon. During the spike, which lasts about 5 msec., the cell is in an absolute or relative *refractory state*, *i.e.* a second impulse does not excite, or excites less readily.

The after-potentials, according to Eccles, consist of two simultaneous and opposing changes, one tending to make the ganglion (cells) negative and one positive.

At first the negative wave is the greater, but the positive one outlasts it (Fig. 145). In the algebraic resultant therefore we have first a negative potential of varying size (N) followed by a positive one (P) (Fig. 144). Both potentials increase in size as the stimulus is increased. During the prevalence of the N-wave the ganglion cells are in a state of supernormal excitability, in consequence of which they respond to a smaller second stimulus and with shorter synaptic delay than before (temporal summation). This stage may last for 150 msec. An N-wave always accompanies the application of a stimulus to the nerve cells, *e.g.* at the synapse, even if this is too weak to excite them (Fig. 144). The appearance of the N-wave coincides with the condition of the cell which was called by Eccles and Sherrington the *central excitatory state* (c.e.s.), *i.e.* a proneness to excitation. Hence if two subthreshold stimuli along the same afferent fibre are so spaced in time that the second arrives during the c.e.s. produced by the first, the raised c.e.s. may enable the cell to respond and discharge an impulse. Since the supernormal phase follows the refractory period of the cell and fibre, therefore, *temporal summation* can occur in ganglia, even when the intervals run into many msecs. When the c.e.s. reaches a certain level the cell discharges its impulse at the slightest provocation, and when it has done so this hastens the subsidence of the c.e.s.

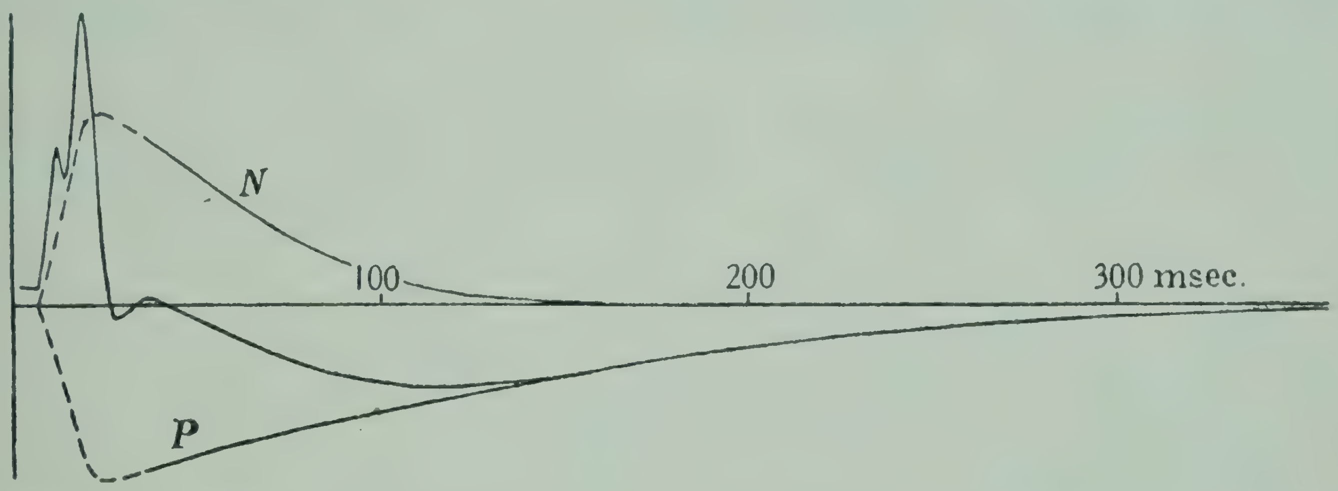

FIG. 145. Ganglion Potential Curve, and the Reconstructed Negative (N) and Positive Waves, which sum algebraically with the spike to give the complete curve. (ECCLES. *J. Physiol.*, 1935, **85.**)

The presence of *small* amounts of adrenaline may facilitate the synaptic response.†

Another kind of summation may be illustrated with the superior cervical ganglion. If stimuli of subthreshold strength be applied to two branches (of the annulus of Vieussens) at F and G (Fig. 143 II), provided the stimuli are not more than about 2 msec. apart, excitation of the cells may result. This is called *spatial summation* because the stimuli act at different points on the soma.

The P-wave, which follows the N, is indicative of a corresponding change in the excitability of the cell, which is now reduced—a condition called *central inhibitory state* (c.i.s.). During this phase, which lasts for 500 msec., the cell is less excitable, *i.e.* its threshold of excitability is raised.

The results of backfiring an antidromic impulse from the post-ganglionic fibres into the ganglion show that the neurone is caused to go through processes very similar to those which occur when it is stimulated in a forward direction.‡ Thus the ganglion shows a spike potential followed by the N- and P-waves, the P-wave being very large and prolonged. After the backfiring there is an absolute refractory period of 2 msec. followed by a long lasting state of depressed excitability running parallel with a prolonged P-wave. In other words, the cell has discharged an impulse, though this has been unable to pass backwards through the synapse, and the discharge has been followed by a prolonged central inhibitory state.

---

† BÜLBRING. *J. Physiol.*, 1944, **103,** 55.

‡ ECCLES. *J. Physiol.*, 1936, **88,** 1.

The after-potentials are essentially due to changes of polarisation in the cell body and do not extend far down the post-ganglionic axons; probably they merely spread electrotonically. They indicate a *state of excitability* of the cell and its synapse and *not* the propagation of a nervous impulse. The N-wave is reduced by nicotine, which also destroys c.e.s.

In further investigations Eccles,* using the stellate ganglion, showed that when this is curarised, so as to block synaptic transmission, preganglionic stimulation causes a local negative potential of the ganglion cells relative to their axons; this is due to a *synaptic potential*, which spreads decrementally and slowly decays. It is this catelectrotonic potential (resembling end-plate potential in curarised muscle), in its earlier and intense phase (peak at 3 msec.), which, in absence of curare, is able to excite the soma. The synaptic potentials show summation with repetition of stimulation. The speed of the synaptic response is one of the difficulties in the way of regarding transmission as a chemical mechanism such as by acetyl choline.† Moreover, the duration of this peak response is not increased by eserine. The c.e.s. set up in the cell does not begin until after the synaptic delay and lasts much longer, reaching a maximum at 10 to 15 msec. It can therefore have no direct action in discharging the impulse, but merely increases the "explosiveness" of the cells.

Transmission at Motoneurones. We may now consider the phenomena of excitation and transmission in less simple neurone arrangements, such as those found in the central nervous system proper. Most valuable investigations have been made by Lorente de Nó ‡ on the motoneurones of the oculomotor nucleus, which supplies the motor fibres of the third, fourth and sixth cranial nerves.

The oculomotor neurones are a final common path in three reflex arcs, one from the labyrinth, one from the fifth nerve and one from the neck muscles.

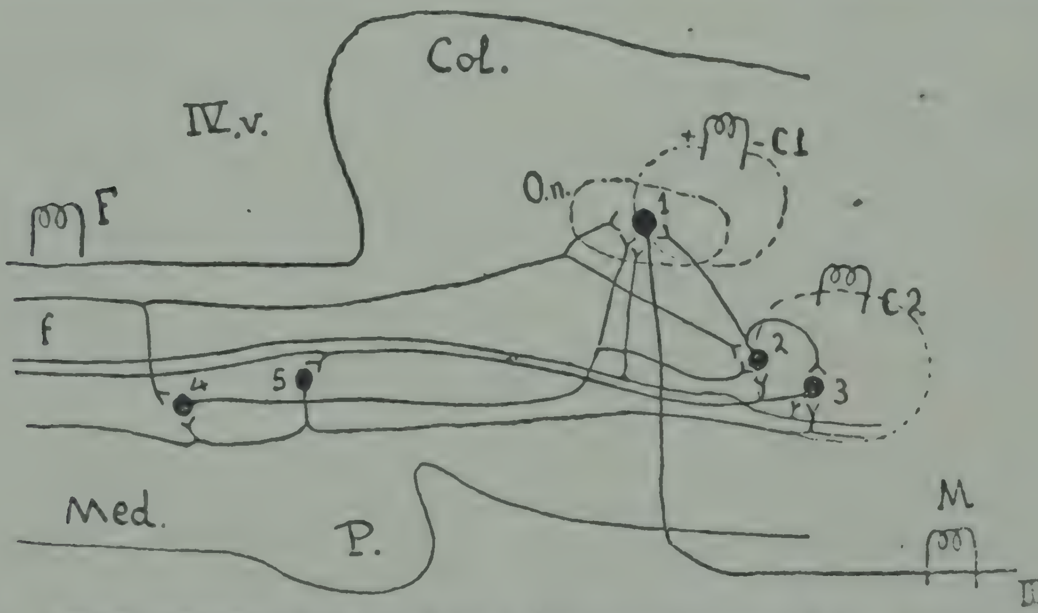

FIG. 146. Arrangements for studying the responses of the oculomotor motoneurones. IV.v. Fourth ventricle; Col, colliculi; Med, medulla; P, pons; F, C_1, C_2 and M., positions for stimulating electrodes; O.n. oculomotor nucleus; III, oculomotor nerve; f, fibres in posterior longitudinal bundle stimulated by F shock; 1, motoneurones of third nucleus; 2, 3, 4 and 5, internuncial neurones of reticular substance; Shocks at C_1 and C_2 stimulate motoneurones and internuncial cells respectively. (LORENTE DE NÓ. *J. Cell. Comp. Physiol.*, 1935, **7**, 47.)

The afferent fibres from these pass in or near to the posterior longitudinal bundle which runs near the floor of the fourth ventricle and can be stimulated there.

The arrangement of some of these experiments is illustrated by Fig. 146.

These neurones can be stimulated, either *viâ* synapses which are formed with fibres of the posterior longitudinal bundle, by electrodes in the floor of the fourth ventricle at the point F in Fig. 146, or directly at C_1, by electrodes buried in the colliculi, and the response can be recorded as an action potential in the third or fourth nerves, or in the eye muscles they supply.

† BROWN. *Physiol. Rev.*, 1937, **17**, 485.

‡ LORENTE DE NÓ. *Amer. J. Physiol.*, 1935, **111**, 272, 283; **113**, 505, 524. *J. Cell. Comp. Physiol.*, 1935, **7**, 47; *J. Neurophysiol.*, 1938, **1**, 187, 195, 207; 1939, **2**, 402.

By stimulation at the electrodes M, on the third nerve, the cells (1) of the nucleus receive an antidromic impulse, and, of course, the muscle is stimulated by the forward impulse. The cells and fibres concerned in these experiments are of higher excitability and faster action than those we have just studied in the sympathetic system, but apart from this difference in the time-scale there is a general similarity between the phenomena in the two places.

Direct stimulation of the nerve cells (position C_1) with one shock, gives, with no appreciable latency, a single volley of impulses; two subliminal shocks, if in sufficiently quick succession, also excite by latent addition. For this to occur they must be not more than 0·2 to 0·3 msec. apart. This shows that the excitatory process caused by stimulation of the motoneurone is of the same duration as that of nerve fibres. Having once responded, the motoneurones pass through a *refractory phase,* which is absolute for about 0·5 msec., which again is identical with that for nerve fibres.

The refractory phase is followed by a long period (30 msec. or more) of *subnormal excitability* which resembles that of a nerve fibre that has received a number of stimuli in quick succession (Fig. 97, p. 179). It is doubtful whether there is a supernormal phase resembling that shown by nerve after a single conditioning stimulus, or by the cells of sympathetic ganglia.

Thus far, then, there is a close similarity between the properties of the soma and those of the nerve fibre.

Synaptic stimulation of the motoneurones can be brought about by a single stimulus applied at the F electrodes (Figs. 146 and 147). When excited in this way there is a delay of about 0·6 msec. in transmission across the synapse. If the motoneurone does not respond within this time it will not respond at all unless restimulated by a new impulse. Since the major part of the spike potential in a nerve fibre (or synaptic knob) lasts about 0·5 msec., it would seem that it is the action potential at the synaptic knobs which isthe synaptic transmitter of excitation.

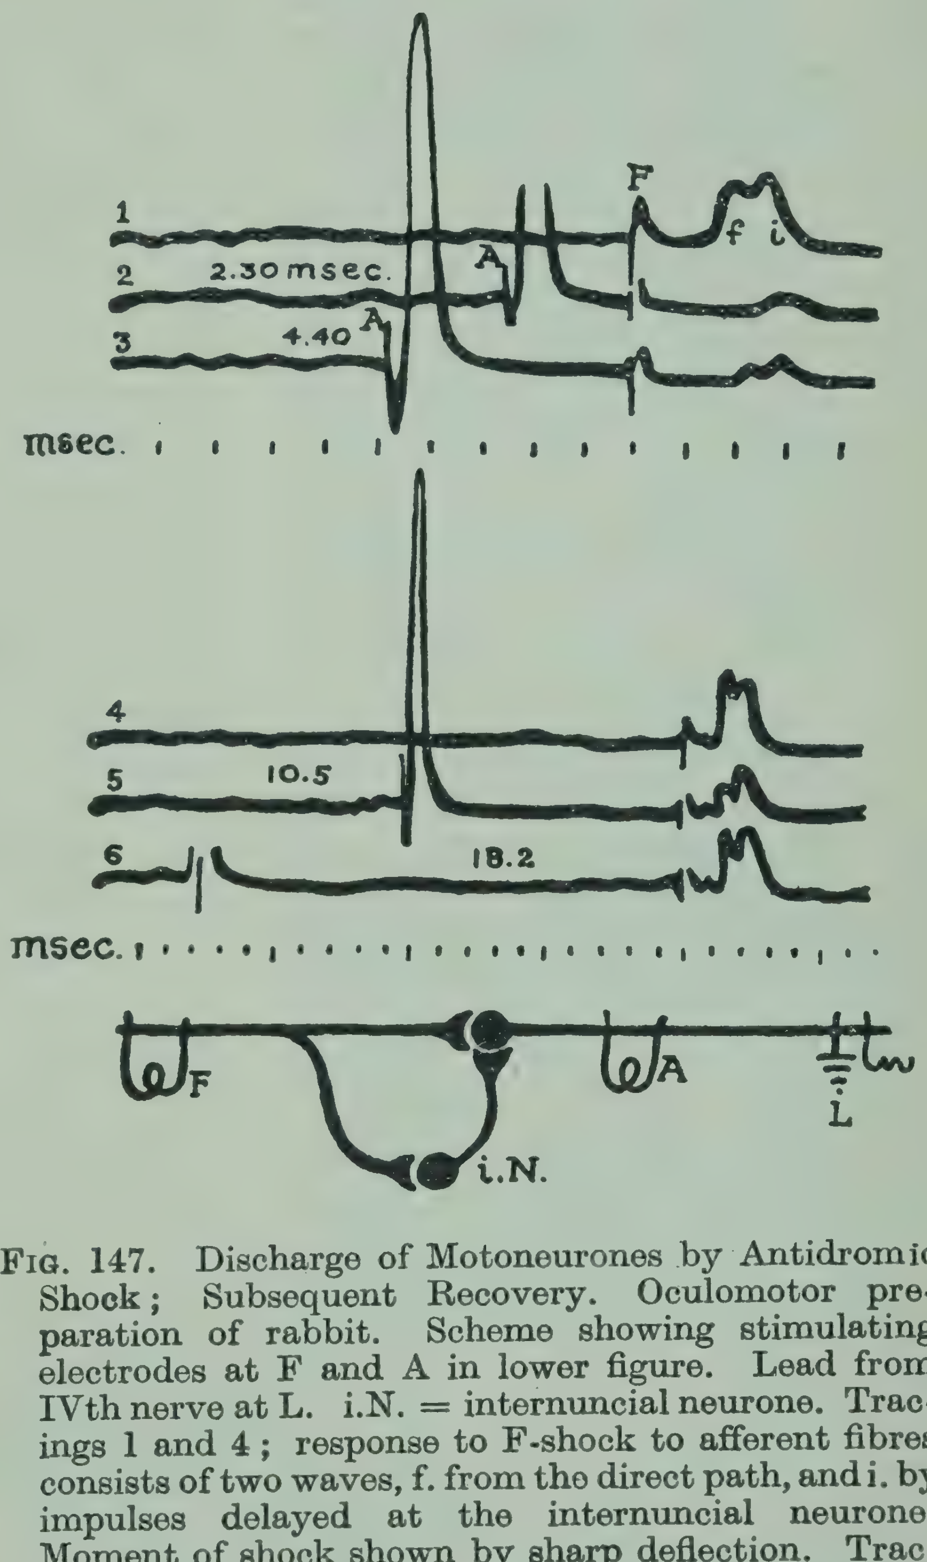

Fig. 147. Discharge of Motoneurones by Antidromic Shock; Subsequent Recovery. Oculomotor preparation of rabbit. Scheme showing stimulating electrodes at F and A in lower figure. Lead from IVth nerve at L. i.N. = internuncial neurone. Tracings 1 and 4; response to F-shock to afferent fibres consists of two waves, f. from the direct path, and i. by impulses delayed at the internuncial neurone. Moment of shock shown by sharp deflection. Tracings 2, 3, 5 and 6, the F-shock has been preceded by an antidromic maximal stimulus at A, the intervals between A and F being shown on records. Time scale in msec. is quicker for 1, 2 and 3 as shown in scales. (Modified from Lorente de Nó and Graham, *Amer. J. Physiol.*, 1938, **123**, 388.)

An antidromic impulse fired into the cells from the point A (Fig. 147) on the motor nerve, discharges the neurones and is followed first by a refractory phase and then by a state of depression (Fig. 147) which lasts for at least

30 msec., just as happens when the cells are stimulated directly; during these stages of depression synaptic stimulation (by an F-shock) produces less or no effect and synaptic delay may be as much as 1 msec.; after repeated A-stimuli the depression lasts still longer.

Internuncial Paths. The response to synaptic excitation is often complicated by the existence of alternative paths through interneurones, and as it is probably to such circuits that some of the characters of conduction through reflex arcs are due, we must briefly consider them. Elementary reflex arcs such as those depicted in Figs. 125 and 126 are merely convenient abstractions, and are probably not often operative, except in the myotatic reflexes. The common flexor, extensor thrust, and crossed extension reflexes all seem to be effected by multineurone arcs. Many neurologists believe, with Ranson and Hinsey,* that in addition to neurone relays intercalated on a direct path there are often multiple bypath interneurones (*principle of plurality of connections*) and also reverberatory side arcs or " re-exciting circuits " (*principle of reciprocity of connections*).† These important types of connections are illustrated in Figs. 147 and 148.

It is clear that circuits of these two types introduce new possibilities into the phenomena of conduction in the central nervous system, because, viewed in the simpler way, each synapse causes a delay of about 0·6 msec. As a result of the principle of multiple connections, an afferent impulse, in addition to being conducted direct to a terminal point, may also be delivered by detour paths to the same or other points and at later times, so that the excitation is spread out both spatially and in time (see

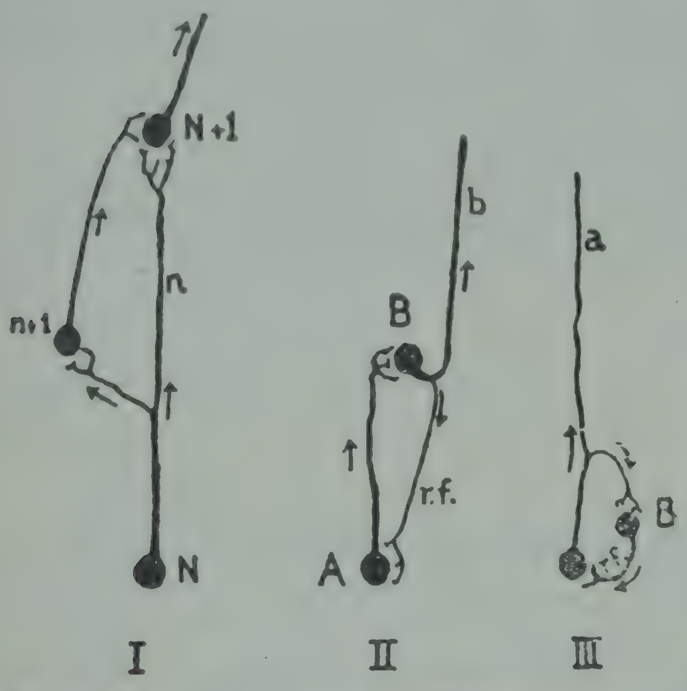

Fig. 148. Diagrams illustrating connections within chains of neurones. I illustrates " law of plurality of connections," II and III the " law of reciprocity of connections." Arrows show directions of impulses. (Lorente de Nó. *Arch. Neurol. Psych.*, 1933, **30**, 245.)

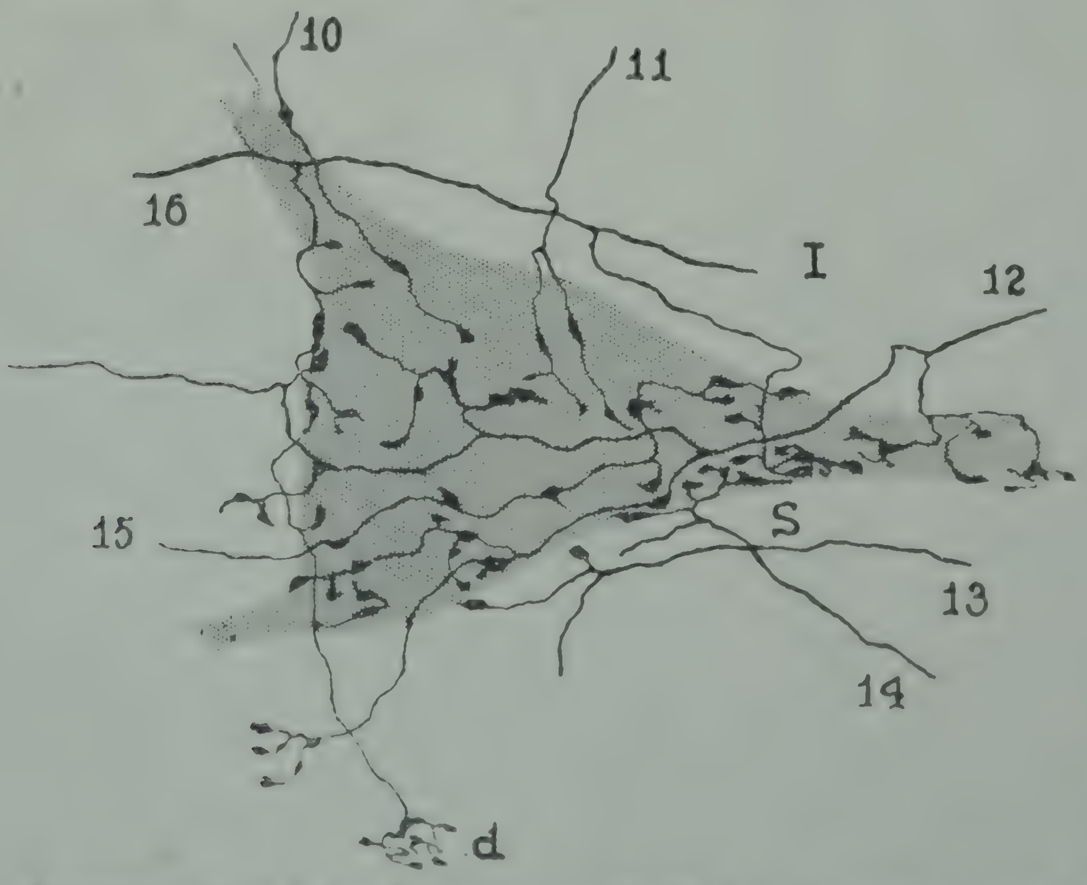

Fig. 149. Synapses on a large Internuncial Cell of the Spinal Cord of a Kitten. (Lorente de Nó. *J. Neurophysiol.*, 1938, **1**, 200.)

---

* Ranson and Hinsey. *Amer. J. Physiol.*, 1930, **94**, 471.

† Lorente de Nó. *Arch. Neurol. Psych.*, 1933, **30**, 245.

Fig. 151). In consequence of the closed chain, one impulse, or an afferent train of only a few impulses, can be worked up by re-excitation through delaying circuits into a longer train of impulses. With both types of circuit it should be noted that there results a slowly rising and more prolonged repetitive discharge of impulses into one or several points of a neurone pool.

It follows from this that the usual delay at a neurone pool, as measured by the time between arrival of the first presynaptic impulse and the resultant postsynaptic action, is likely to be much longer than the synaptic delay as evoked under the simplest conditions by a presynaptic volley. It is distinguished by the term *nuclear delay* (Lloyd).

Facilitation. The neurones of the oculomotor nuclei are most responsive, and their synaptic delay is shortest, when their c.e.s. is kept up by continual bombardment from internuncial neurones, too weak to actually excite the cells to discharge. Such cells are in a state of what is called by Sherrington "*subliminal excitation.*" Each cell in this condition is "on its toes," and ready, on receipt of a small additional stimulus, to discharge an impulse. This additional stimulus cannot come in the form of a second impulse at the same synapse, because the refractory period of the fibre is longer than the period of latent addition in the cell (see below), *i.e. temporal facilitation cannot occur* like it does in sympathetic ganglia.

Now if we consider the arrangement of the synaptic knobs in relation to the soma of a nerve cell, as shown in Fig. 149, it will be seen that a neurone receives contributions from several axon terminations, and that the synaptic knobs (of which there may be 1,000 or more on a single soma), are not necessarily terminal, but are distributed along the course of the fibrils in interlacing clusters of knobs surrounding the soma and dendrites, the synaptic terminals of different fibres often being at a distance from one another.

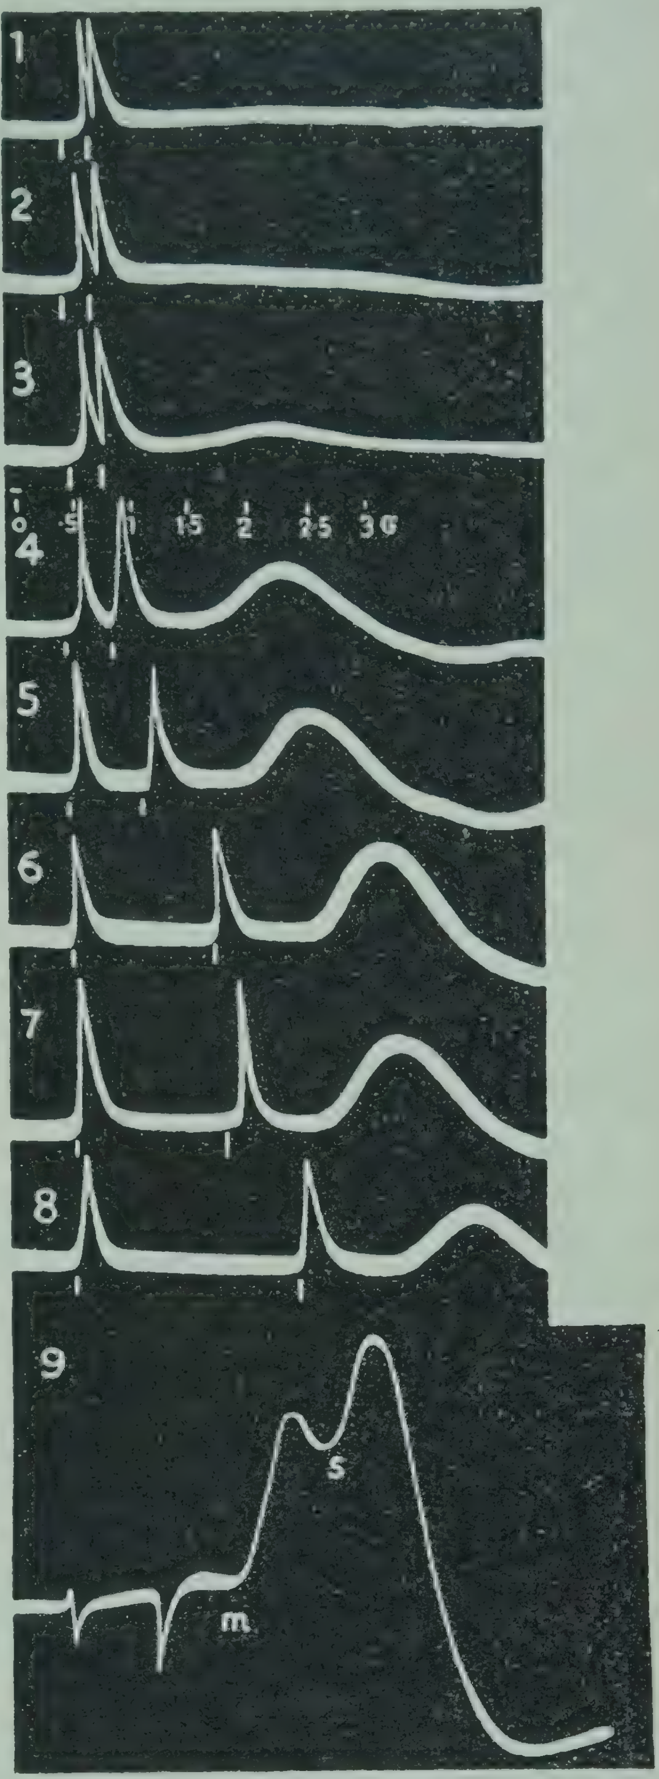

Fig. 150. Facilitation in motoneurones. *Curves* 1—8 : An F-shock, followed at the interval shown, by a C-shock. No effect at intervals below 0·25 msec., maximal effect at 1·25 msec. *Curve* 9 : Two C-shocks, the first one sub-threshold, the second one adequate, 1 msec. later. The m-wave the direct motor response, the s-wave the delayed synaptic response. (LORENTE DE NÓ. *J. Cell. Comp. Physiol.*, 1935, **7**, 47.)

It would seem probable, then, that facilitation would be seen when the later impulses arrived at new loci on the same soma. Evidence was, in fact, obtained by Lorente de Nó that usually more than one afferent fibre needs to be stimulated in order to activate, in any given zone of the soma, a sufficient number of synaptic knobs to cause excitation culminating in the discharge of a nerve impulse. A similar conclusion was reached by Sherrington for the motoneurones of the spinal cord. If too limited a zone at the surface of the neurone is excited the excitation remains a local non-propagating one which presumably dies down unless reinforced within a brief period (0·2 msec.), just as occurs with the non-propagated disturbances in nerve fibres.

In consequence of this it often happens that the stimulation of motoneurones by one set of synapses may be too weak and localised to result in excitation. Many of the motoneurones of the oculomotor nucleus are normally in a state of sub-liminal excitation as a result of the receipt of impulses from internuncial neurones, *e.g.* those from the labyrinth, and under these circumstances a stimulus applied at F in Fig. 146 is able to excite them.

This "tonic" subliminal excitation is abolished by destruction of the reticular substance of the medulla and pons, in which the internuncial paths lie. When this has been done a single shock at F gives no response, though two shocks 1 to 1·5 msec. apart usually do. Similarly, if a subliminal electrical stimulus is given to the motoneurones at the point C_1 (Fig. 146), and followed by a subliminal stimulus *viâ* the synapse by stimulating at F, say, 1 msec. later, a response may ensue.

At first sight the fact that facilitation occurs best when F-shocks are as much as 1 msec. to 1·5 msec. apart seems to conflict with the statement made above that the maximum period of latent addition of subliminal stimuli is 0·2 to 0·3 msec., after which the local c.e.s. dies away. The explanation shows that the matter is less simple than appears at first sight, and is as follows: The F-shock causes local synaptic excitation, and this dies away in 0·2 msec.; but it also excites a by-pass neurone having its own synapse, *viâ* which a delayed impulse reaches the motoneurone about 0·6 msec. later; if there are two by-pass neurones in series the delay will be at least 1·2 msec., and if at this moment, or within a short time after it, a second impulse arrives by the direct fibre from F, latent addition will occur. Facilitation, according to this, is therefore really due to the arrival, by two different paths, of almost simultaneous impulses at different synaptic points on the same soma. If in addition to these by-pass circuits we have closed reverberatory circuits the bombardment of the motoneurones can be kept up for much longer periods, so that facilitation may still be possible 30 msec. or more after a first stimulus.

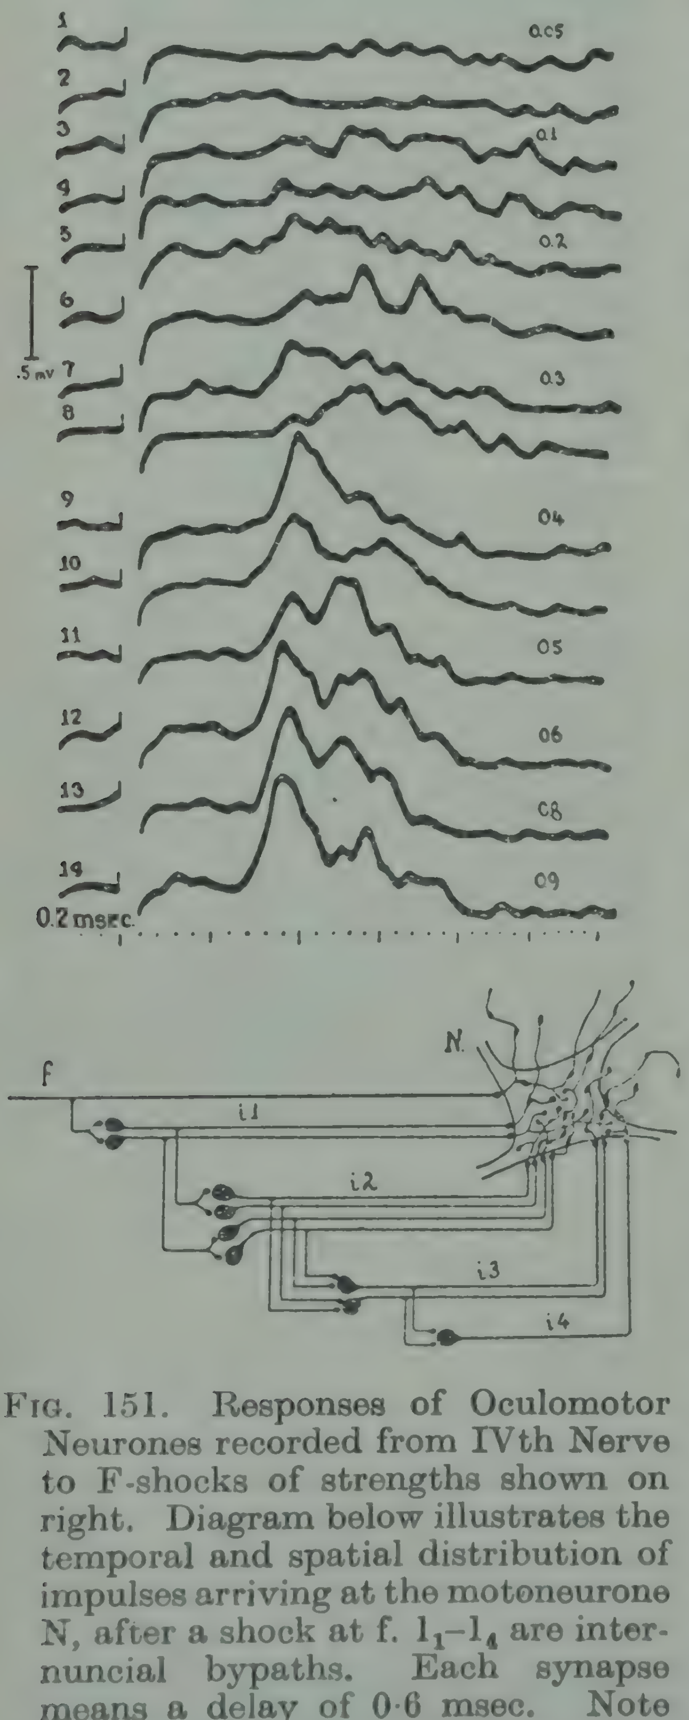

FIG. 151. Responses of Oculomotor Neurones recorded from IVth Nerve to F-shocks of strengths shown on right. Diagram below illustrates the temporal and spatial distribution of impulses arriving at the motoneurone N, after a shock at f. 1_1–1_4 are internuncial bypaths. Each synapse means a delay of 0·6 msec. Note that each fibre has several synaptic knobs on the soma. (LORENTE DE NÓ. *J. Neurophysiol.*, 1938, **1**, 207.)

This phenomenon of facilitation is well shown by Fig. 150, in which a subliminal F-shock is followed at varying intervals by a subliminal C-shock, *i.e.*, by a direct shock to the motoneurones. It will be seen that the earliest indication of a response was when the interval was something over 0·25 msec. Up till then the time is occupied by transmission from the F electrodes, say, 0·1 msec., followed by a lowering of the threshold of the motoneurone which reaches its maximum after about another 0·15 msec. After this we may suppose that delayed-path impulses continue to arrive at the motoneurones, and reach a maximum at 1·25 msec., afterwards declining. The effect of the C-shock is therefore greatest when it follows the F-shock at about 1·25 msec. (curve 7, Fig. 150).

It often happens that the latent period of the response of a motoneurone is considerably reduced by a previous excitation. This is not because facilitation shortens the synaptic delay, which is almost unaltered; it is because facilitation enables excitatory impulses to be effective directly without further (delayed) reinforcement through internuncial neurones.

It would seem that *the multiple chain of neurones is a normal unit of transmis-*

sion in the nervous system, and supersedes the classical and diagrammatic reflex arc of a fixed number of synapses. If the number of neurones in use in the chain at any time is large, facilitation may be continuous, and any applied stimulus may be followed by an "*after-discharge*." As is shown in Fig. 151, in which there was a background of internuncial bombardment, an increase in the strength of an F stimulus leads to a more sustained response, with shorter latent period. This response, however, even with the strongest stimuli, never engaged more than about a third of the possible motoneurones. As the Oxford school would say, the motoneurone pool response was *fractionated* into an active and an inactive group, the latter, or part of it, representing a *subliminal fringe*.

Inhibition. Sometimes, after a strong conditioning F-shock, there is a brief period of facilitation followed by a period in which responses to the testing shock are reduced or abolished. The explanation* of this phenomenon is that a refractory state and a state of subnormal excitability, as we have seen, follows the excitation of a neurone. Hence, since the first stimulus was a strong one, many internuncial neurones became involved—hence the early facilitation. But after this those neurones became refractory, and so the second shock from F received no facilitation and became ineffective. *Inhibition, therefore, is in this case not an active process happening in the neurones, but is merely lack of facilitation.*

In some parts of the central nervous system inhibition is very long lasting. Thus in the cerebral cortex a conditioning shock leads to prolonged extinction of the response to a testing shock.†

Transmission in the Spinal Cord. The phenomena of transmission in the spinal cord are necessarily more complex than those we have so far considered, because there are many possible paths.

When a single volley of impulses is fired along an afferent nerve, *e.g.* by giving a weak single shock to the central end of the popliteal nerve in a spinal cat, a reflex twitch of the ipsilateral flexor muscles, *e.g.* tibialis anticus, results. If a record of the electrical potential changes in the muscle (or in the motor nerve) is made, it is found that, if the afferent shock was weak, one efferent volley only is caused, *i.e.* the efferent fibres, or some of them, have each conducted one impulse in response to one afferent impulse.‡

If a very strong stimulus is given to the afferent nerve, then two impulses may pass along it, two also emerge by the motor path, and the muscular contraction is longer because of summation. But it also happens that a strong stimulus may cause only one afferent impulse in each fibre, but two or more efferent ones, with a resultant longer muscular response. This must mean that in some manner the motoneurones have been caused to fire at more than one moment in response to one afferent volley—a result called *repetitive discharge.* This phenomenon is readily explicable in the light of the information given in previous pages and does not necessarily mean that all the individual neurones are firing repetitively. The stronger stimulus excites more afferent fibres and causes impulses not only along the more direct paths but also along new internuncial paths, by which a belated volley of impulses arrives at the motoneurone pool, and excites the same or a fresh set of motoneurones, so that a later volley of impulses is fired either along the same efferent fibres, or along new ones not previously employed.

When two weak stimuli are given in succession to an afferent nerve for the spinal flexor arc, two impulses emerge from the efferent side if the two stimuli are more than 1·0 to 1·9 msec. apart.§ If the interval is less than this, the second stimulus is ineffective because it falls in the refractory period of some part of the reflex arc. Actually this refractory period (absolute and relative) may be as much as 4 to 6 msec., but when two or more afferent stimuli are given at, say, 1 msec. intervals, the second one travelling in the wake of the first is conducted more slowly, so that it only arrives at the centre about 6 msec. after the first, *i.e.* not until the arc has recovered.

§ Adrian and Olmsted. *J. Physiol.*, 1922, **56**, 426.

It cannot be said precisely where in the arc the refractory state is longest. There is, of course, a refractory state in the nerve, but the absolute refractory period is only of the order of 0·4 msec. and the relative about 3 msec. for the fast fibres. It would seem probable that the neurones of the spinal cord have very similar properties, and that owing to the delayed conductance for second impulses these do not reach the neurones until their refractory period has passed off.

If a series of stimuli are given to the afferent nerve, so that a train of impulses passes along it, the efferent nerve also conveys a train of impulses at the same frequency, provided the afferent stimuli are not too close together. The minimum interval between stimuli in a series is about 3·5 msec., *i.e.* the maximum frequency at which a series of afferent nerve stimuli can be translated into efferent ones is about 300 per second.* It would appear then that if, in these experiments, the same motoneurones respond to each volley, these motoneurones cannot be made to send out a regular series of impulses at a greater frequency than about 300/sec. (and if the spinal cord is cooled the rate is slower). The muscle, as we already know, is able to respond to stimuli faster than this, so that there is no question of the motoneurones being able to discharge impulses more rapidly than the muscles can follow them.

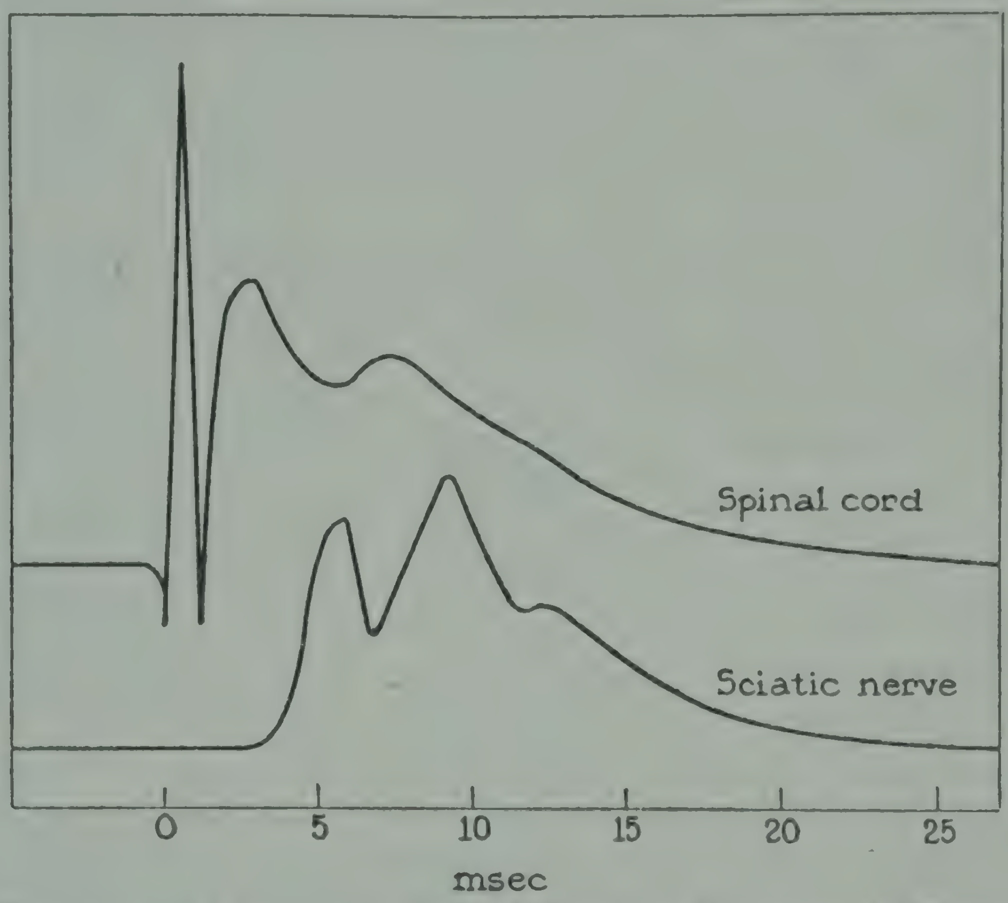

Fig. 152. Relation of Afferent Spike and Negative Internuncial Potentials in the Lumbar Cord of the Spinal Cat to the Reflex Discharge into the Sciatic Nerve. The positive after-potentials come later and are not shown. Gasser. Harvey Lectures, 1936, 182.

In reflex contractions brought about by ordinary sensory stimuli, *e.g.* pinching the foot, the impulses pass along the motor nerves at a frequency up to 100 to 250/sec. With frequencies of this order the muscle, of course, gives a perfectly smooth contraction, and the component excitations can only be seen in the electrical record.

Cord Potentials. Studies of the electrical potentials of the cord yield further important information. If an afferent volley is sent into a dorsal root, it may be traced as a spike potential into the cord and for some distance along the dorsal columns. Leads from the spinal cord surface show that this spike potential is followed by slow waves, which according to Gasser are due to the excitation of internuncial neurones.* The potentials produced in the motoneurones are obscured by these, but their discharge is indicated by the volley which finally emerges from the ventral root. The original afferent spike, the discharge potentials of the internuncials, and the efferent discharge along the motor nerve are shown in Fig. 152. It will be seen that the discharge along the efferent nerve runs parallel with the curve of negative cord potential. This negative phase is attributed to the excitation of internuncials and not of motoneurones, because an antidromic impulse which would discharge the latter, does not modify it. During the time that there is a negative potential (10 to 20 msec.) the internuncial neurones are emitting impulses which pass on to the motoneurones. According to Hughes and Gasser † the negative cord potential represents the overlapping of these internuncial spikes. During this period the reflex arc is facilitated. Each spike discharge of an internuncial is presumably accompanied by a refractory period, after which there is no demonstrable negative after-potential comparable with that of fresh nerve, and accordingly there is no supernormal phase like there is in fresh nerve fibre, but instead, there is an immediate subnormal state, accompanied by prolonged (100 msec. or more) positive after-potential (Fig. 153), as is seen in nerve fibres after many previous stimuli (*v.* p. 177, Fig. 97). During this period the reflex arc is therefore in a state of depressed excitability, so that a second volley, say 50 msec. after the first, causes a smaller response, *i.e.* the reflex is *inhibited*.

---

* Cooper and Adrian. *J. Physiol.*, 1924, **59**, 61.

It will be seen later that these internuncial waves negative (10 to 20 msec.) and positive (70 to 200 msec.) correspond roughly with the time course of c.e.s. and c.i.s. respectively.

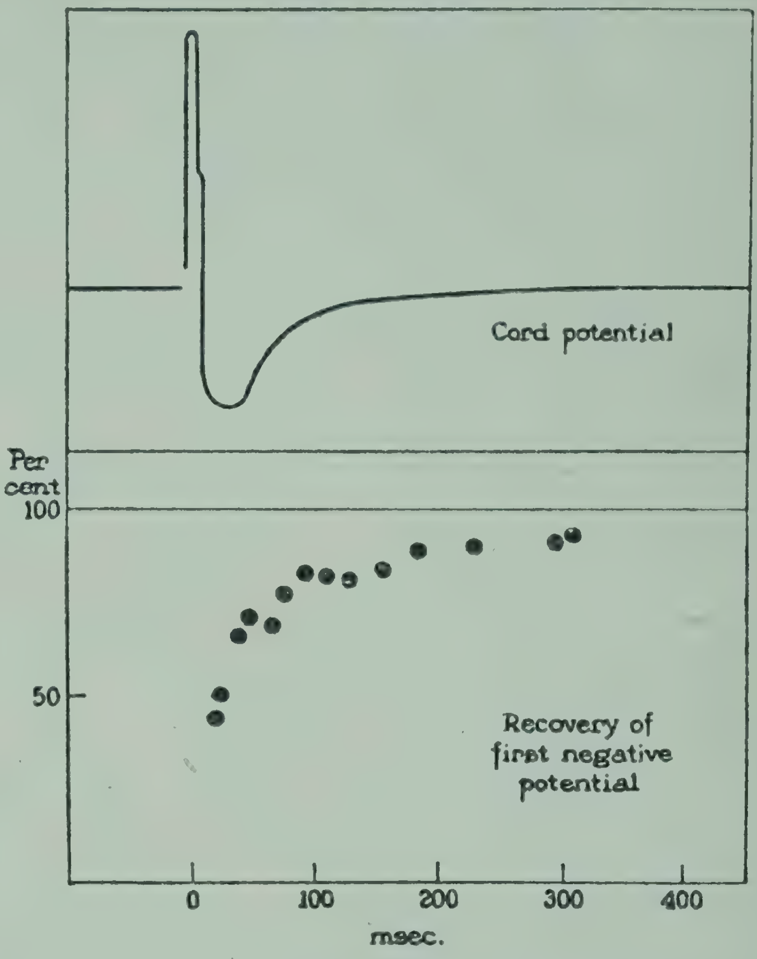

FIG. 153. *Above*, Course of the Cord Potential in response to one Volley. *Below*, size of negative internuncial response caused by a second volley to same root. Internuncial negative potential is reduced during period of positive after-potential. (HUGHES and GASSER.)

Root Potentials. A somewhat different interpretation of spinal cord potentials is given by Barron and Matthews,‡ who recorded the potential changes in the dorsal and ventral nerve roots, when afferent impulses entered the cord as a result of either electrical stimuli to the dorsal roots or natural stimuli to the nerve terminals. In both cases they found that (apart from spike potentials), slow negative potential waves occurred, *i.e.*, the electrode nearer the cord was negative to the other. The waves last for from 0·1 sec. up to periods of seconds, and are seen in both dorsal and ventral roots whenever these are involved in reflex actions (Fig. 154). The waves in the dorsal roots are seen not only in stimulated roots, but also in neighbouring roots on the same or the opposite side. Hence they cannot be caused by the passage of nerve impulses along all the nerve fibres that show the waves. The spike potentials, when they occur, of course, represent the passage of nervous impulses, and need not be further described. They are always superimposed on the slow negative waves, and these are larger and longer the more intense and prolonged the afferent stimulus. With very brief and weak stimuli the slow potentials may occur in the dorsal roots without any spikes appearing at all. What they indicate is a tendency to discharge spikes. These slow negative potentials, which are probably similar to those ascribed by Hughes and Gasser to overlapping internuncial spikes, are differently interpreted by Barron and Matthews. They regard them as being due to a depolarisation of the axons of the roots due to electrotonic spread from sites where an active depolarisation obtains. The roots merely act as leads by which electrotonic currents can be tapped off from these sites (*v.* p. 191). This state of depolarisation is an essential accompaniment of excitation, and in fact is the ultimate cause of it. When a motoneurone is sufficiently depolarised it emits nerve impulses rhythmically at a frequency depending, among other things, on the degree of the depolarisation. In evidence of this they adduced the fact that it is possible by the passage of a *constant* current to the surface of the cord (Fig. 155) to depolarise the motoneurones and so to cause them to discharge rhythmically (Fig. 156). In this respect the motoneurones are therefore different from normal nerve fibres and more closely resemble the sensory terminals.

CHAPTER XVII

CHARACTERISTICS OF REFLEX ACTIONS

In his classical "Integrative Action of the Nervous System," Sherrington showed in 1906 how reflex actions are organised and modified to serve the needs of the individual, and the continued researches of his school from that time to the present have further widened and deepened our knowledge of the phenomena of nervous action. Most investigations on reflex action have been on motor reflexes, because of the ease with which they can be studied quantitatively. A convenient measure of a response in a given muscle is the isometric tension produced when it contracts. We may consider a given muscle to be innervated from a group of ventral horn nerve cells, which is called the *motoneurone pool*.

The Motor unit. Each motor neurone has an axon which branches freely near its termination and so supplies many muscle fibres. These all contract together. This is an example of the principle of divergence. The actual number can be determined by dividing the number of muscle fibres in a given muscle by the number of nerve fibres in its motor nerve. The average is around 150 fibres per motor neurone, but is greater with powerful muscles (*e.g.* 500 in cat's gastrocnemius) and less with delicate and precise ones such as the eye muscles. A motor neurone with all its muscle fibres is called a *motor unit* or motounit. If the motor nerve to a muscle is given a maximal tetanic stimulation for a second or so, the tension produced when divided by the number of motor units, gives us the maximal tension per unit. This for the cat varies from 6 g. for semitendinosus to 30 g. for gastrocnemius; for simple twitches tensions about one-fourth as great result. A muscle like the cat's soleus having about 250 motor units and giving a maximal tension of about 2,500 g. can thus have 250 gradations of 10 g. each as its tension rises from zero to maximum.

CHARACTERISTICS OF REFLEXES. Let us first take as an example the flexor reflex already mentioned (p. 230); it illustrates certain properties common to them all.* We shall mention later the respects in which the extensor reflexes show points of difference. Stimulation of almost any afferent nerve in the same limb will evoke the flexor reflex. Thus, stimulation of the tibial (popliteal) nerve is commonly used to produce reflex contraction of the tibialis anterior, which is a favourite flexor for experiment: its motor nerve is peroneus.

(1) Localisation. The flexor-reflex is normally caused by a nociceptive stimulus applied to the same limb; the response is quite regular and automatic in appearance. It is determined by the fact that the nerve fibres, mostly of small or medium diameter, which carry the impulses from, say, the toe, into the spinal cord, divide there and make connections with the motoneurone pools whose axons are distributed to the several muscles involved in the reaction. The connection of the sensory with the motor neurone is not direct, since the impulse has to pass through at least one intermediate neurone before arriving at the motor neurones. The main path of the impulse, however, is definite and unvarying, despite the fact that innumerable other paths are theoretically possible, and that the reflex may spread into these if afferent stimuli are powerful.

(2) Co-ordination. In the flexor response all the physiological flexors are brought into action. A reflex achieves, not the contraction of a particular muscle, but the performance of a significant movement. This always involves *groups of synergistic muscles*, and is brought about through the agency of multi-neurone arcs.

The effect varies with the strength of the stimulus. The minimal effective stimulus causes simply flexion of the foot. As its strength is increased, this is attended by flexion of the leg on the thigh, and finally by flexion of the thigh on the body. With still stronger stimulus there is a spread to the opposite hind limb, which, however, extends. Increase in the strength of stimulus causes not only an increase in the strength of contraction of the reacting muscles, but also a spreading of the reaction to more and more muscles, or groups of muscles. The spread occurs always in definite order. The stimulus when represented by the prick of a needle can affect only one or two nerve fibres. The impulse carried along these spreads in the cord, reaches the motor neurones and causes them to discharge. The first discharge is, as a rule, limited to those in the immediate proximity of the entering impulses, but, even when minimal, involves the simultaneous action of more than one ventral root. We may say that the response is determined to a certain extent by the

* Eccles and Sherrington. *Proc. R.S.*, 1931, **107B**, 511, 535, 586, 597.

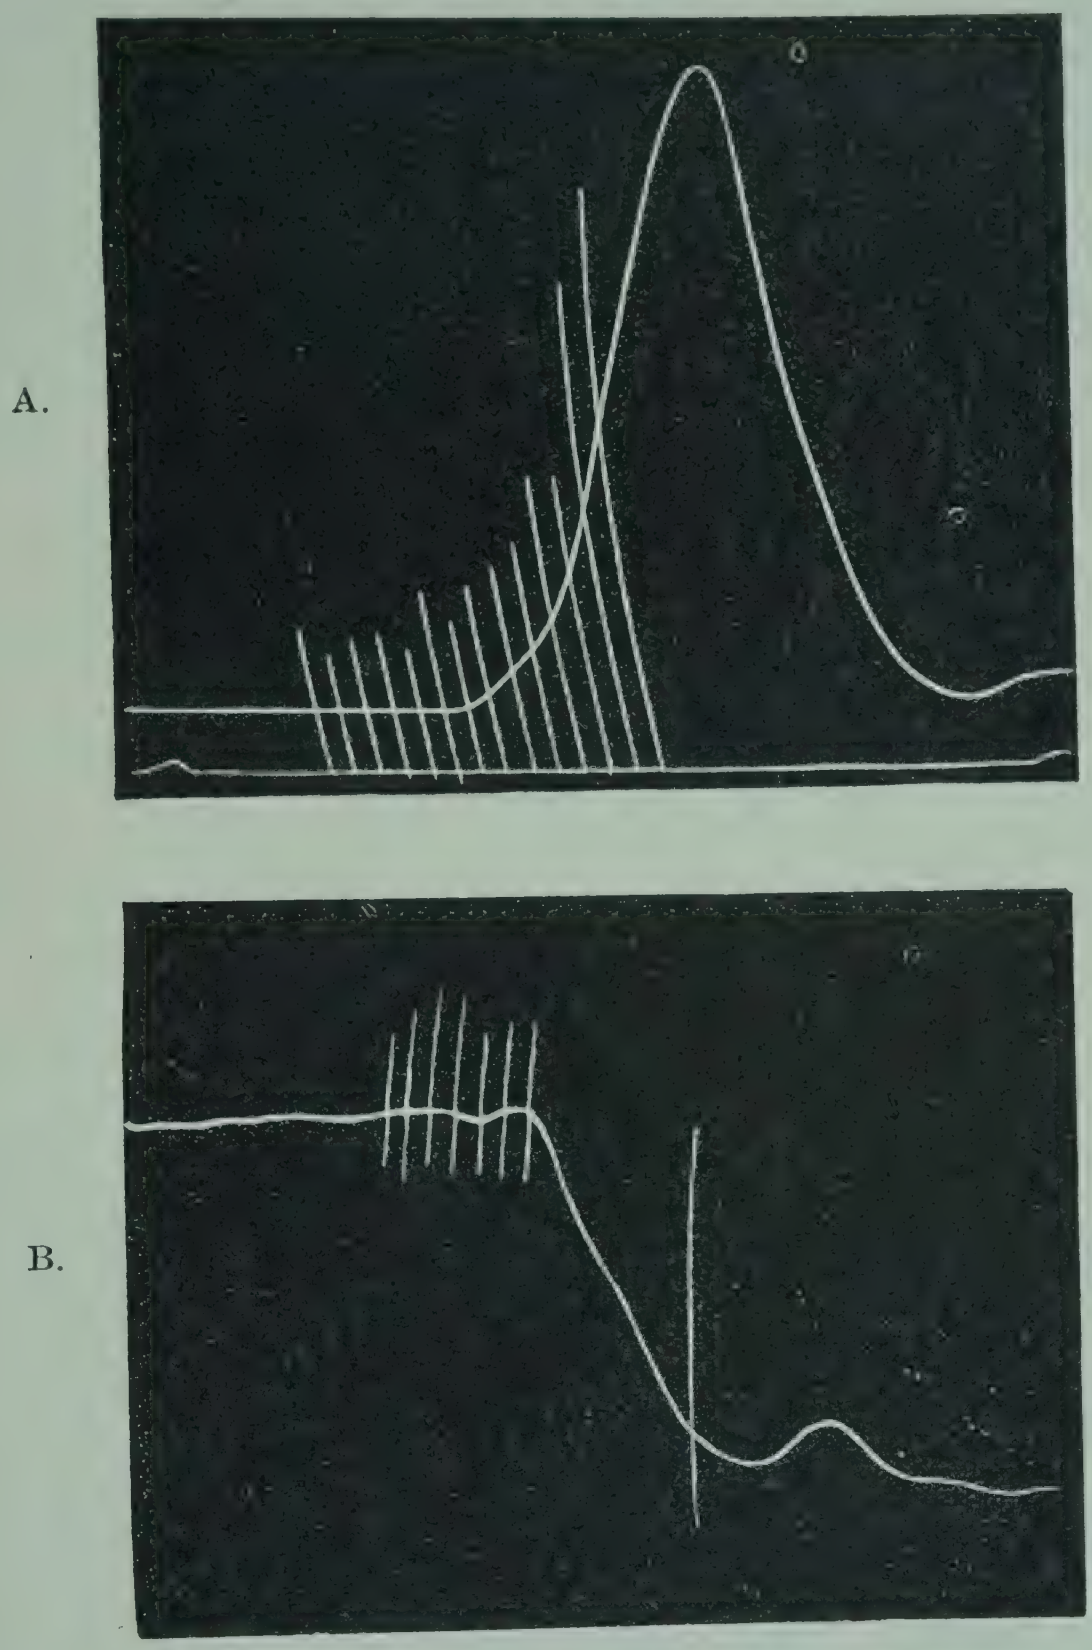

Fig. 158, A and B. (Sherrington.)

The Flexion Reflex observed as Reflex Contraction (Excitation) of the Flexor Muscles of the Knee (A), and as Reflex Relaxation (Inhibition) of the Extensor Muscle (B).

The stimulus was a series of weak break induction shocks applied to a twig of the internal saphenous nerve below the knee. Observation B was made four minutes after A. Note the summation of stimuli, in each case six stimuli being required before the reaction was evoked.

proximity of the afferent to the efferent paths, but that it is nearly always plurisegmental, the most important determining factor being the adaptation of the movement to the stimulus.

The gradual spread of the response with increasing strength of stimulus is spoken of as "*irradiation.*" The nature of the response is determined by the place of application of the stimulus, and by the quality of the latter. While a painful stimulus causes flexion of the leg, firm pressure on the plantar surface of the paw causes the extensor thrust—the "stepping" reflex. However extensive the irradiation, the muscles which are set into action are always such that their actions co-operate towards a given end. Thus, when the impulse spreads to the opposite limb and produces an extension, the reaction is such as would ensue when the animal steps on a sharp point and immediately retracts the irritated limb away from the injurious agent, while it extends the other limb as support, and in the first act of movement away from the spot.

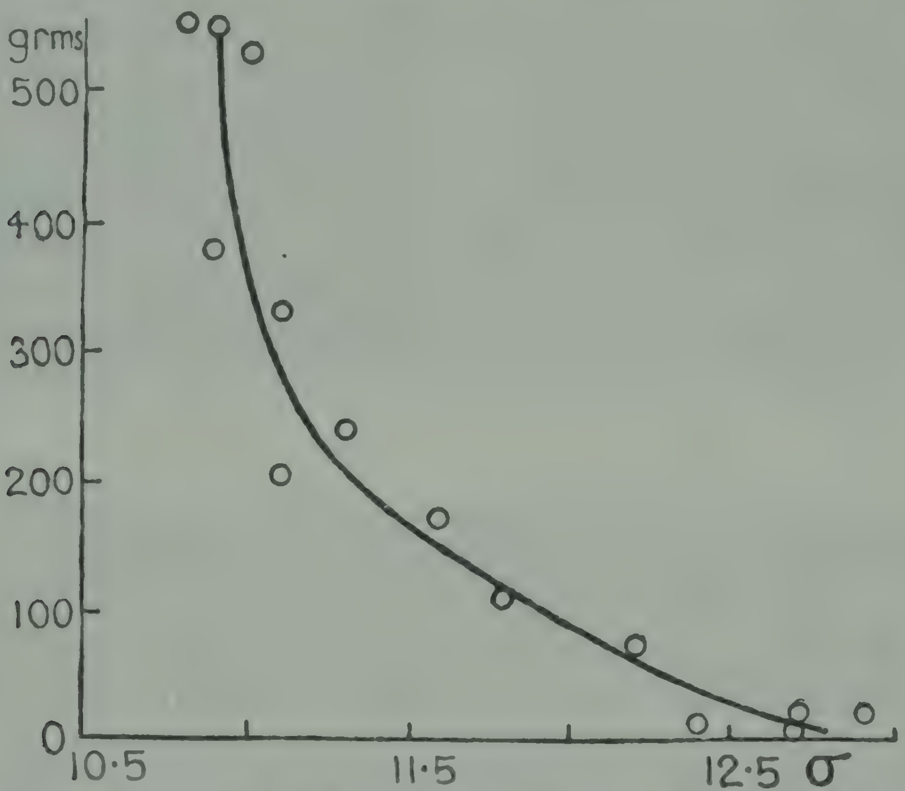

Fig. 159. Effect of Strength of Stimulus on Latent Period of Reflex Response. Reflex excitation of tibialis anticus through tibial nerve of same side. The strength of stimulus is indicated in the figure by the strength of the response. (Creed *et al.* "Reflex Activity of the Spinal Cord." Oxford Univ. Press, 1932.)

(3) **Reciprocal Innervation.** A superficial study of this reflex might lead us to suppose that, by the varying resistance in different synapses, the impulses are directed so as to affect exclusively the muscles whose contraction will co-operate in the primary reflex. Such a description, however, would represent only one-half of the process. Every muscle in the body is in a variable state of tone. If the tone in the opponent muscles is not to interfere with the carrying out of a reflex movement, there must be some means by which it can be inhibited. Such an inhibition always occurs, and the remarkable fact was brought out by Sherrington that the impulses, which start on the surface of the body and set loose the co-ordinated contraction of certain muscles, spread at the same time to the motor mechanisms governing the muscles antagonistic to the movement, and exercise on these an inhibitory effect.

This inhibition can be best shown in the following way: The extensor thigh muscles are cut away from their attachments to the tibia, and the patellar tendon is connected with a recording lever. The flexor muscles of the knee are similarly detached from their insertions and connected with another lever. On then exciting the flexor reflex by stimulation of an afferent nerve of the leg, the lever attached to the flexors shows a contraction, while that connected with the patellar tendon falls (Fig. 158), showing that the extensor muscles have undergone actual elongation. The inhibition of the extensor tone is thus a direct result of the primary stimulus.

(4) **Delay.** When the latent period that elapses between stimulus and response in the flexor reflex is measured, and the time taken in conduction along the nerve fibres is deducted, we get what is called the *central reflex time.* Thus if the latent period was 10·4 msec., and the nerve conduction time was 6·5 msec., then the time spent in central processes was 3·9 msec. This time is spent in two ways ; first, and chiefly, in raising the c.e.s. of the neurones concerned, and secondly in true synaptic delay, which is probably quite brief. We find that central reflex times vary greatly according to the particular reflex ; *i.e.* to the number and properties of the neurones, and also according to the strength (Fig. 159), number and frequency of the stimuli given. The flexor response is a brisk one, with central delay of 3 to 6 msec. Contralateral reflexes usually occupy a longer time, but in all cases the stronger and more frequent the stimuli the shorter the latent period will be. We may suppose that this is because with stronger stimuli a given motoneurone receives a greater number of impulses from different synaptic knobs in a given time.

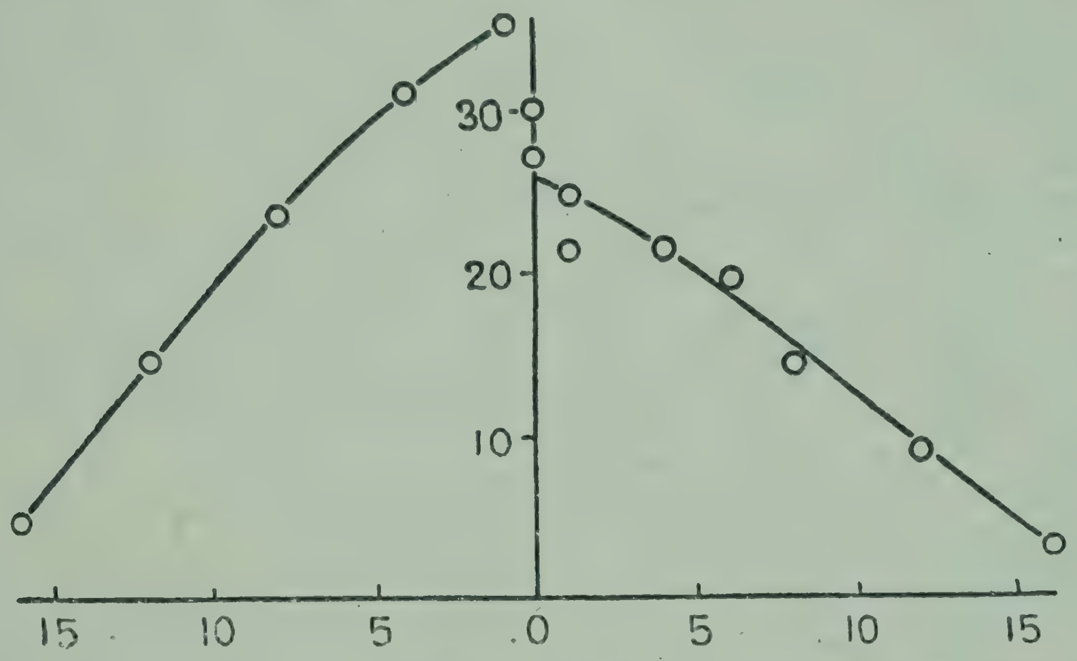

Fig. 160. Reflex Contraction of *Tibialis Anticus* to Pairs of Threshold Stimuli separated by the Intervals shown on the Abcissæ. Ordinates, tension in g. The stimuli were given first to medial gastrocnemius nerve, second to lateral gastrocnemius nerve (on left of zero) and in reverse order (to right of zero). (Creed *et al.* "Reflex Activity of the Spinal Cord." Oxford Univ. Press. 1932.)

When natural stimuli are given the afferent impulses are not volleys, but are dispersed, so that latent periods may be quite long.

(5) **Summation** of stimulation is a conspicuous feature of reflex actions. A single shock of a strength which would excite strong contraction of the tibialis anticus when applied to its motor nerve (the peroneal) is often found to be without effect when applied to an afferent nerve such as the tibial.

Summation may be obtained when two stimuli are applied to different afferent nerves, and experiments on summation are usually made in this way (Fig. 160), because then there can be no question of the nerve fibres being in a refractory state following the first stimulus. If the two stimuli are simultaneous, this type of summation is sometimes called *spatial summation* or "immediate induction." Its occurrence illustrates the fact that different afferent paths may converge to a final common path. The facts of summation are represented diagrammatically in Fig. 161.

It will be seen from this figure that when a fibre is excited, in addition to affecting certain neurones in the pool an area of subliminal c.e.s., called the *subliminal fringe*, is created around these. When a second fibre commanding the same reflex is stimulated at the same time, it also creates a subliminal fringe, and if and where these adjacent fringes overlap, the result is that the c.e.s. there will rise to a sufficient level to cause excitation.

Although, as we have seen, temporal summation at the synapse itself does not occur in the C.N.S., yet if the two (or more) stimuli, instead of being given simultaneously, are given in succession, summation (temporal summation, or "successive induction") can still occur if the interval between them does not exceed a certain amount, in the case of the flexor reflex about 15 msec. (Fig. 160). This may be interpreted as meaning that the c.e.s., which takes about 4 msec. to be established, will all have declined after 15 msec. In some reflexes (*e.g.* scratch reflex) Sherrington found that as many as forty stimuli may be needed to release a reflex, and the latent period may then amount to seconds. Similarly, two stimuli, each of which gives only a small response, may summate to give a larger one. Naturally the greatest effects of two stimuli are seen when they are simultaneous, because then the c.e.s. due to each reaches its maximum at the same time.

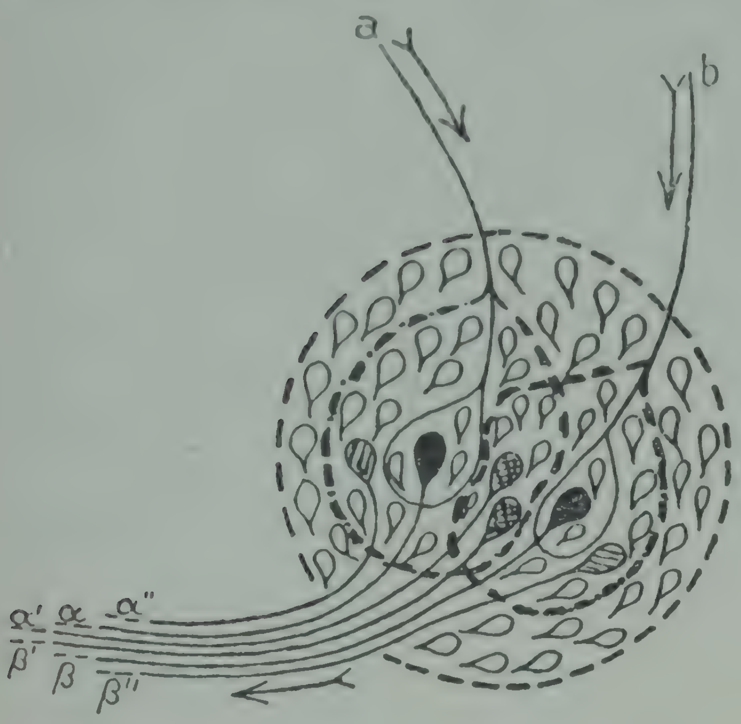

FIG. 161. Two Afferent Fibres, *a* and *b*, are shown entering a Motoneurone Pool, *α*, *β*, etc. are efferent fibres. The continuous line shows the field of threshold action (one neurone excited in each). The dotted lines inside the pool show the subliminal fields (three neurones in each). Each fibre alone excites only one neurone ; concurrently stimulated four neurones are excited, *i.e.* one from each threshold field and two from overlap of the subliminal fringes. (After CREED *et al.* "Reflex Activity of the Spinal Cord.")

Owing to the facilitating effect of the first volley, the central reflex time of the response to the second is shortened even to less than 0·5 msec.

It will be clear that the explanation of summation is to be found in the facilitation phenomena which we have already studied. The succeeding stimuli no doubt open up delaying by-paths through internuncial neurones until finally a sufficient number of impulses arrive within a given time at the motoneurones concerned.

Successive spinal induction is said to be positive when a previous stimulus favours a succeeding one, as in the examples we have mentioned. In some cases, however, where two reflexes are opposed, a reflex will favour the appearance of the opposing one. Thus a flexor reflex may be followed by an extensor movement, thus revealing a pre-existing state of subliminal extensor excitation. This is called *negative successive induction*, and such phenomena are probably responsible for rhythmic reflexes such as those of stepping.

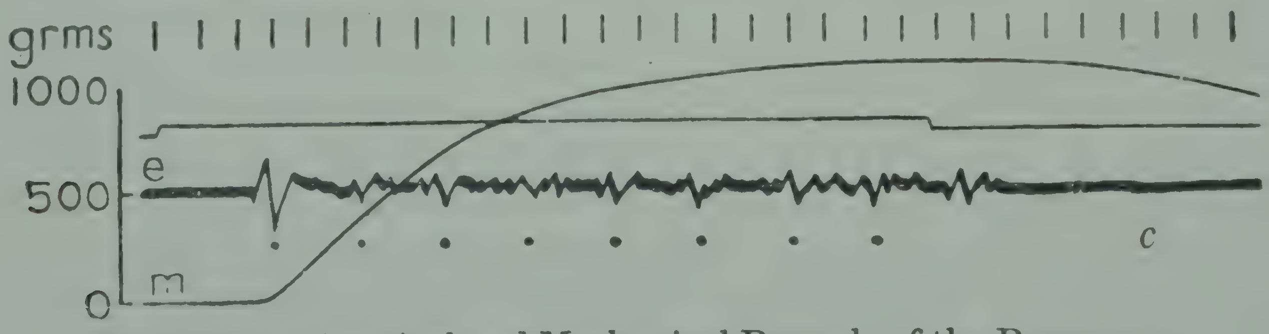

FIG. 162. Electrical and Mechanical Records of the Response of Tibialis Anticus to Repetitive Stimulation of Posterior Tibial Nerve. Frequency of stimuli marked by dots and large waves in electrogram ; note the secondary waves. Time 10 msec. (CREED *et al.* "Reflex Activity of the Spinal Cord." Oxford Univ. Press, 1932.)

(6) **After-discharge.** When the motor twitch of the tibialis anticus caused by stimulation of its motor nerve by a single shock is compared with the reflex contraction caused by a single powerful shock to the tibial nerve, it is seen that the reflex contraction lasts for about 0·1 sec. longer than the motor-nerve twitch. This is due to what is called "after-discharge" and in extensor reflexes is very much more prolonged still.

It is also longer after repeated stimulation than it is after a single afferent shock (Fig. 162), and electrical records show that there are efferent nerve impulses after stimulation of the afferent nerve has ceased.

The cause of after-discharge has already been discussed when dealing with the properties of central conduction. It is due to the fact that the impulses travelling to the motoneurones are delayed to varying extents.* Some arrive almost direct, others are delayed in internuncial by-paths and reach the motoneurones later (Fig. 163); if the refractory period of these has passed off, these later impulses may cause them to fire off another impulse. Hence there are more efferent impulses than afferent stimuli (Fig. 162); with strong stimuli some of the later impulses also reach motoneurones not previously affected, and so the motor discharge is prolonged.

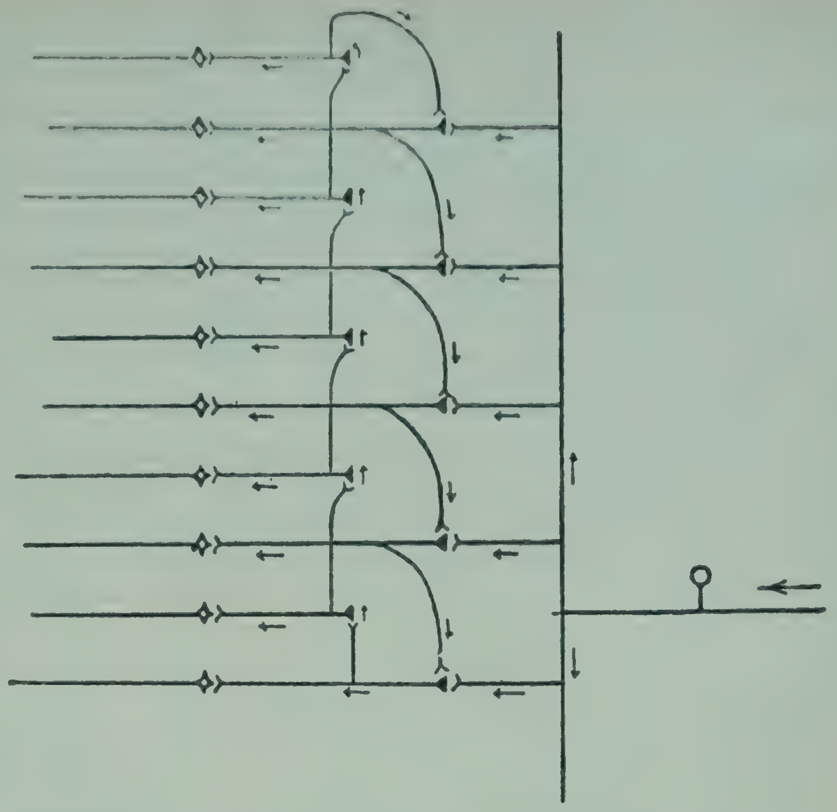

Fig. 163. Diagram to Illustrate Causation of After-discharge by Passage of Impulses along Delay and Re-exciting Circuits. Arrows show directions of impulses but not their time-relations; these latter depend on the number of synapses passed. (Ranson and Hinsey *Amer. J. Physiol.*, 1930, **94**, 471.)

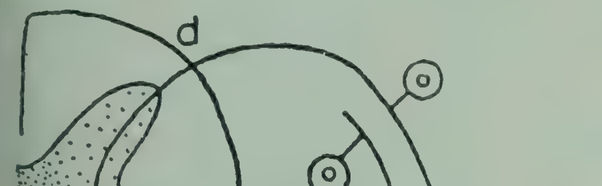

Fig. 164. Schema of Arrangement for Firing Antidromic Volley. v, d, ventral and dorsal roots; a, electrodes on motor nerve; c, electrodes on an afferent nerve. Needle electrodes stuck into muscle lead to a string galvanometer for recording action potentials. (Creed *et al.*)

If an antidromic volley is fired back from the motor nerve, the after-discharge lapses for from 20 to 60 msec. and then reappears; this fact is in accordance with the explanation given above, the antidromic volley serving to discharge all the motoneurones simultaneously. After the quiet interval belated impulses again succeed in causing excitation.

(7) **Refractory Period.** The neurones, after having discharged an impulse pass through a refractory period, but this is not easily measured with accuracy. The best method is to apply an antidromic stimulus to the motor nerve † (Fig. 164). This causes all the motoneurones to discharge, and it is found that for about 11 msec. afterwards afferent stimuli are ineffective. Hence the refractory phase is assessed at about 11 msec. Longer periods of irresponsiveness in reflexes occur, but are usually attributed to inhibition, *i.e.*, the neurones are not refractory, but are probably not receiving enough afferent impulses.

(8) **Fractionation.** When a given afferent nerve is stimulated with a maximal shock, the reflex contraction of a muscle is only a fraction of what it is capable of producing when its motor nerve is stimulated directly. Thus a given tibialis anticus muscle

---

* Forbes. *Physiol. Rev.*, 1922, **2**, 361.

† Eccles. *Proc. R. S.*, 1931, **107B**, 557.

could exert a tension of 2,160 grammes when directly stimulated. When reflexly stimulated through the internal saphenous nerve the tension was only 800 grammes, when by the musculocutaneous branch of the peroneal, 1,700 grammes; by the external plantar 1,240 grammes; by the internal plantar 1,330 grammes; by the small sciatic 680 grammes, and so on. This phenomenon is called "fractionation." It means that each afferent nerve can only command a portion of the motoneurone pool that supplies the muscle.

It should be noted, however, that the *sum* of the tensions independently obtainable from *all* the afferents greatly exceeds the maximal tension on motor nerve stimulation. In the above example the tensions produced by separately stimulating ten different afferent nerves, added up to 8,370 grammes, whereas the motor tetanus gave 2,160 grammes. This is readily explicable as an example of the *Principle of Convergence*, the areas of influence of the various afferents overlapping considerably, as illustrated in Fig. 165.

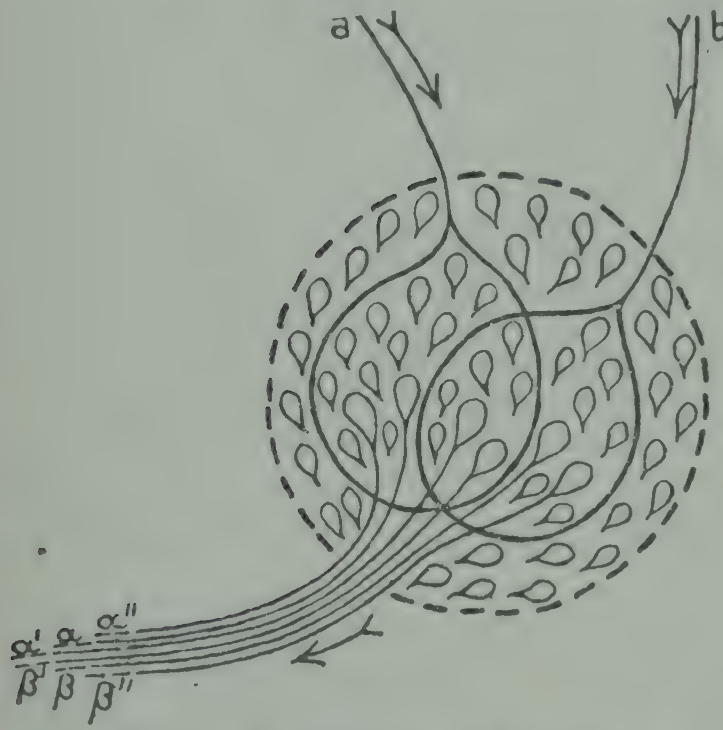

FIG. 165. To illustrate the principle of Convergence and the phenomenon of Occlusion, due to overlap in the neurones activated respectively by the two afferents a and b. The efferent neurones α' and β', for instance, are activated by both afferents. (CREED, DENNY BROWN, ECCLES, LIDDELL and SHERRINGTON. "Reflex Activity of the Spinal Cord," Oxford University Press, 1932.)

(9) Occlusion. The phenomenon called occlusion is another consequence of the principle of convergence. When reflex contraction of a muscle is produced by the simultaneous stimulation of two afferent nerves, the resulting tension is usually definitely less than the sum of the tensions set up by stimulation of the two nerves separately. Thus, when either of two plantar nerves was stimulated, 1,570 grammes tension was produced in a tibialis anticus muscle. If both nerves were stimulated one might therefore expect a tension of 3,140 grammes, but that actually developed was only 1,810 grammes, *i.e.* 1,330 grammes less. This phenomenon is again due to certain of the motor neurones being stimulated by both afferent nerves. Whereas one plantar nerve causes reflex stimulation of x motor neurones, and the other plantar nerve causes the reflex stimulation of y motor neurones the two nerves together do not activate $x + y$ motor neurones because some of those included in x are also included in y, *i.e.* there is considerable overlap, or "occlusion."

Occlusion is greatest in closely allied afferent nerves, because they are more likely to control adjacent parts of the motoneurone pool; it is also greater with more powerful and numerous stimuli, because these extend the area controlled by each afferent and so increase the overlap.

We may now consider some other characteristics which are seen to greater advantage in reflexes other than the flexor.

(10) Inhibition. This can be elegantly demonstrated on the crossed extensor reflex. If the central end of the contralateral sciatic nerve is stimulated by rapid shocks the quadriceps extensor enters into sustained contraction. If, during this tonic state, the central end of an ipsilateral afferent nerve, *e.g.* tibial, be strongly stimulated, the extensor contraction is instantly abolished. In a similar way the flexor reflex which is excited by an ipsilateral afferent can be inhibited by stimulating a contralateral afferent. It will be evident that this phenomenon of central inhibition, *e.g.* of an extension by a flexor reflex, must be closely related to that of reciprocal innervation, and results in a smooth and economical functioning of the muscles; the afferent nerve which causes reflex flexion, at the same time inhibits extension, and *vice versâ*.

The anatomical basis of the various events involved in the carrying out of such a reflex as that just studied is shown in Fig. 166. In this diagram the nerve fibre α represents the nociceptive nerve from the skin of the foot. This passes by a dorsal root into the spinal cord, where it gives off a number of collaterals. Those collaterals, which affect the motoneurones to the two hind limbs, can be divided into two sets, one of which produces excitation in some neurones, whilst the other produces inhibition of the motoneurones to the antagonistic muscles. The single afferent nerve fibre is, therefore, with regard to one set of its central terminal branches, specifically excitor and, in regard to another set, specifically inhibitor. In the case in point the central terminal branches of the nerve α are excitor for the flexor and inhibitor for the extensor muscles of the same side, and the reverse for the muscles of the opposite side.

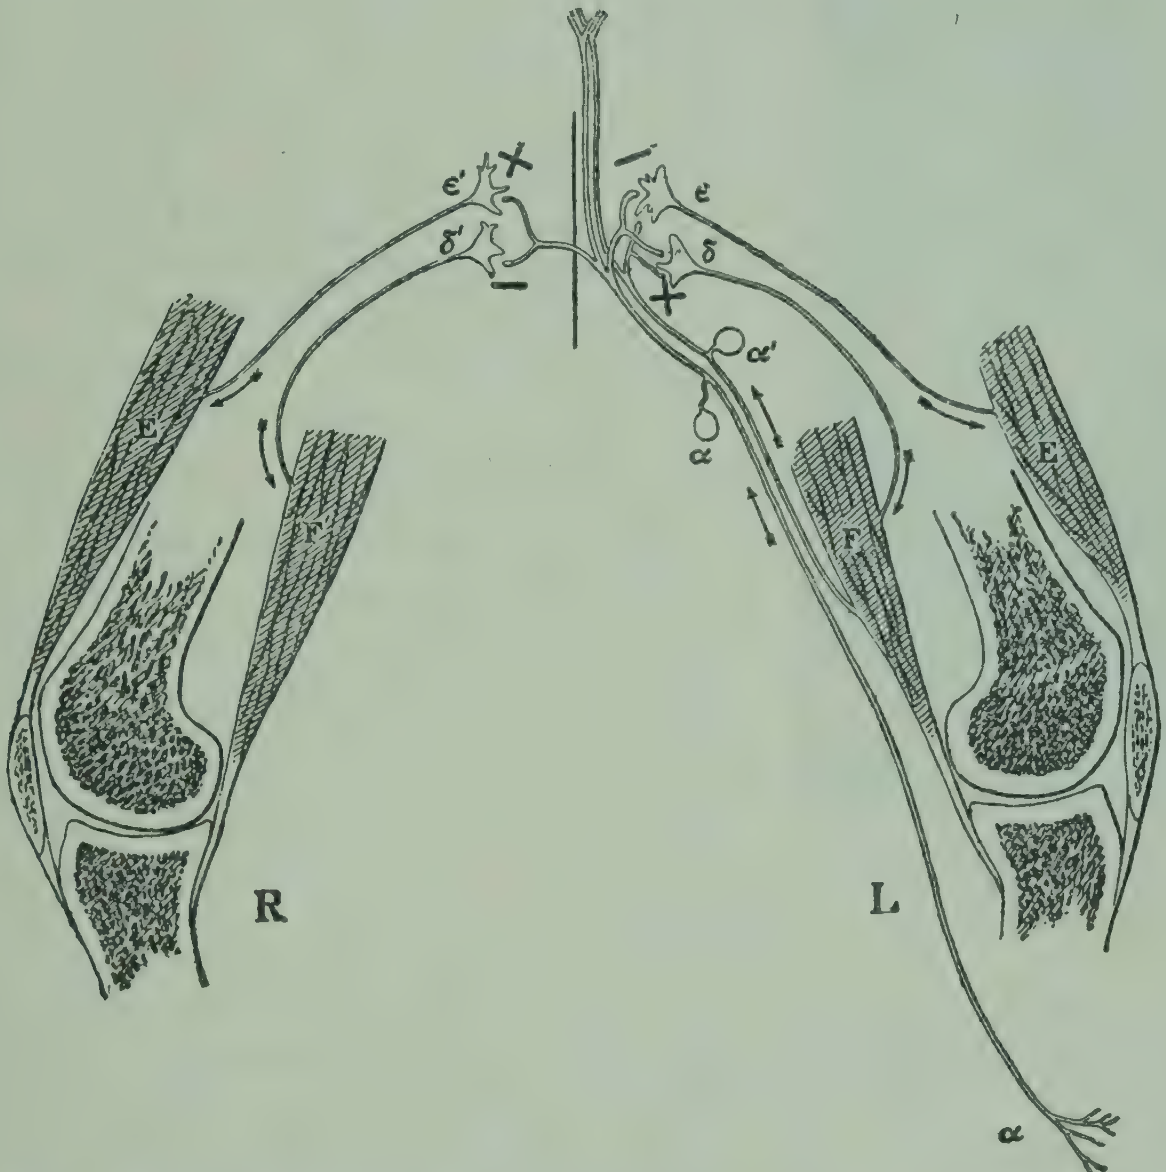

FIG. 166. Diagram indicating Connections and Actions of two Afferent Spinal Root Cells a and a' in regard to their reflex influences on the extensor and flexor muscles of the two knees. The sign + indicates an excitatory effect, the sign — an inhibitory effect. (SHERRINGTON.)

The diagram shows also how the contraction of the flexor muscle itself initiates a secondary reflex process from the muscle up the nerve fibre α' and back again to the muscle by the efferent neurone. This muscular afferent nerve also has central terminations of two signs—excitor to itself and inhibitor to the antagonistic muscles.

It is important to note that the efferent path innervating, say, the flexor muscles is common to many reflexes. It is used, for instance, by mutually exclusive reflexes such as the "scratch reflex" and the "flexor reflex." Evidently the mutual inhibition of opposed reflexes occurs, not in the "final common path"—*i.e.* in the motor neurones, which must always remain open—but farther back in the arc, probably at interneurones near its afferent side.

The biological value of inhibition is clear. For proper co-ordination there must be no clashing between opposing activities of different parts. One stimulus may *reinforce* another if the reactions ensuing on the two stimuli are *allied*—*i.e.* tend to co-operate one with another. But if one part is engaged in any action, this action must be the policy of the body as a whole. Yet the surface of the body is being continually played upon by ever-changing stimuli, tending to excite first one reflex and then another, and the activities so excited would produce confusion in the conduct of the animal, if there were not some means by which at any one time only one reaction should be carried out. The imperative stimulus should dominate the actions of the body as a whole. There may be a struggle of different stimuli, but one must finally be *prepotent* and annul altogether the influence of the others. The study of the spinal reflex shows that this end is obtained by the process of inhibition. Every successful reflex inhibits all other reflexes which are not co-operative with it. We may, for instance, stimulate the area of skin which gives rise to the scratch reflex, and at the same time apply a painful stimulus to the foot. The result is not a movement compounded of the two reflexes, but the scratch reflex immediately comes to an end, and the flexor reflex occurs. When this in its turn stops, the scratch reflex may be once more resumed (Fig. 167).

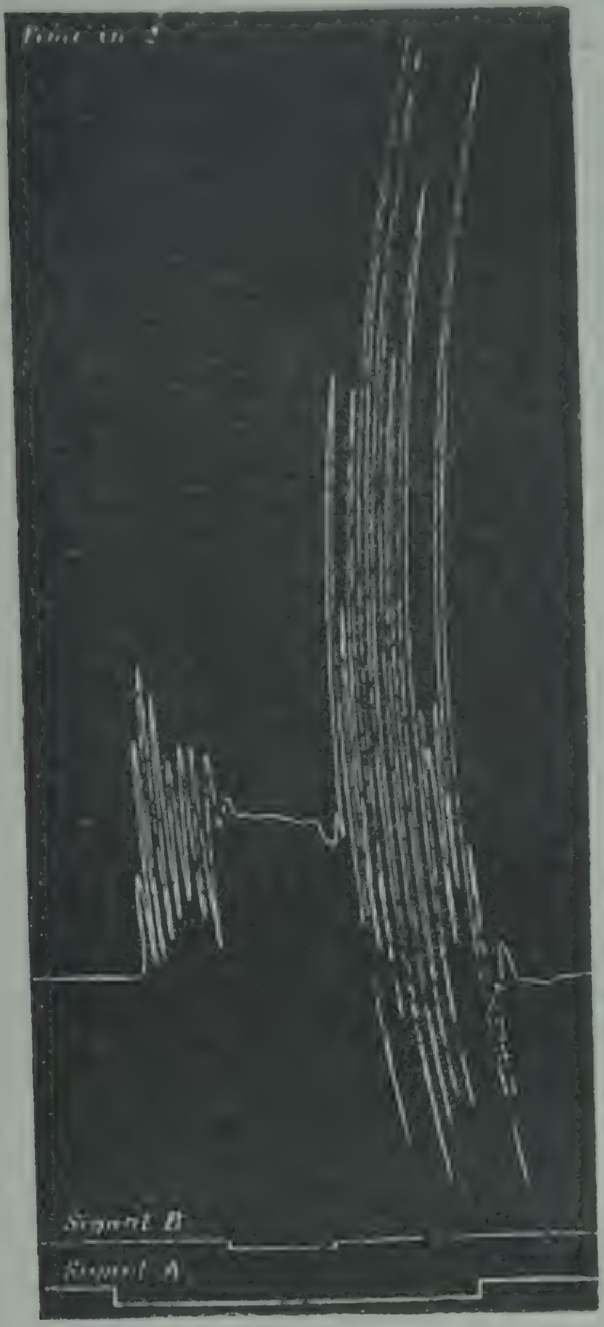

FIG. 167. Scratch Reflex temporarily inhibited by application of a Nociceptive Stimulus to Foot.

Signal A, stimulation of scratch area. Signal B, stimulation of paw by strong induction shock.

Central Inhibitory State. Inhibition is believed to be produced as a result of the establishment in the centres of a condition called the *central inhibitory state* (c.i.s.), which is antagonistic to the c.e.s. As we have already seen, some of the phenomena of inhibition may be due to nothing more than a lack of facilitation. But in other examples, what is called "*direct inhibition*" has been proved to occur. In this, a testing volley (*e.g.* along 6th L. dorsal root) even if of threshold strength * can inhibit a reflex from a stimulus synchronously despatched along a two-neurone arc (*e.g.* from 1st S. dorsal). This means that some positive

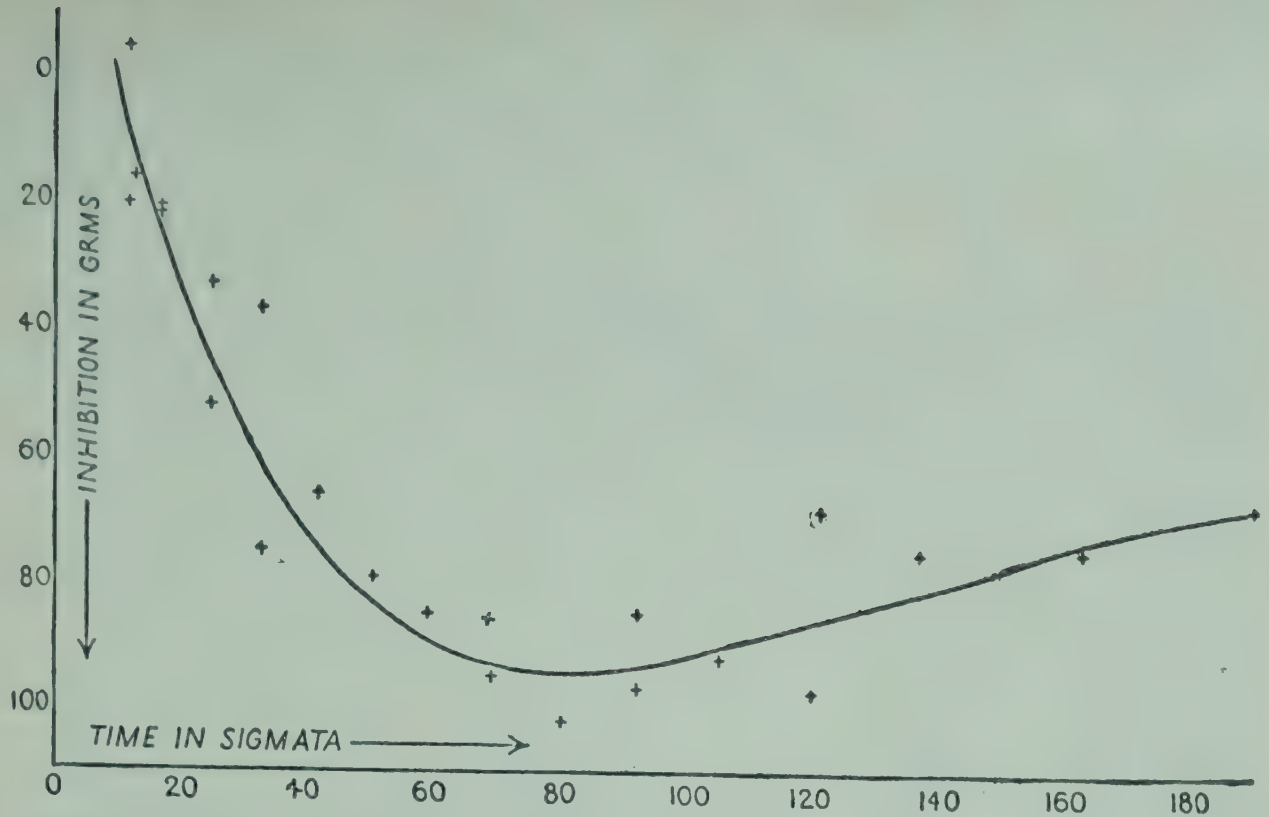

Fig. 169. Tensions of Reflex Twitches (Ordinates) Plotted against Intervals by which an Inhibitory Volley precedes the Excitatory (abscissæ). (Creed *et al.* "Reflex Activity of the Spinal Cord.")

inhibitory effect has been produced on the motor neurones, but the nature of this effect is unknown.

In most instances, inhibition occurs, not at the effector neurones, but at interneurones; its duration is then longer.

If an inhibitory volley *precedes* the excitatory one, the extent of the resulting inhibition depends on the time interval between them. It is maximal (for the inhibition of the flexor reflex) at about 80 msec. (Figs. 168 and 169).

The c.i.s. produced by an afferent stimulus thus rises more slowly than c.e.s. (which is at a maximum in about 6 msec.). It also lasts longer, and then slowly subsides.

The c.i.s. can be summated, either temporarily or spatially. Thus two inhibitory stimuli produce more inhibition than one, if suitably spaced. An antidromic volley cannot, however, discharge c.i.s. as it can c.e.s. Excitation and inhibition can be quantitatively balanced one against the other and the stronger can ultimately overcome the other (Fig. 170).

The exact way in which inhibition is produced has been the subject of many speculations. Many kinds of inhibitory phenomena are met with in the body, and the explanation of one may not be applicable to another. Recent evidence seems to point to the probability that the neurones of the central nervous system are normally exposed to constant subliminal bombardment with impulses and that excitation occurs when new impulses arrive in sufficient numbers and at appropriate instants. Inhibition then comes about if this background of facilitation is withdrawn, because, as we have seen, it needs more than one impulse to excite a motoneurone to the discharge point.

Examples of direct inhibition of motoneurones (*i.e.* like that of vagus on the heart) have been discovered, but cannot at present be explained.

An explanation of reciprocal innervation has been advanced by Gasser on the following lines (Fig. 171). Suppose that two synapses must be excited within 0·5 msec. in order to excite the neurones. When fibre I is repeatedly excited *b* and *c* and hence F, a flexor motoneurone, are stimulated.

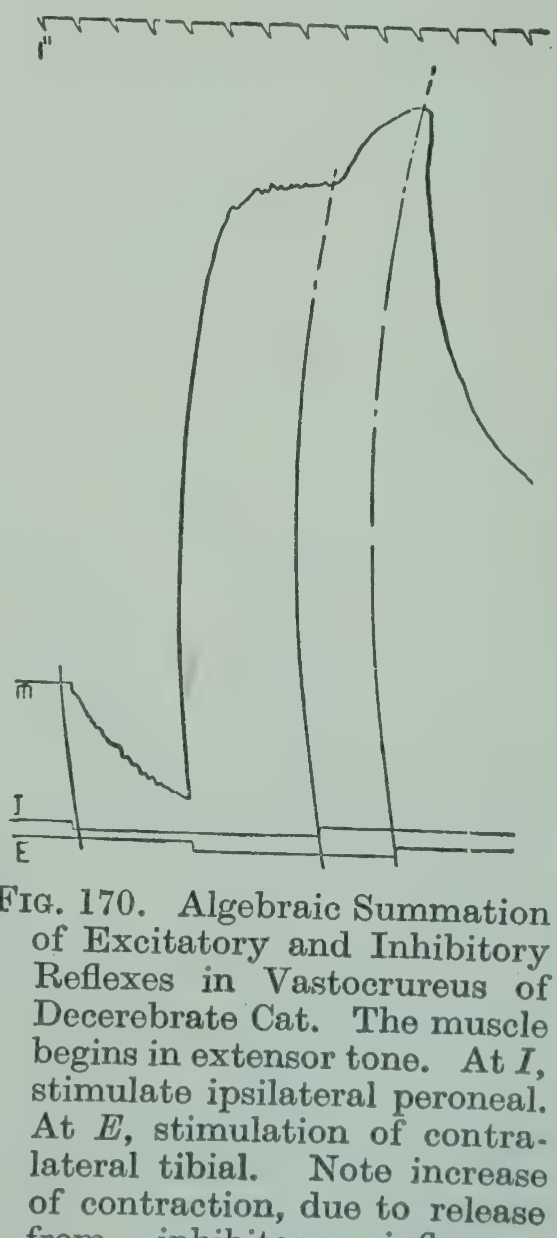

Fig. 170. Algebraic Summation of Excitatory and Inhibitory Reflexes in Vastocrureus of Decerebrate Cat. The muscle begins in extensor tone. At *I*, stimulate ipsilateral peroneal. At *E*, stimulation of contralateral tibial. Note increase of contraction, due to release from inhibitory influence, when *I* ceases. (Creed *et al.* "Reflex Activity of the Spinal Cord.")

Now, suppose that while this is happening, fibre II is stimulated. It has three synaptic knobs on *b* (and two on *a*), and can excite *b* at its own rhythm, which is different from that of I. Neurone *b* now comes under the control of II, and discharges at a different rate from *c*, so that F does not receive successive impulses from *b* and *c*, within 0·5 msec. and therefore ceases to respond. Neurones *a* and *b*, however, act in unison and so excite E, causing contraction of the extensor.

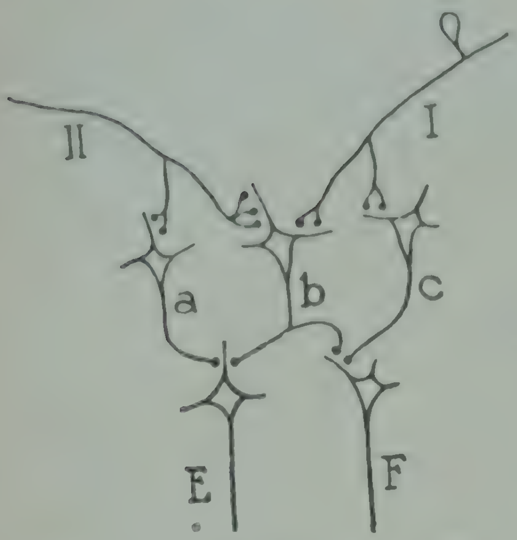

FIG. 171. To illustrate Theory of Central Inhibition and Reciprocal Innervation. (GASSER. Harvey Lecture, 1937.)

One suggestion as to the nature of central inhibition is that it is due to a polarisation change on a different part of the nerve cell. According to this theory,* the arrival of impulses at the cell body or dendrites (the excitatory pole) causes polarisation changes which result in an electrotonic current, as shown in A of Fig. 172. This current, arriving at the axon hillock, may generate an impulse along the axon. But other synapses end on the axon hillock (the inhibitory pole) and these cause a current which opposes the electrotonic current from the excitatory pole, as shown in B, Fig. 172. Excitatory and inhibitory afferent stimuli can thus be balanced one against the other. The theory also accounts for reciprocal inhibition as shown at C, Fig. 172, by supposing that collaterals from the cells of opposing neurons pass each to the inhibitory pole of the other.

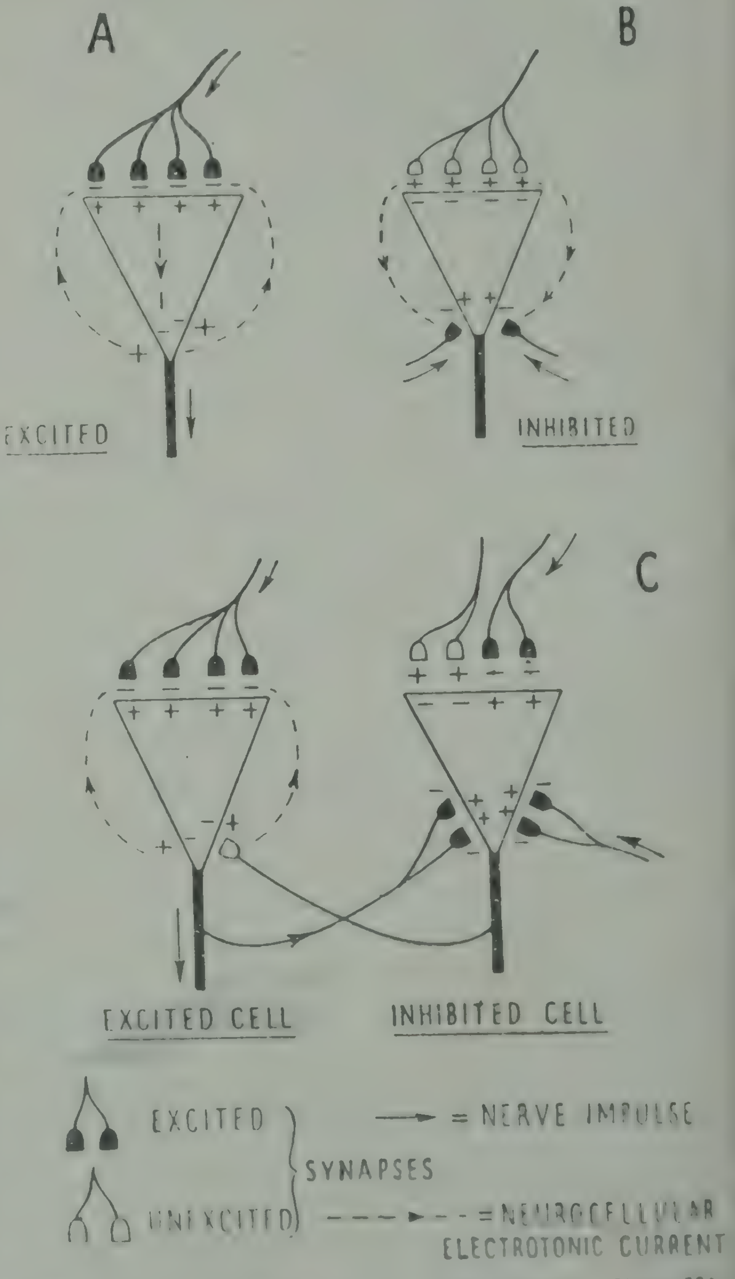

FIG. 172. Diagram to illustrate Gesell's theory of central inhibition.

(11) "Rebound." Inhibition is often followed by a condition of increased excitability, as a sort of swing-back of the state of excitation. Thus, suppose the scratch-reflex is excited and then, while the excitation is still continued, the reaction is inhibited by excitation of the flexor reflex. As soon as the flexor reflex has passed off, the scratch reflex returns with an intensity greater than before (Fig. 167, p. 258). It may also be seen sometimes as an increased after-discharge following the cessation of an excitatory stimulus. In the knee-jerk a succession of inhibitions and rebounds may result in a clonic contraction.

(12) Negative Successive Induction. When a reflex subsides, it often tends to be followed by an opposing movement, a phenomenon called *negative successive induction*. This explains the tendency of the spinal cord to an alternation of response; every act tending as a result of negative spinal induction to induce the antagonistic act. Thus if a spinal dog be held up vertically, so that the hind limbs hang freely, these latter execute a series of alternate movements of flexion and extension—the "*mark-time*" *reflex*. The starting point of these is the stretching of the anterior thigh muscles. Once started they continue of themselves, each act exciting the alternating antagonistic act (Fig. 173).

---

* GESELL. *Ergebn d. Physiol.*, 1940, **43**, 477; *Amer. J. Physiol.*, 1947, **148** 515.

The movements of biting and mastication are probably largely effected by a series of rebounds aided by negative successive induction, originated by the mechanical stimulus of food in the mouth.

(13) Recruitment. Many reflexes, especially the extensor ones, show a much slower development than does the flexor response or that obtained by stimulation of the motor nerve; this is due to the fact that the motor units are not thrown into action all at once, but are brought into play in regularly increasing numbers up to the maximum. The decline of these reflexes is also gradual. This phenomenon is called *recruitment*, and is responsible for the steady rise and fall of contraction in certain natural movements, such as those of the respiratory muscles.

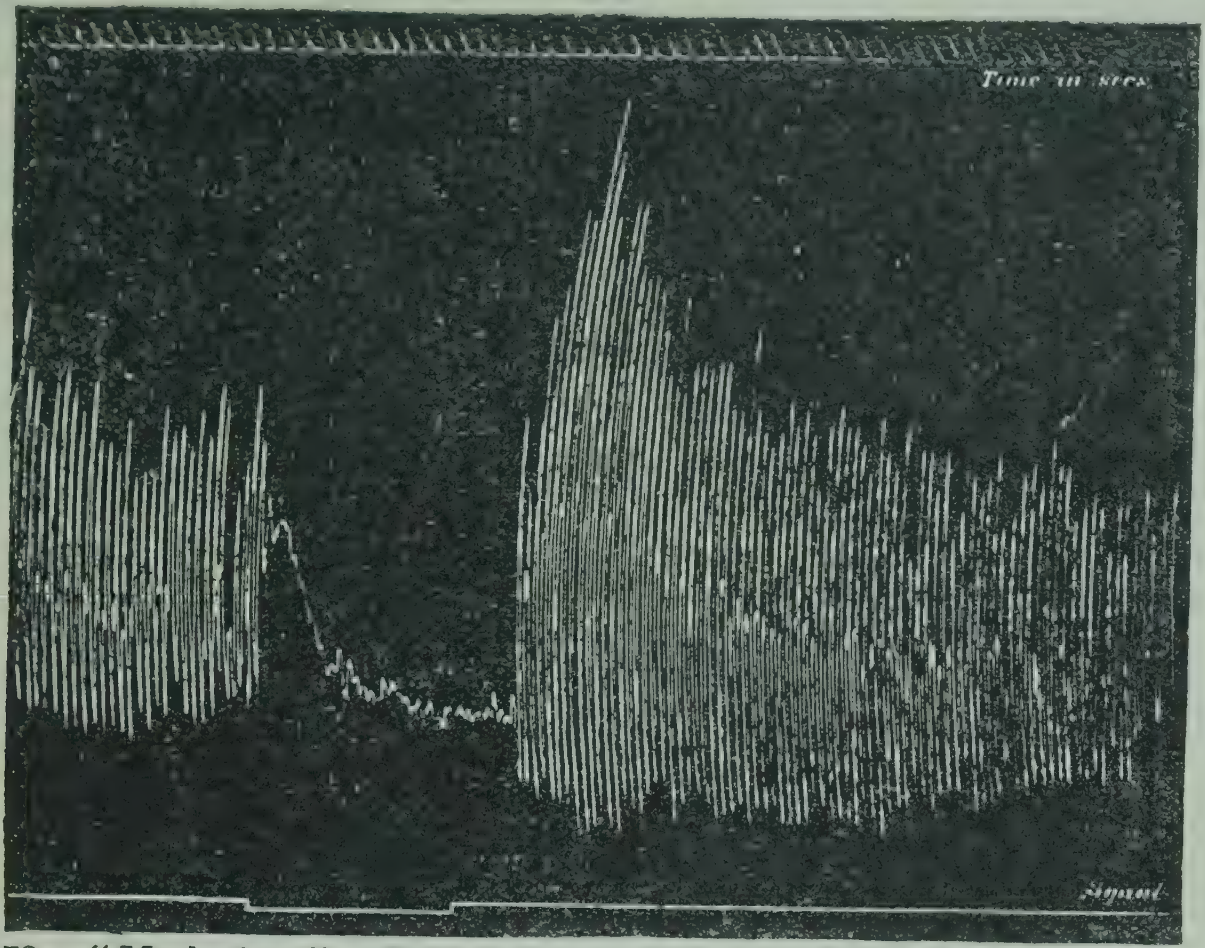

FIG. 173. "Mark-time" reflex in spinal dog, inhibited by slight stimulation of the tail (duration of stimulation shown by signal). Note the augmentation of the mark-time reflex following the inhibition (*rebound*). (SHERRINGTON.)

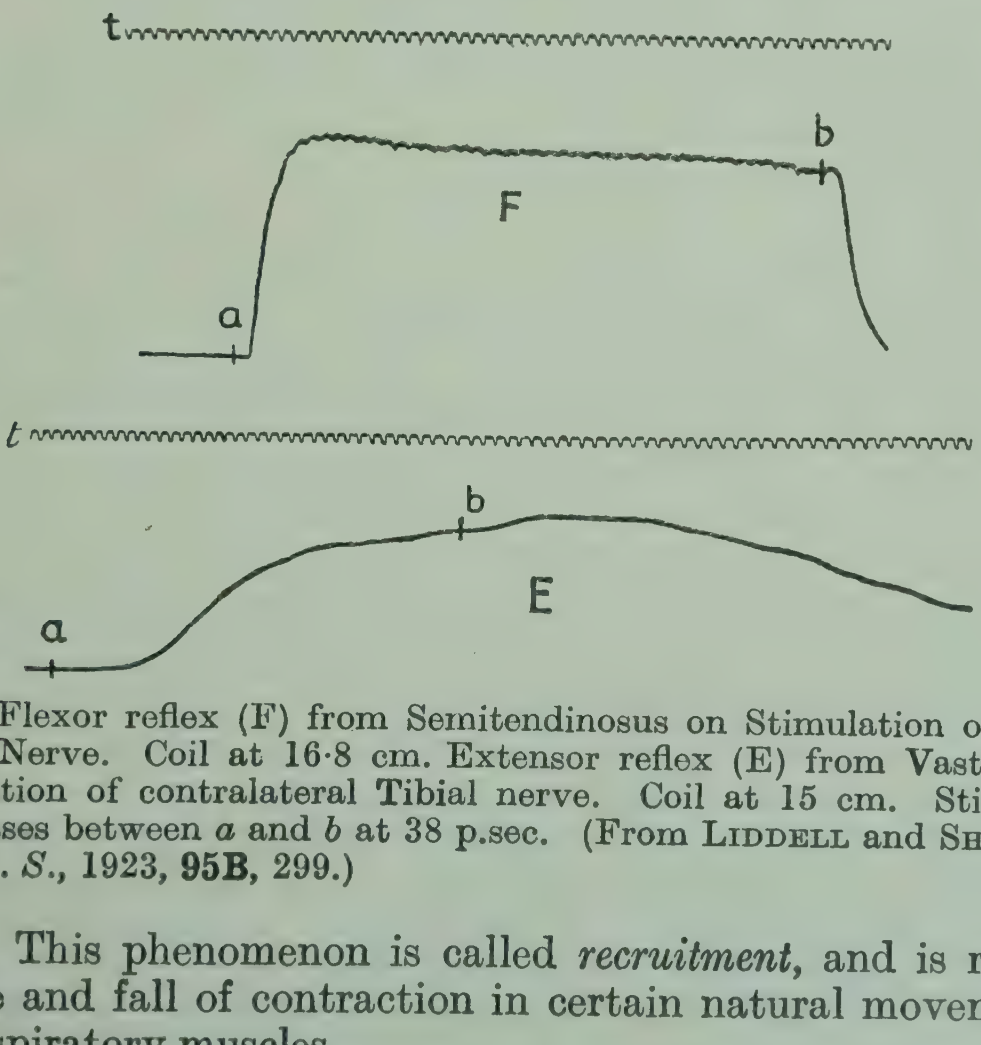

FIG. 174. Flexor reflex (F) from Semitendinosus on Stimulation of Ipsilateral Tibial Nerve. Coil at 16·8 cm. Extensor reflex (E) from Vastocrureus on stimulation of contralateral Tibial nerve. Coil at 15 cm. Stimulation in both cases between *a* and *b* at 38 p.sec. (From LIDDELL and SHERRINGTON. *Proc. R. S.*, 1923, **95B**, 299.)

When, as in many flexor reflexes, all the motor units employed are thrown into use at the commencement of the response, the onset is sudden, and is of the type called by Sherrington "*d'emblée*" reflexes. Fig. 174 shows the striking difference between flexor and extensor reflexes.

It will be seen that the flexor response shows less delay, needs a weaker stimulus, has a more abrupt rise and fall, has little after-discharge, and shows the rhythm of the afferent stimuli. The slow falling-off of the extensor response is clearly due to prolonged after-discharge. Its slow rise, or recruitment, is probably explicable as due to a larger number of internuncial neurones in the reflex arc. Hence the delay in commencement is longer than for the more direct flexor reflex, because the c.e.s. takes longer to work up to an excitatory level; it also more slowly reaches a maximum as the later impulses trickle into the motoneurone pool. Also, owing to the many different delay paths the rhythm of the afferent stimulus is damped out, so that a smooth contraction results even when the rate of afferent stimulation is relatively slow.

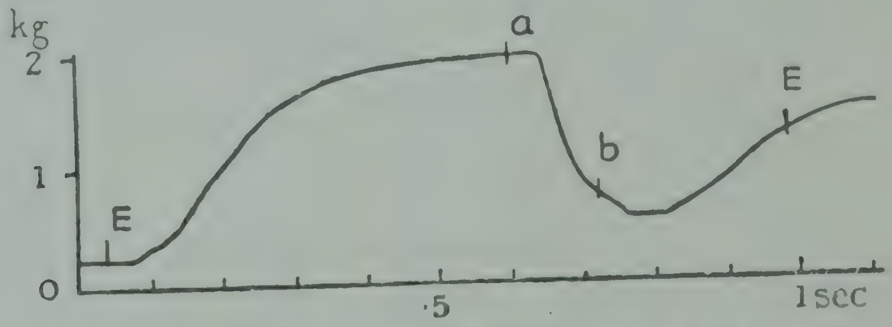

FIG. 175. Recruitment and "after-discharge" of Inhibition. *Rectus femoris.* E to E, stimulation of contralateral afferent causing crossed extensor reflex. *a* to *b*, stimulation of ipsilateral afferent causing inhibition of slow onset and outlasting the stimulation. (LIDDELL and SHERRINGTON, *Proc. Roy. Soc.*, 1925, **97B**, 488.)

Inhibition, as well as excitation, shows the phenomenon of recruitment, if the inhibitory stimulus is weak, *i.e.* the motoneurones cease working in succession, not all at once (Fig. 175); it also shows after-discharge.

There is an alternative explanation of recruitment. The extensors in the decerebrate preparation are normally in a state of tone, due to stretch-reflexes. When an extensor contraction begins, the stretch is relieved, so that the rise of tension is slowed down: also, afferent impulses having an inhibitory effect pass up from the muscle, and these have the same effect of acting as a brake on the rise of tension. The converse happens when relaxation occurs. The evidence for this view is that if the afferents from the extensor muscles are divided, the characteristic recruitment and after-discharge are much lessened, and hence they must be partly proprioceptive in origin.*

The extensor muscles therefore tend to give smooth contractions and steady relaxations.

(14) **Fatigue.** If a given reflex be repeatedly elicited, the reaction becomes feebler and finally disappears altogether (*e.g.* the flexor reflex in 30 seconds) long before any signs of fatigue in the motor apparatus can be detected on stimulation of the motor nerve. Since we know that it is practically impossible to fatigue nerve fibres, we must conclude that the seat of fatigue is in the grey matter of the spinal cord itself.

Central fatigue might be due to a variety of causes, *e.g.* depletion of energy-yielding materials in the soma, depletion of sources of humoral transmitters at synapse, accumulation of substances causing block at the synapses, or failure of normal electrical polarisation at the synaptic membrane. The first of these can be discounted because the fatigue changes are strictly localised at the synaptic endings. This is shown by the fact that only one path of approach may be fatigued: thus after the flexor reflex has been fatigued by prolonged stimulation of the popliteal nerve, it can still be elicited by stimulation of the peroneal nerve, and *vice versâ*.†

---

* SHERRINGTON. *Q. J. Exp. Physiol.*, 1909, **2**, 109.

† FORBES. *Am. J. Physiol.*, 1912, **31**, 102.

The phasic reflexes, such as the flexor reflex, are much more readily fatiguable than are the tonic reflexes, such as the extensor and postural ones. These latter also are evoked from less quickly adapting sensory receptors, and are better equipped for sustained activity. We may suppose that this is possible without synaptic fatigue because the synapses function in rotation, and have time to recover between their spells of action.

(15) " Block " or Resistance. As we have seen, there is an absolute block to the passage of an impulse backwards through a synapse. The phenomena of fatigue show that there may be resistance even to the passage of an impulse in the normal direction. When we study the structure of the central nervous system, we find that although there are certain shortest possible paths for every impulse, yet so extensive is the branching of the entering nerve fibres and so complex are the neurone systems with which they come into connection, that if all resistance were removed, an impulse entering along any given fibre could spread to practically every neurone in the spinal cord and brain. Such a result is indeed observed in animals poisoned by strychnine. In these, the slightest stimulus applied to any part of the skin excites strong tonic spasms in the musculature of the whole body. Every sensory nerve fibre, that is to say, can discharge into every motor neurone of the cord. That this result does not ensue on localised stimulation in a normal animal is because of the varying resistance to the passage of an impulse into the several neurones with which the entrant fibre comes into anatomical relation. A small stimulus will discharge only along the few neurones where the resistance is lowest. Increase of the stimulus, either by adding to its strength or by summation of weak stimuli, will enable the impulse to irradiate and therefore will elicit a more widespread response. Only when the " blocks " are entirely removed by the administration of strychnine, or when the stimuli are abnormally powerful and long continued will the impulse spread to all regions of the central nervous system, so that the response becomes general and inco-ordinate.

STRETCH REFLEXES

Normal muscles are in a state of slight constant tension, or *tone*, and in the decerebrate animal this is greatly exaggerated in the extensor muscles. Section of either the motor or the afferent nerves of the muscle destroys this tone and the muscle becomes limp. When the tendon of such a denervated muscle is pulled upon, the muscle is merely passively stretched. It is quite different if a pull is given to the tendon of an innervated extensor muscle, such as the quadriceps, of a decerebrate preparation. The muscle in such a case returns pull for pull, actively contracting against and in proportion to the stretching forces. This response is a *stretch reflex*. Such an experiment is illustrated by Fig. 176. The quadriceps of a decerebrate cat was attached by the patellar tendon to an isometric lever and was subjected to stretching by pulling the animal in the opposite direction to the lever by lowering the animal table by a few millimetres.

A tension of nearly 4 kg. resulted, but after denervation the passive lengthening of the muscle by the same stretch gave only a little over 1 kg. tension. The reflex and proprioceptive character of the pull is demonstrated by the fact that it disappears completely if the afferent fibres from the muscle are divided by section of the appropriate dorsal nerve roots.

The stretch reflexes are shown especially well in the extensors of decerebrate preparations ; sustained stretch reactions are not seen in flexors. These proprioceptive reflexes originate in the stimulation of the stretch receptors in the muscle and tendon. As we have already seen (Chapter XIV) the stretch receptors start off trains of impulses when the muscle is stretched, and as the stretch increases the impulses follow each other more frequently, and along more and more fibres. Muscle stretch receptors do not adapt rapidly, and so keep up trains of impulses along the afferent fibres from the muscle as long as the stretch is maintained, and if this is increased, more and more motoneurones are recruited. The contraction is therefore as sustained and as strong as the stretching force, but only affects the muscle, or that part of it, subjected to stretch—it never spreads, as flexor reflexes do. Indeed, it is probable that each muscle spindle serves as the starting point for stretch reflexes confined to immediately neighbouring fibres.

The pain receptors, by way of contrast, adapt quickly, and so are more suited to evoke the brisk but more evanescent flexor responses.

Stretch reflexes are mediated by large afferent fibres, are effected by simple two-neurone arcs, and therefore have short latent periods (6 to 20 msec.) and show little after-discharge. They can at once be inhibited, as Fig. 176 shows, by exciting an opponent reflex. The rate of discharge of the neurones is slow, *e.g.* about 8 p. sec., asynchronous, and involves little metabolic cost. It is probably on this account that fatigue does not occur.

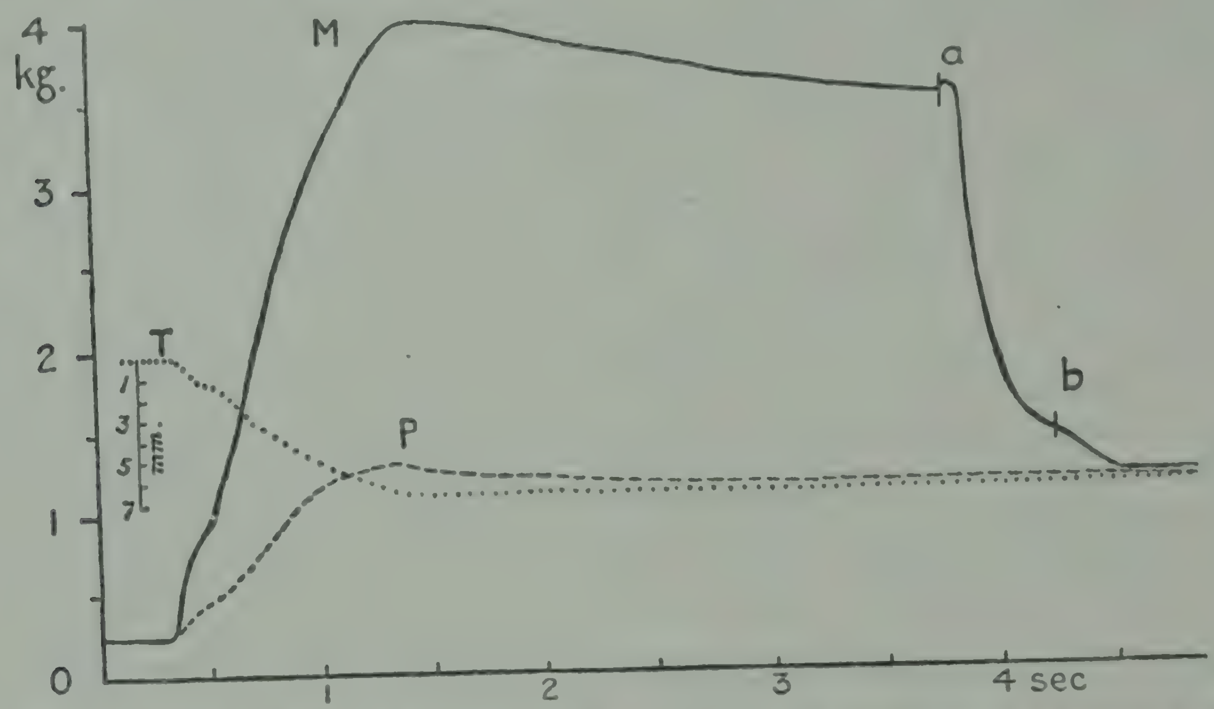

FIG. 176. Stretch Reflex of *Quadriceps*, decerebrate Cat. Extent of stretch shown by curve T; M, tension of muscle; P, passive tension by repeating stretch after denervation of muscle. *a*, *b*, inhibition by stimulation of ipsilateral tibial nerve. (LIDDELL and SHERRINGTON, *Proc. Roy. Soc.*, 1924, **96B**, 212.)

The stretch-reflexes have great importance in connection with the maintenance of posture, of which they form the background. They are seen in those muscles that normally counteract the effect of gravity, and their tonic nature enables an animal to maintain its normal posture without fatigue. When an animal stands erect, gravity tends to cause flexion at hip, knee and ankle, but any tendency of the limbs to give way is instantly corrected by the stretch-reflexes, which convert the limbs into rigid pillars.

Types of Muscle. Most of the pure flexor muscles are made up of pale fibres, the rapid contraction of which is suited to their function. Extensor muscles, on the other hand, are capable both of slow, sustained contractions, as in stretch reflexes, and of quick ones, and accordingly consist of two parts, a quick acting part, of pale muscle, and a slow one of red muscle.* Thus, soleus and gastrocnemius extend the ankle, the former slowly, the latter quickly; medial short head of triceps extends the elbow slowly and the lateral short head quickly, and so on. Physiologically they are distinct muscles, though often associated anatomically as separate "heads." Usually the slower muscle is the more deeply placed.

Tendon-reflexes. The knee-jerk, and other examples of "tendon-reflexes" already referred to in Chapter XIII, are special cases of the stretch reflex. In them the tug on the muscle is very brief and the response is brisk. They originate from the stretch of the muscle and not from the tendon, since they can still be elicited after cocainising the tendon. The latent period is very short (6 to 8 msec.) because a synchronous volley is sent up from the muscle, and because the arc is short.

---

* DENNY-BROWN. *Proc. Roy. Soc.*, 1929, **104B**, 371.

The electric potential changes during a tendon-jerk show a burst of impulses immediately preceding the contraction, followed by a sudden cessation—the "silent interval" at its height, and then a further train during and after the peak. The silent period has been shown to be partly due to the relief of tension on the stretch receptors when contraction has occurred, partly to reflex inhibition, but mainly to the fact that since the motoneurones are put into action synchronously they naturally all reach the state of lowered excitability at about the same time. The tendon-jerk can be abolished by inhibitory excitation, *e.g.* the knee-jerk by stimulation of an ipsilateral afferent.

The reason why tendon-jerks and stretch reflexes are more easily shown in the decerebrate preparation is probably that there is a constant state of extensor excitation facilitating the responses. In man the knee-jerk is facilitated, or "reinforced" by clenching the fists.

Lengthening and Shortening Reactions. If one attempts forcibly to flex one of the rigidly extended limbs of a decerebrate preparation, the resistance due to the stretch reflex is at first encountered, but if the pressure is continued, the limb quite suddenly folds up—"*clasp-knife reaction.*" This sudden yielding in the face of threatened rupture is a protective response, and is called the *lengthening reaction.* It is due to the fact that at a certain degree of tension inhibitor afferents gain the ascendency. Accompanying this inhibition is a tonic increase of extension in the opposite limb, which is called Philippson's reflex (Fig. 177). It is akin to the crossed extensor reflex.

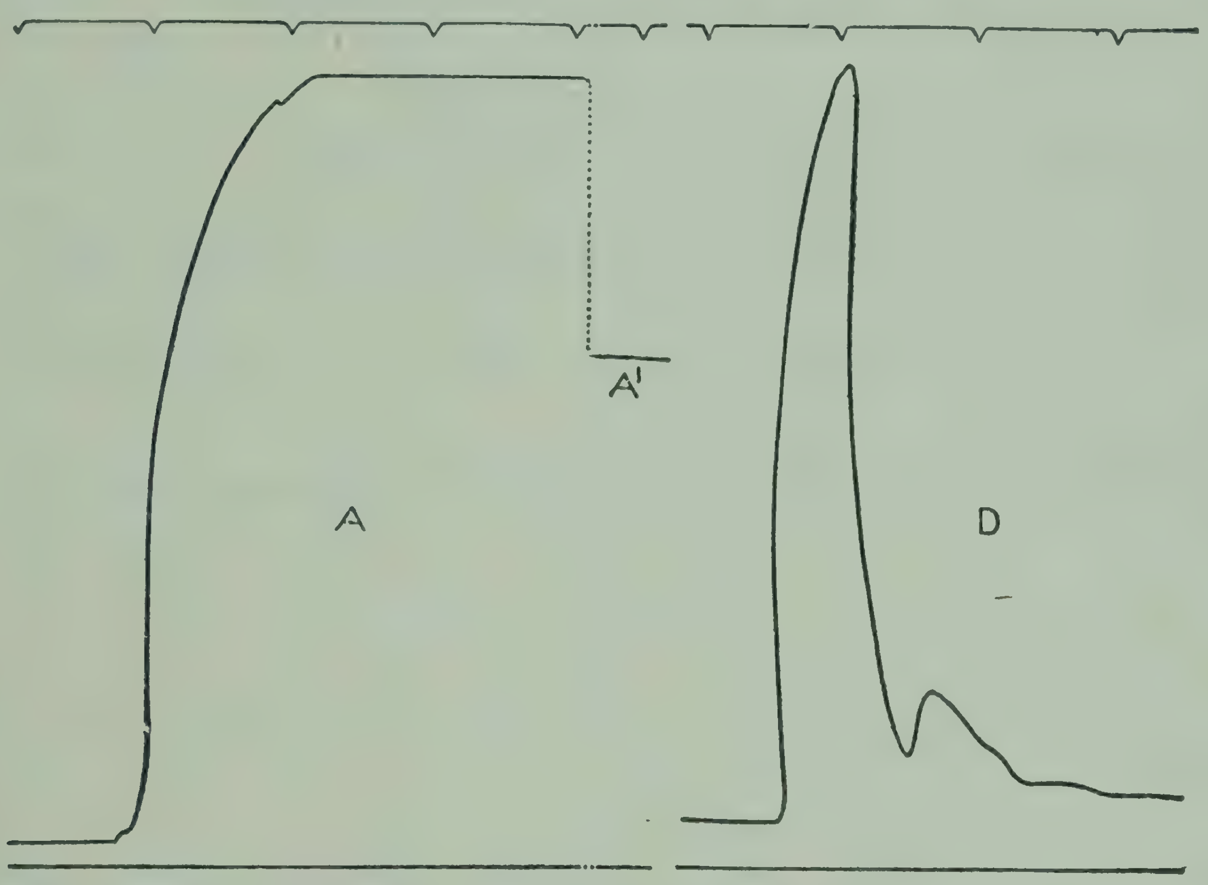

FIG. 177. A, Philippson's Reflex, a Contraction of the Extensors of a Decerebrate Preparation when the opposite Limb is forcibly bent at the Knee. A¹, the same 1 minute later. D, the response 48 days after section of afferent roots of the muscle. Time = secs.

Like the crossed extensor reflex it is converted from a tonic to a phasic response if the extended muscle is first deafferented (Fig. 177, D). This shows that in some manner the extensor reflex is maintained in a tonic state as a result of afferent impulses from the extended muscle—possibly from its own stretch receptors.

The converse of the lengthening reaction is the *shortening reaction* seen if, after passive flexion, the limb is passively re-extended, when it "stays put" in extensor tonus as at the start. By these two reactions a certain plasticity is imparted to the exaggerated postural tonus of decerebrate rigidity.

There is evidence that when a muscle is stretched two opposing reflexes compete. The tendon receptors originate impulses which have an inhibitory effect on contralateral extension, while the annulo-spiral spindle endings of muscle have an excitatory one, provoking the Philippson reflex.*

IPSILATERAL EXTENSOR REFLEXES

Although the commonest type of reflex elicited by the artificial stimulation of afferent nerves consists in ipsilateral flexion, with contralateral extension, there are, nevertheless, various reflexes of ipsilateral extension. Some of these play an important part in the natural co-ordination of reflexes due to the normal stimuli to receptors. The stretch reflex, and the tendon-reflexes are examples of this: the extensor thrust and the positive supporting reactions are others.

---

* MORSON and PHILLIPS. *J. Physiol.*, 1937, **88**, 199.

An ipsilateral extensor reflex is also sometimes obtained on artificial stimulation of an afferent nerve, particularly of one placed distally on the limb. In these circumstances, the contraction of the extensor muscle precedes the normal inhibitory response accompanying the flexor reflex. It is believed that this extensor contraction competes, usually unsuccessfully, with the more powerful inhibitory one, so that it is only sometimes evident, and then often only for a time.

It would seem that each afferent nerve can excite two opposing reflexes, of which one is normally the stronger; the other is called a "*concealed reflex.*" The motoneurones are always subjected to continual processes of excitation and inhibition, and their activity at any moment represents the algebraical sum of these opposed influences.

Reversal of Effect. Owing to the existence of concealed reflexes, it may happen that stimulation of an afferent gives first one reflex and then the reverse one. This may happen especially if the strength of stimulation is altered, or if the stimulation is prolonged, or the conditions changed, as by drugs. Terminal rebound is often such an instance, and possibly the rhythmic reflexes, such as stepping, the scratch reflex, etc., are others.

It was inferred by Graham Brown * that the spinal reflex centre for a limb consists of two "half-centres," one flexor and one extensor, and each afferent fibre reaching the centre divides into branches, some of which go to each half-centre.

CHAPTER XVIII

THE LABYRINTH, AND POSTURAL REFLEXES

Although quite complex reflexes can be carried out through the mediation of the spinal cord, most of these reflexes are, in the intact animal, considerably modified owing to the action of the higher parts of the central nervous system. This process of modification consists of augmentation of some, and suppression of other reflexes, and a general grouping together of reflexes so that a co-ordinated response of greater complexity results. As an example of this kind of higher function we shall now consider the reflex aspects of posture maintenance. Although this involves the final employment of spinal arcs, the proper association of the various factors which are concerned is carried out largely by centres in the brain stem.

The various movements of the normal body are effected against a background of muscular tonus, which maintains the various postures. The postural tonus of the musculature is effected reflexly, being built up from afferent impulses from two chief sources, viz. the *labyrinths*, and the *muscle proprioceptors*, and from various subsidiary sources. This state of tone is suitably modified when any movement takes place. Many of the movements of normal animals are effected reflexly, and their study provides a good example of the manner in which elementary reflexes, carried out by lower centres, are modified and integrated by the intervention of higher centres of activity.

It is interesting to note that the pathways and arcs responsible for postural maintenance are rapidly conducting two-neurone arcs, whereas those concerned with flexor-reflexes and voluntary action are slow-conducting multi-neurone arcs. Probably this ensures that the initial postural state provides a suitable foundation for the movement.

THE LABYRINTH

The primitive auditory sac arises as a simple involution of the surface. In the course of development the anterior part is modified to form the canal of the cochlea, which is set apart entirely for hearing. From the posterior part there are formed two sacs—the saccule and utricle—and the three semicircular canals. The saccule and the utricle, which receive each a large branch

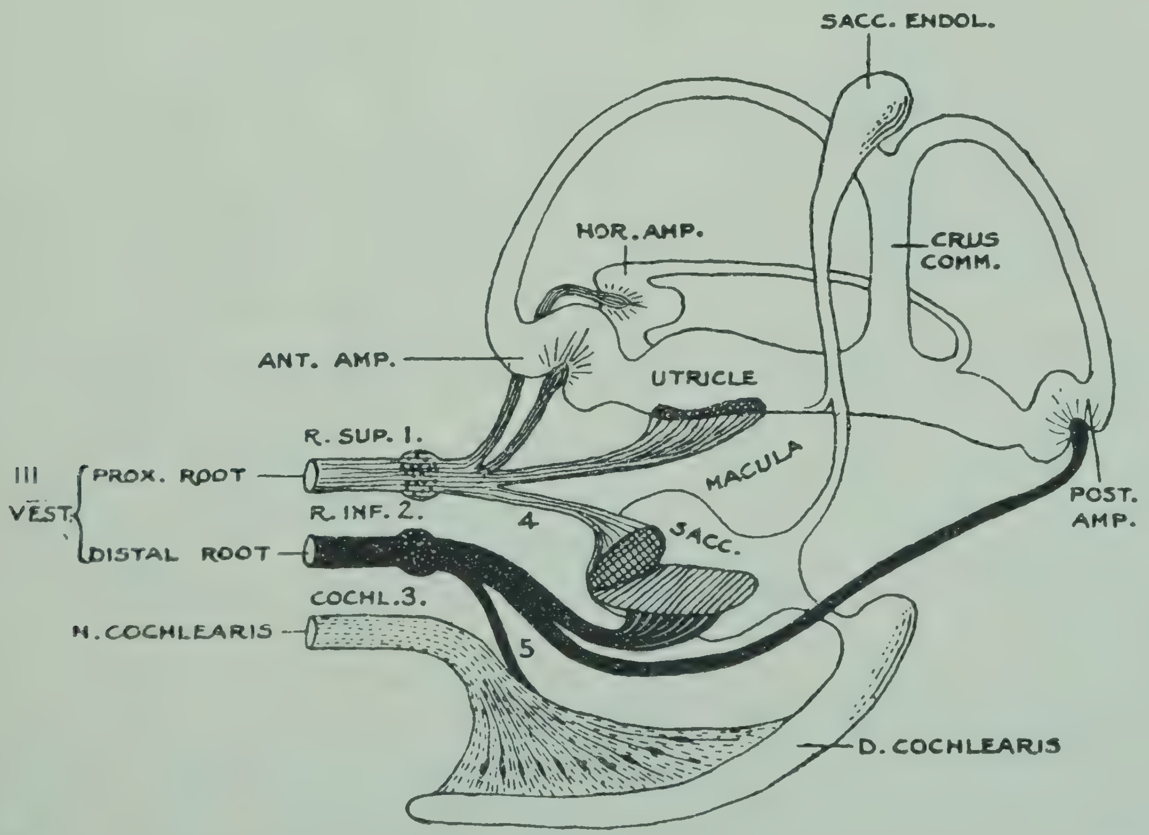

Fig. 178. Scheme of the Innervation of the Membranous Labyrinth. (H. M. de Burlet, *Anat. Anzeiger*, 1924.)

of the vestibular division of the VIIIth nerve, represent the *otolith organ*, which is found in almost all classes of animals.

In mammals, that part of the labyrinth which represents the primitive otolith organs consists of a bony casing containing perilymph, in which is contained the membranous labyrinth, filled with endolymph. The osseous labyrinth consists of a cavity, the vestibule, into which open behind the three bony semicircular canals. In the vestibule are contained two little membranous sacs, the utricle and saccule, the cavities of which are connected by means of the *ductus endolymphaticus* (Fig. 178).

Into the utricle, by five openings, open the three semicircular canals. These semicircular canals are arranged in three planes, each of which is at right angles to the other two, so that the three planes of space are represented. We may distinguish on each side an external or horizontal canal, an anterior vertical canal, and a posterior vertical canal. The two external canals on the two sides lie always exactly in the same plane, which in the normal position of the head slopes backwards and downwards at 30° to the horizontal. Each posterior vertical canal lies in a plane which is parallel to that of the anterior vertical canal of the opposite side. We thus see that these semicircular canals form together three planes, one nearly horizontal and two vertical, the two latter being at right angles to one another (Fig. 179). The membranous canal lies within the osseous canal, a considerable space intervening between the two canals. At one end each of the osseous canals is dilated and the membranous canal undergoes a corresponding dilatation so as to fill up the whole bony canal. In this dilatation, which is known as the *ampulla*, we find the ending of a branch of the vestibular nerve in a special sensory epithelium forming the *crista acustica* (Fig. 180). The crista is composed of hair cells with sustentacular cells between them. The fibres of the vestibular nerve end in arborisations among the hair cells, the hairs of which project into a dome-shaped mucilaginous body, the *cupola*, which lies in the endolymph filling the ampulla (Fig. 180).

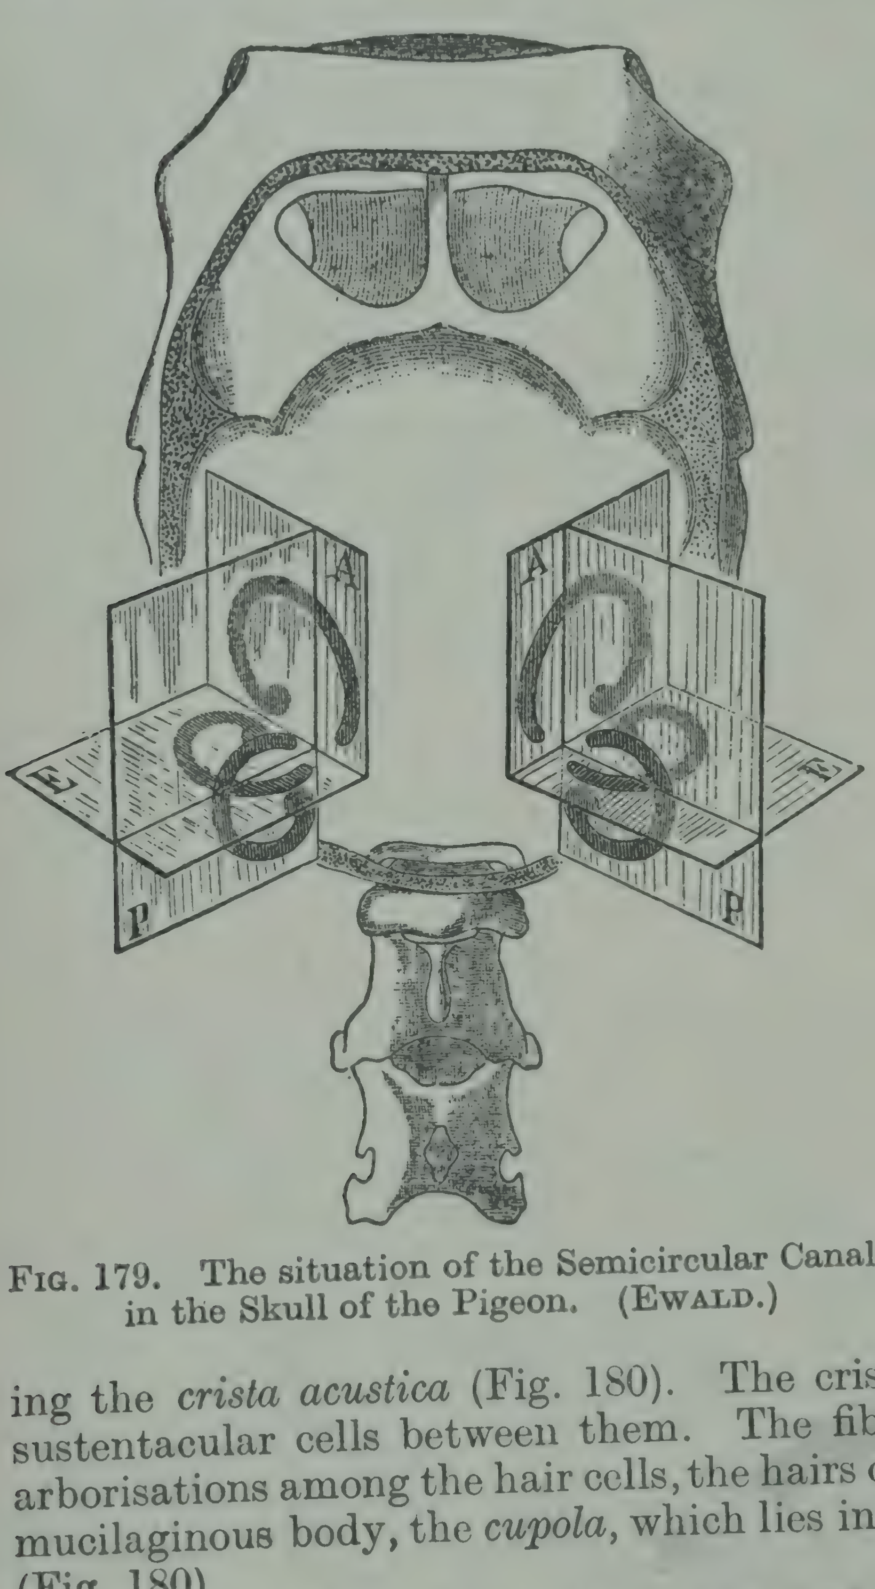

FIG. 179. The situation of the Semicircular Canals in the Skull of the Pigeon. (EWALD.)

In the utricle and saccule we also find in each an oval patch of modified epithelium. These are special receptor organs, known as the *maculæ acusticæ*, the structure of which is very similar to that of the crista in the ampullæ. In the mucilage covering the hairs of the macula, however, are found numerous small calcareous concretions, the *otoliths*. The macula of the utricle is in a horizontal plane, that of the saccule vertical.

NERVE PATHS CONCERNED. The vestibular part of the VIIIth cranial nerve has its cells of origin in Scarpa's ganglion. It enters the pons abov the cochlear division and passes between the inferior cerebellar peduncl and the descending spinal root of the Vth cranial nerve. Its fibres end b

c.r., restiform body ; v, descending root of fifth nerve ; *p*, cells of principal nucleus of vestibular root ; *d*, fibres of descending vestibular root ; *n.d.*, a cell of the descending vestibular nucleus ; D, cells of nucleus of Deiters ; B, cells of nucleus of Bechterew ; *n.t.*, cells of nucleus tecti (fastigii) of the cerebellum ; *p.l.b.*, fibres of posterior longitudinal bundle. No attempt has been made in this diagram to represent the actual positions of the several nuclei. Thus a large part of Deiters' nucleus lies dorsal to and in the immediate vicinity of the restiform body.

arborising round one of four different collections of nerve cells of which the lateral is called "Deiters' Nucleus." Fibres originating in these nerve cells form four pathways which convey impulses of importance in movements of the eyes, neck and trunk; in addition, large numbers of them go to the cerebellum (Fig. 181).

These paths are (i.) the *posterior longitudinal bundle*, to the oculomotor nuclei. These fibres, concerned with the co-ordinated movements of the eye muscles, run principally from the superior vestibular nucleus ("Bechterew's N.") and from Deiters' Nucleus; (ii.) the *vestibulo-spinal tract*, descends to spinal motoneurones; (iii.) the *vestibulo-cerebellar tract*.

Fibres conveying impulses to the cerebellum run principally from Deiters' Nucleus, but some go direct; all of them enter the inferior cerebellar peduncle, relay in the n. fastigii, and are distributed to the cortex chiefly of the flocculonodular lobe of the cerebellum. From here impulses pass to the red nucleus, some back to the vestibular nuclei, and to various other destinations.

(iv.) The vestibulo-reticular tract to the bulbar nuclei.

The Functions of the Labyrinth. The functions of the labyrinth may be divided into those of the vestibule, and those of the semicircular canals. They can be studied by the methods of extirpation, and stimulation. Both procedures result in disturbances of posture or of voluntary movements.

Unilateral labyrinthectomy in the rabbit leads to skew deviation of the eyes, nystagmus, rotation and lateral flexion of the head and spiral rotation of the neck and trunk towards the side of the lesion, diminution of tone of the limbs of the same side and increase in those of the opposite side, and frequently rolling movements, in which the animal turns over and over. In cats and dogs the deviation of eyes is lateral. The nystagmus is transitory, with the quick component to the normal side. The deviation of the eyes becomes maximal if the head is passively rotated to the normal side, but the nystagmus stops, and the rotation of the trunk ceases. The head and eye movements are direct effects of the extirpation of the labyrinth, while the neck and trunk reflexes are secondary and determined by the abnormal position of the head.

The rolling movements are only seen for a short time after the operation. Since the muscular tonus is diminished on the side of the lesion, the effect of any attempted progression movement is to cause the animal to turn over towards the injured side.

Bilateral Labyrinth Extirpation. The higher an animal is in the scale, the less important and the more readily dispensed with are its labyrinthine postural reflexes. Experiments on apes and cats show that, provided use of the eyes is retained, the animal behaves much as a normal one, except under two conditions.

The first of these is in falling free through the air. It is well known that a cat always falls on its feet, and this is accomplished by the employment of ordinary postural reflexes, especially labyrinthine ones. During the fall, first the head is righted, then the fore limbs and thorax, finally the hinder part of the body, aided by the tail. After bilateral labyrinthectomy this power of righting the body during a fall is lost.

The other case in which a response is lost is when the animal is placed in water. Under these circumstances the labyrinthectomised animal fails to orient itself, and would soon drown. The tonus of the muscles is not permanently lowered by removal of both labyrinths, but is kept up, as Sherrington has shown, by proprioceptive impulses from the muscles themselves, or from the muscles or other structures, such as joints, in other parts of the body, *e.g.* the neck.

The most usually accepted hypothesis is that the macular (otolith) organs are concerned chiefly with the *positions* of the head, and with *linear acceleration*, while the ampullæ of the semi-circular canals are concerned in notifying *movements*, particularly *rotations*. Whereas the former are largely static organs, the latter are entirely kinetic.

Two views have been held regarding the causes of stimulation of the maculæ: (*a*) That bending of the hairs causes stimulation; (*b*) that pulling on the hairs is the stimulus. As we shall see later, it is probable that the maximal stimulation is produced when the otolith organ hangs from and pulls upon, the hairs (A, Fig. 182), and the weakest stimulus when it pushes down vertically upon them (C, Fig. 182).

Denervation of the utricle was found by Tait and McNally to cause loss of muscular tone on the same side of the body.

The functions of the macula of the saccule are not clear. Denervation seems to have no evident results. It is possibly an organ that responds to vibration.

The responses of the labyrinth to various stimuli have been investigated by Ross,* who used the severed head of the frog, and led off the auditory nerve, and by Adrian,† using the cat, and leading off from the region of the vestibular nucleus. Responses were shown by action potentials in the nerve, and occurred when the preparation was subjected to tilting, angular acceleration, or deceleration or (in the frog), to vibration. The response to tilting or to linear acceleration was associated with the utricle macula, that to rotation with one of the canals and that to vibration, in frog, chiefly with the saccule macula. No other function has been attributed to the saccule.

Function of Semicircular Canals. It is now considered that each canal operates in one direction of rotation only. Thus, on rotating the head about a vertical axis so that the nose moves to the right, there is stimulation of one horizontal canal (the right). By rotation in the transverse plane, the right posterior canal ampulla is stimulated when the head moves to approximate right ear to right shoulder. Probably it is the bending of the hairs which is the essential factor. If the head is suddenly rotated about a vertical axis, the walls of the horizontal canals will rotate in the same direction. But the contained fluid, being rather viscous, and remaining stationary owing to inertia, will tend to apply forces to all structures with which it is in contact. The cupola and hairs in the ampullæ will then have a force applied to them tending to bend them, like reeds in a flowing stream. It has been objected that the canals have bores far too fine for any streaming of fluid to take place, but direct observation ‡ of the canals during rotation shows that movement does occur. The movement is slow,§ and if rotation is maintained, the cupola by its elasticity returns to its original position in the ampulla. On cessation of rotation the cupola is bent in the opposite direction.

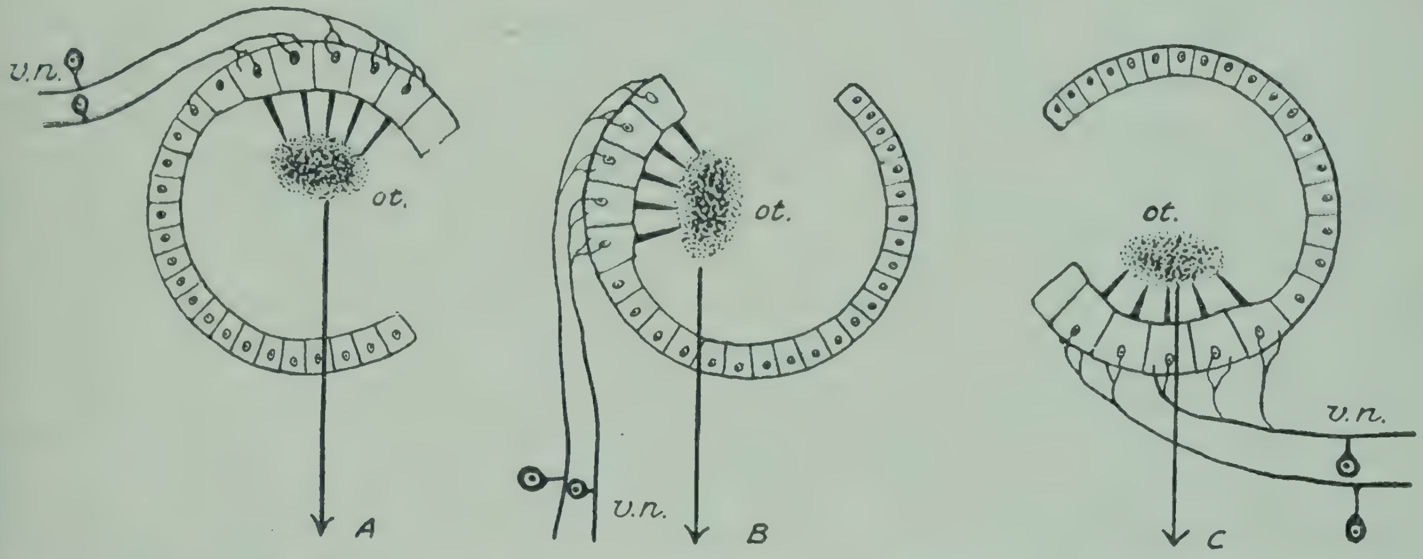

FIG. 182. Diagram to Illustrate the Influence of Position of the Head in Space on the Otolith Organ. In *A*, the otolith organ hangs vertically from the hairs, in *B* it pulls sideways, and in *C* it presses down on them, *v.n.*, fibres of the vestibular nerve. *ot.*, the otolith organ. The arrows indicate the pull of gravity.

Tait and McNally ‖ denervated one or more of the semicircular canals in the frog. When all the canals were denervated the animals assumed a normal posture, provided they were unmoved. Sudden tilting of the animal, however, failed to produce the normal compensatory movements of head and limbs. Their experiments show clearly that the horizontal canals only respond to rotations in the horizontal plane, while the vertical canals respond to rotation, each in its own plane. They infer that each horizontal canal is stimulated when moved in a direction away from its ampulla ("ampulla-trailing"), *e.g.* the right one only by turning the head to the right. The vertical ones, on the other hand, they believe to be stimulated when movement is such that the ampulla is foremost ("ampulla-leading"), *e.g.* the left anterior vertical by a movement of the head obliquely forwards and to the left (cf. Fig. 179). These results have been confirmed by Ross's direct recording of action potentials in the vestibular nerve, and by the work of Adrian.

Tonic movements of the musculature are produced when the cristæ of the canals are stimulated by suitable means, *e.g.* by rotations. The horizontal canals affect the musculature on the two sides of the body in opposite ways. When, for example, the whole animal is rotated to the right, the head itself turns to the left, the (extensor) tonus of the limbs on the right side is increased and the tonus on the left side is reduced. The vertical canals each affect a corresponding quarter of the body; thus stimulation of the left anterior vertical canal causes increased tonus of the left fore-limb, that of the left posterior canal increased tonus of the left hind limb, and so on.

Stimulation of the Semicircular Canals in Man. This can be carried out by rotation, or by galvanic or caloric stimulation. The results of rotating a subject on a turn-table or rotating chair at about one revolution per second, are similar to those obtained with animals. They comprise nystagmus, vertigo, and post-rotatory reactions. Nystagmus is a compensatory movement of the head and/or eyes, and consists of a slow reflex component, and a jerky (cerebral) return. They are due to the fact that the gaze tends to remain fixed on some stationary point. Hence, if rotation is to right, the eyes (and sometimes the head), in keeping the gaze fixed, move to the left slowly, and when the limit has been reached, jerk rapidly back again to the right to recommence the next slow movement. This is called a right horizontal nystagmus, the indication being conventionally given to the *quick* component. Vertical nystagmus can also be produced by appropriate movements. After the rotation, a nystagmus in the opposite direction occurs, due to inertia of the endolymph.

Vertigo, or giddiness is well known as a result of rotation. It is most marked after the rotation is over, and leads to compensatory movements in the opposite direction. Vertigo is a common clinical accompaniment of labyrinthine disorders. As a consequence of the tendency to fall over, various compensatory changes of muscular tone also occur after rotation, but are better seen after caloric stimulation.

Caloric stimulation (Barány's Test) is carried out by bending the head backwards at 60°, so as to bring the horizontal canals into a vertical plane, and then syringing the ear with cold water (20° C.). Vertigo and nausea result, and also definite after-effects, *e.g.* nystagmus to the opposite side, a curious twisting of the trunk, with extension of the arms, both of which are turned towards the side stimulated by cold ("discobolus position"); later the position is reversed. Another effect of the altered tonus is the "Past-pointing Test"—on attempting to touch a given point with eyes closed, the arm is deviated towards the stimulated side. The explanation of these caloric phenomena may be that convection currents are caused in the endolymph.

DECEREBRATE RIGIDITY

The state of decerebrate rigidity has already been mentioned as a release phenomenon, which is a caricature of the standing posture. The rigidity does not follow section of the medulla below the upper limit of Deiters' nucleus; thus, Section VI. of Fig. 183 does not produce it, but Section V. does; hemisection causes rigidity on the same side only. The rigidity is at once diminished or abolished if the vestibular nuclei (including Deiters') are destroyed,* or if the ventro-lateral columns of the cord are divided. If the vestibular nuclei on one side are destroyed, the rigidity on that side is abolished. These facts indicate the vestibular nuclei, and the vestibulo-spinal tract which descends from them, as essential for the condition, and suggest that these nuclei normally exercise on the extensor muscles a tonic influence, which is here exaggerated by release from the modifying influence of some centres still higher up.

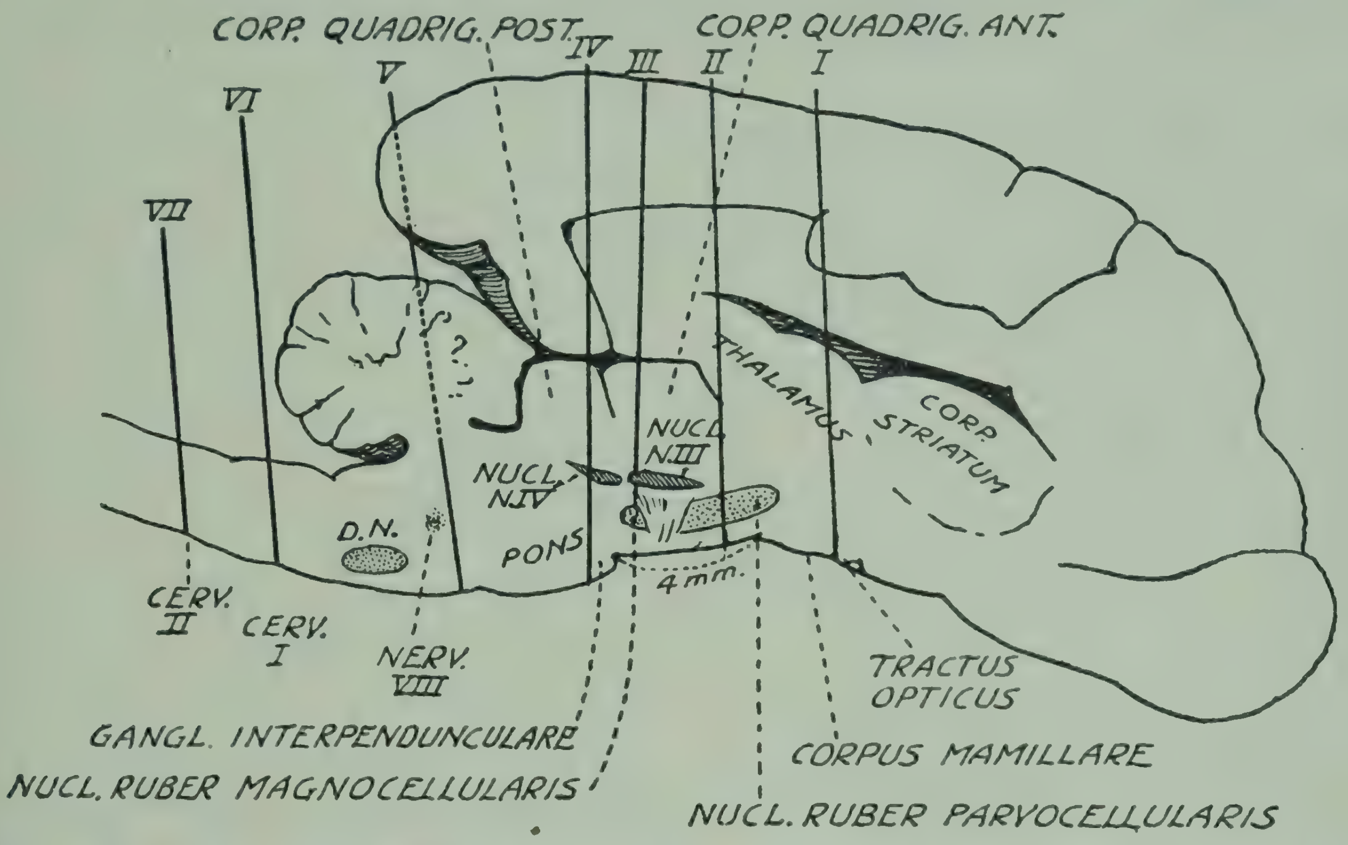

FIG. 183. Longitudinal Section of Cat's Brain, showing the various sections of the brain stem in their relation to decerebrate rigidity.

Section I. The Thalamus animal. Possesses heat regulation and normal postural reactions.

Section II. Mid-brain animal. Temperature regulation lost; posture normal.

Section III, below red nucleus. Decerebrate rigidity.

Section IV, decerebrate rigidity present.

Section V, just above vestibular nuclei; decerebrate rigidity.

Section VI, below vestibular nuclei (D.N.); no rigidity. Neck reflexes still present.

Section VII, spinal animal. No neck reflexes. (Re-drawn, after MAGNUS.)

The location of these higher centres is ascertained by making sections from before backwards. It will be seen from Fig. 183 that rigidity does not then appear until the section passes through the mid-brain, just below the red nucleus, or through its anterior part. It is inferred, therefore, that centres which in the normal condition keep the vestibular nuclei from overacting are at the level of the red nuclei, but it does not necessarily follow that the red nucleus is the only centre concerned. Doubtless it is one of them, but destruction of the red nucleus alone does not cause rigidity.† Nor is it certain that section of the rubro-spinal tract alone will cause rigidity.

* FULTON, LIDDELL and RIDDOCH. *Brain*, 1930, **53**, 327.

† INGRAM and RANSON. *Amer. J. Physiol.*, 1932, **102**, 466.

The rigidity is of reflex origin, the afferent impressions concerned arising from the muscles themselves, and from the labyrinth, and being in both cases relayed from the vestibular nuclei. The afferents concerned in the rigidity of the hind limbs come from the muscles only; hence, division of the afferent roots of the muscular nerves abolishes it, while removal of the skin does not. For the fore limbs, de-afferentation does not remove the rigidity, but destruction of the labyrinths as well will do so.*

These relations are shown diagrammatically in Fig. 184.

The muscles which become tonic in decerebrate rigidity are those which counteract the effects of gravity, in maintaining the normal posture of the animal. These are, in most animals, the extensor muscles. In the sloth, which hangs upside down, it is the flexor muscles which are the tonic ones.

Decerebrate Rigidity in Man. A condition closely resembling decerebrate rigidity is also seen in the human subject as a result of certain lesions of the brain stem, *e.g.* the result of suprapituitary tumours. The subject shows extension of the legs, with the feet pointed down in plantar flexion; the arms are semi-flexed at elbows, forearm pronated, and wrists and fingers flexed † (Fig. 185).

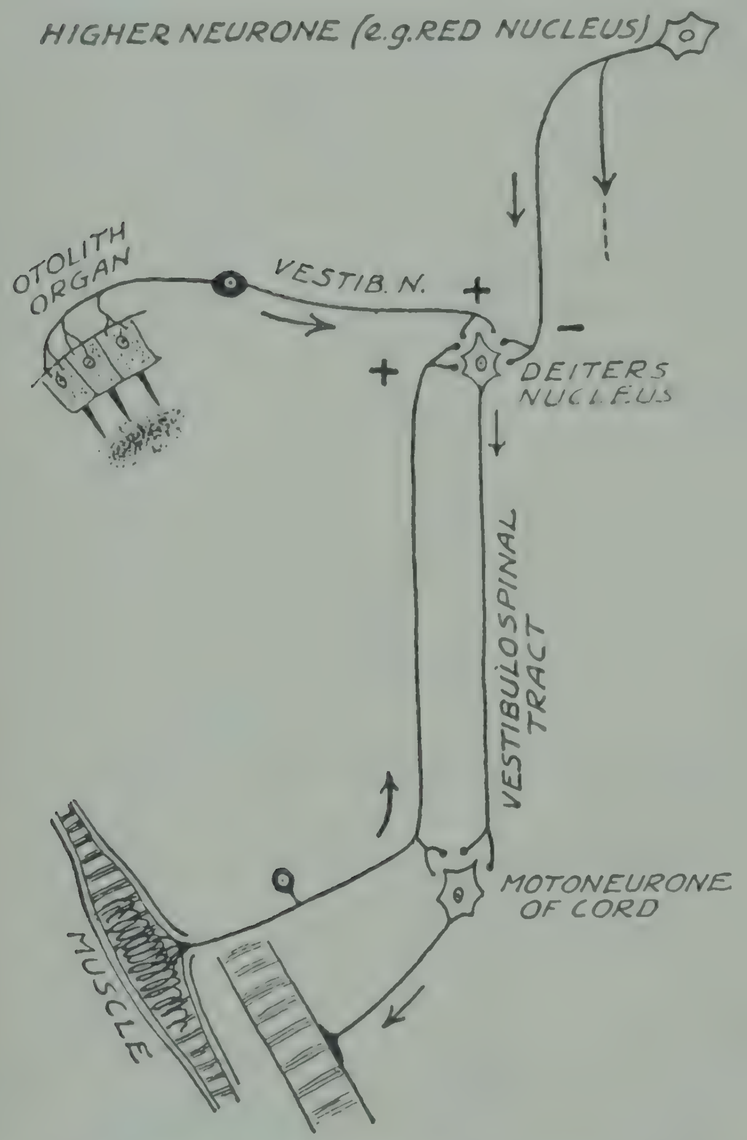

FIG. 184. Diagram to Illustrate the paths concerned in Postural Tonus and Decerebrate Rigidity (Interneurone in cord omitted.)

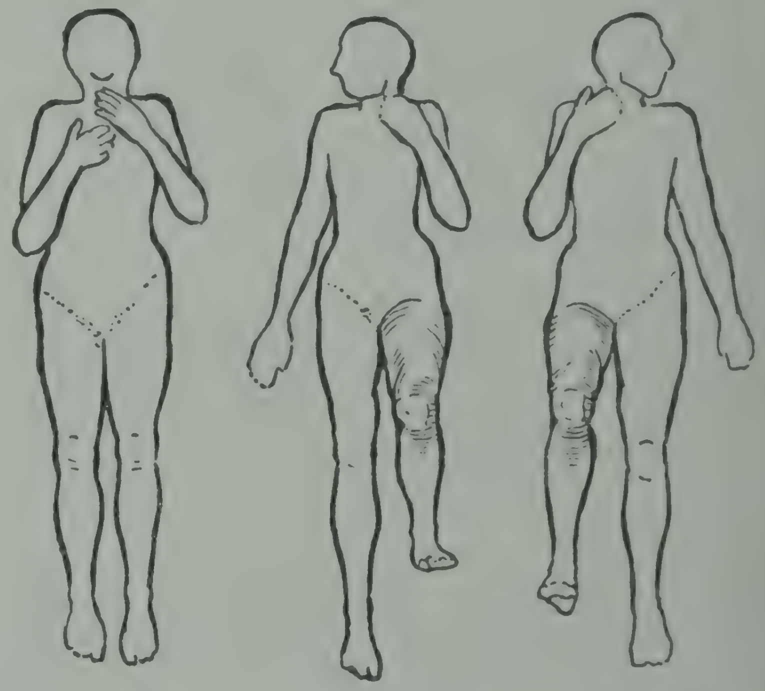

FIG. 185. Decerebrate Rigidity in Man. (SAMSON WRIGHT, after WALSHE, "Applied Physiology," Oxford University Press.)

Rotation of the head causes extension of the arm on the side to which the nose is turned, and flexion, with augmented Babinski response, of the opposite leg (Fig. 185). This is a postural reflex, which is explained later.

THE POSTURAL REFLEXES

The higher animals normally exhibit characteristic attitudes in repose or action, by which they are oriented with reference to gravity. To any circumstance which tends to displace the animal from its posture there is offered a resistance which prevents the displacement, or which tends to restore the animal to its correct attitude.

* POLLOCK and DAVIS. *Amer. J. Physiol.*, 1931, **98**, 47.

† WALSHE. *Lancet*, 1932, **101** (ii), 644.

Static postures are often maintained for long periods of time without fatigue. The state is one of tonic contraction of the muscles concerned, and the assumption of any posture is the result of a delicate condition of balance in the muscular system. In the maintenance or recovery of posture many separate types of reflex converge to produce a common result; these reflexes arise from the labyrinth, the eyes, and the muscles themselves.

The removal of the cerebral hemispheres has but little effect on normal posture, or on the righting reactions by which that posture is resumed after having been interfered with. It is clear, therefore, that these reactions are true reflexes. In a fully conscious animal, of course, voluntary movements may be added to the reflex reaction.

Some muscular tonus persists in the spinal animal (Fig. 186B), but this is slight and bears no resemblance to normal posture. The bulbo-spinal animal, by contrast, shows the condition of *decerebrate rigidity* (Fig. 186A), which is due to an exaggerated state of tonus of those muscles (extensors) which are employed in the posture of standing. Such a decerebrated animal can, in fact, maintain a standing posture, but when upset it makes no movements which would tend to place it in its former standing pose. It was shown by Sherrington that the tonus distribution in the decerebrate preparation is not entirely proprioceptive, but depends, for instance, on the position of the head.

When the whole of the mid-brain is left as well, the attitude of standing is normal (Fig. 186C), and, moreover, the animal will now of its own accord return to the standing posture when displaced from it. Most of the postural reflexes of the "thalamus" animal (*i.e.* with intact thalamus and mid-brain) are practically identical with those of the normal animal. (The advantage of leaving the thalamus is that temperature regulation is retained.) This fact, and the knowledge which we derive from our own experience, teach us that the afferent impulses upon which posture is based and adjusted but rarely obtrude into the field of consciousness, and can, therefore, only be studied by objective methods. Such studies have been made by Magnus, and to translate his own words freely, have shown "that many different sense organs are involved, that very different centres integrate their stimuli, that the muscles are concerned in many different combinations in the production of the reactions, and that a whole series of diverse reflex groups are balanced together."

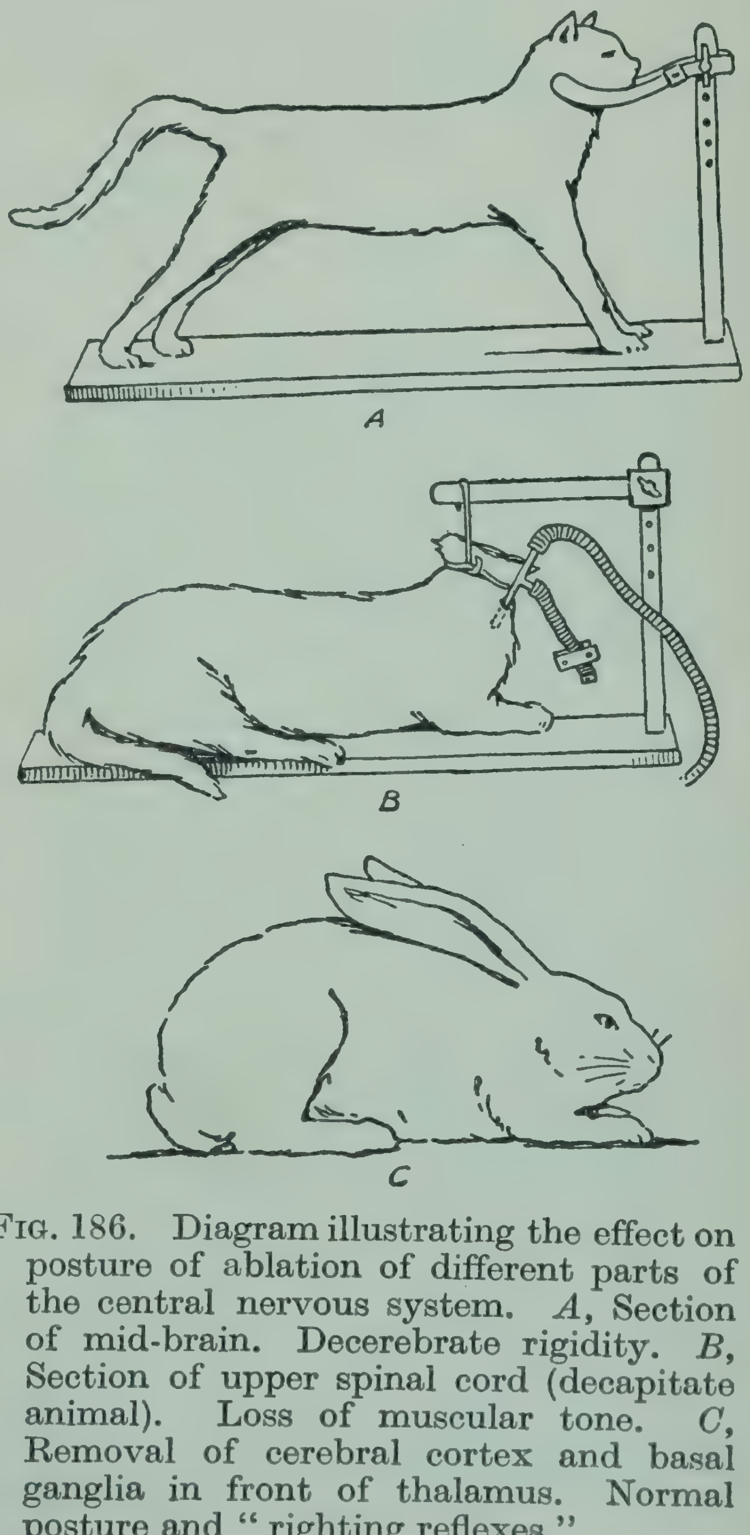

FIG. 186. Diagram illustrating the effect on posture of ablation of different parts of the central nervous system. *A*, Section of mid-brain. Decerebrate rigidity. *B*, Section of upper spinal cord (decapitate animal). Loss of muscular tone. *C*, Removal of cerebral cortex and basal ganglia in front of thalamus. Normal posture and "righting reflexes."

The postural reactions of the body when at rest are called *static reflexes*, and fall into two groups: the *stance reflexes* or reflexes of *pose*, in which the body, or a part, remains in a definite attitude, and *righting reflexes*, by means of which the pose is restored after disturbance. The former, so to speak, "keep you right way up when you are" while the latter "put you right way up when you are not."

The postural reactions of the body when in movement are called *stato-kinetic reflexes*, and are produced in a definitely predictable manner by the movement itself, which in turn is largely guided by them under normal conditions of life.

These important postural reflexes fall into the following heads and it will be noted that there is a good deal of inter-dependence :—

I. STATIC REFLEXES

(i) *Local Static Reactions*, *e.g.* confined to one limb.
(ii) *Segmental Static Reactions*, involving one segment, *e.g.* both hind limbs, both fore limbs, or the neck.
(iii) *General Static Reactions*, involving more than one segment. These may be again divided into :—

A. *Reflex Stance.*
  (1) Influence of the Head on Stance.
    (*a*) Effect of Tonic Neck Reflexes on Limbs.
    (*b*) Effect of Tonic Labyrinth Reflexes.
      (α) On the Limbs.
      (β) On Neck and Trunk.
    (*c*) Collaboration of Neck and Labyrinth Reflexes.
    (*d*) Indirect Influence of Labyrinth on Limbs through Action on Neck Reflexes.
  (2) Indirect Influences on Posture.

B. *Compensatory Pose of Eyes.*
  (1) Effect of Tonic Labyrinth Reflexes on Eyes.
  (2) Effect of Tonic Neck Reflexes on Eyes.
  (3) Collaboration of Tonic Labyrinth and Neck Reflexes on Eyes.
  (4) Collaboration of Compensatory Eye Poses.

C. *Righting Reflexes.*
  (1) Effect of Labyrinth Reflexes on the Head.
  (2) Effect of Body Posture on the Head.
  (3) Neck Postural Reflexes.
  (4) Effect of Body Postural Reflexes on the Body itself.
  (5) Visual Postural Reflexes.

II. STATO-KINETIC REFLEXES

A. *Reactions to Rotation.*
  (1) Head Reactions.
  (2) Eye Reactions.

B. *Reactions to Progressive Movement.*
  (1) Reactions of Head.
  (2) Reactions of Extremities.

We must now consider these types.

I. Static Reflexes

(i) LOCAL STATIC REACTIONS

It is a remarkable fact that a limb which at one time is freely movable, at another time is converted into a rigid pillar capable of supporting the weight of the body. The formation of the rigid support by simultaneous contraction of flexors and extensors is due to a local reflex, called by Magnus the *positive supporting reaction*, while its resolution, enabling the limb to be used for other purposes, is also a local reflex, called the *negative supporting reaction*. These reflexes receive their explanation from the researches of Sherrington and Liddell, and of Magnus and his collaborators, Rademaker, Schoen and Blake Pritchard.

The afferent stimuli for the positive supporting reflex are in part proprioceptive stimuli evoked by movements of the distal parts of the limbs, by which some of the flexor muscles are stretched, and in part are due to exteroceptive stimuli from the skin, *e.g.* contact of pad of foot with the ground. A direct consequence of the stretching is that these flexor muscles themselves are reflexly contracted (stretch reflex); a second result is that there is reflex contraction of flexors and extensors, whether stretched or not, the antagonistic muscles thus acting synergically in fixation, at the proper angle, of the joints concerned. In this complex local reaction very different reflexes co-operate, reinforce, and if necessary replace each other, so that standing under very different positions of the joints is possible.

In the negative supporting reaction, the active stimulus is proprioceptive, due to volar or plantar flexion which unlocks the series of positive reflexes and loosens the limb for action.

(ii) Segmental Static Reactions

A good example of these is the crossed extension reflex already studied.

(iii) General Static Reactions

A. Reflex Stance. (1) *Influence of the Position of the Head.* Experiments on the effect of the position of the head on the tonic pose of the body are carried out on decerebrate animals. The distribution of tonus is modified as a result of stimuli from the neck when the head is moved with reference to the trunk, and also, by the operation of labyrinthine reactions, when the head (with the body) has its position altered in space. These two effects can be separated experimentally.

(*a*) *Tonic Neck Reflexes.* These are obtained in a pure form on animals deprived of both labyrinths, and are also seen in certain clinical cases. When the head is moved by bending or twisting the neck, the extensor tonus of the decerebrate preparation shows modifications which persist so long as the altered relation of head to trunk is kept up. These alterations are due to altered tensions on the neck muscles when the head is moved. The muscles of the right and left sides or of the fore and hind limbs behave in opposite ways.

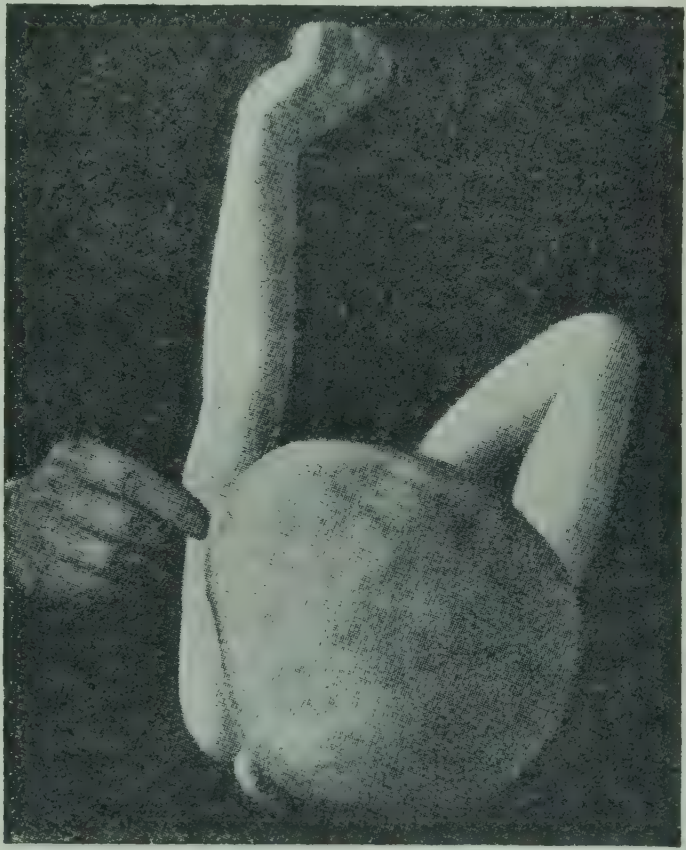

Fig. 187. Hydrocephalic infant. Turning of head to left gives increased tonus of left arm, due to tonic neck reflex. (Magnus, "Körperstellung.")

When the head is rotated on the atlanto-epistropheal joint, the extensor tonus of the fore and hind limbs is increased on the side towards which the nose is turned, and diminished on the other side (Fig. 187).

When the head is inclined sideways by bending the neck, so that, say, the left ear approaches the left shoulder, the extensor tonus of the limbs is increased on that side, while on the right side there is a diminution. This reaction to bending of the neck obviously serves the purpose of keeping the centre of gravity of the body over the feet.

Bending the neck backwards causes increased tonus of the fore limbs, with reduction of tone of the hind limbs. This results in a posture such as is seen in a normal cat craning the neck upwards to look on a table. When the head is bent downwards, the tonus distribution is in the opposite direction, as in a normal cat eating food.

The centre which is responsible for these neck reactions is located in the upper cervical spinal cord and lower medulla.

(*b*) *Tonic Labyrinth Reflexes.* These reflexes are best studied on decerebrate cats with intact labyrinths, and fixed to a holder in such a manner that the head cannot be moved on the trunk.

The most conspicuous effect is that on the limbs, all of which react similarly. Maximal extensor limb tonus is seen when the animal is placed on its back, so that the mouth cleft is inclined upwards at 45 degrees to the horizontal; when the animal is placed on its belly so that the mouth cleft is downwards at 45 degrees, the extensor tonus falls to a minimum. At intermediate positions the tonus is of intermediate intensity.

The receptors concerned in these reflexes are the maculæ, chiefly those of the utricles. The utricle macula lies in a horizontal position when the head is normally oriented, and the otolith then lies above the hair cells which spring from the macula. The macula of the saccule is situated on the medial wall, and is, therefore, vertical when the head is normally placed, the hairs of its hair cells lying horizontally in the otolith. The exact orientation of these maculæ in the rabbit is illustrated in Fig. 188, which shows a rabbit's skull in the normal position in space, with enlarged models of the maculæ, represented by oval plates, in their proper spatial arrangement, attached to it. The surface of the macula to which the otolith is attached is indicated in the utricle by white dots, and in the saccule by white stripes.

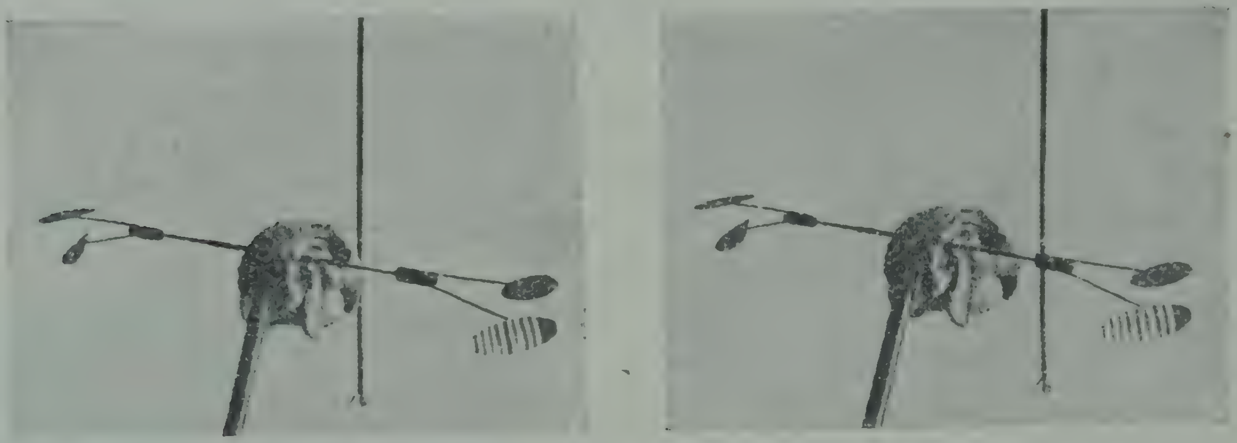

FIG. 188. Rabbit's Skull with Oriented Magnified Models of the Utricle and Saccule Maculæ. Skull in normal position. Stereoscopic. (MAGNUS, "Körperstellung.")

When the animal is placed in the position which gives the maximal labyrinth tonus it is found that the utricle otolith is hanging vertically beneath its macula; when the head is placed in the position which gives the minimum of limb tonus, then it is found that the otolith is vertically over its macula. Hence it is concluded that the otolith produces the greatest stimulus when it hangs from, and so pulls upon, its hair cells, and the least when it presses them downwards on to the macula. The stimuli are continual, and give rise to steady reflex tonus so long as the position is kept up. Similarly, the saccule macula is most stimulated when the otolith hangs from it, as on the left side when the left side of the head is below. Hence there arise, from the asymmetric nature of the stimuli from the two saccules, asymmetric states of tonus, which constitute the righting reflexes of labyrinthine origin.

Deprivation of both labyrinths leads to complete disappearance of the reactions to altered orientation of the head in space.

The tonic neck and labyrinth reflexes show an algebraic summation in the normal animal, in which they both have full play. It is also found that the labyrinth exerts an indirect action by giving rise first to tonus changes in the neck, which produce neck movements, and hence, by the operation of the neck reflexes, exert an effect on the limbs. The two effects of the labyrinth on the body are algebraically summated.

In these postural reflexes the red muscles play a larger part than the pale muscles (Fig. 189).

(2) *Indirect Influences on Posture.* Posture in the normal animal is largely influenced by impressions received from the outer world through the senses of sight and hearing. These lead to voluntary movements of the head and, by the operation of the reflexes so far described, to an automatic modification of the pose. To take the cat as an example, we have already referred to certain characteristic postures related to neck reflexes, and a little consideration will show that the pose will be further reinforced by the action of the labyrinth reflexes.

Suppose that a cat hears a mouse moving on its right. The head is turned to the right; this alters the centre of gravity, but, as a result of the tonic neck reflex, there is an increase of tonus on the muscles on the right side of the body, which preserves the balance by throwing the weight on the right limbs. Now, because the left limbs are less loaded, they will be the first to move if the animal springs to its prey, so that the cat will automatically move in the right direction.

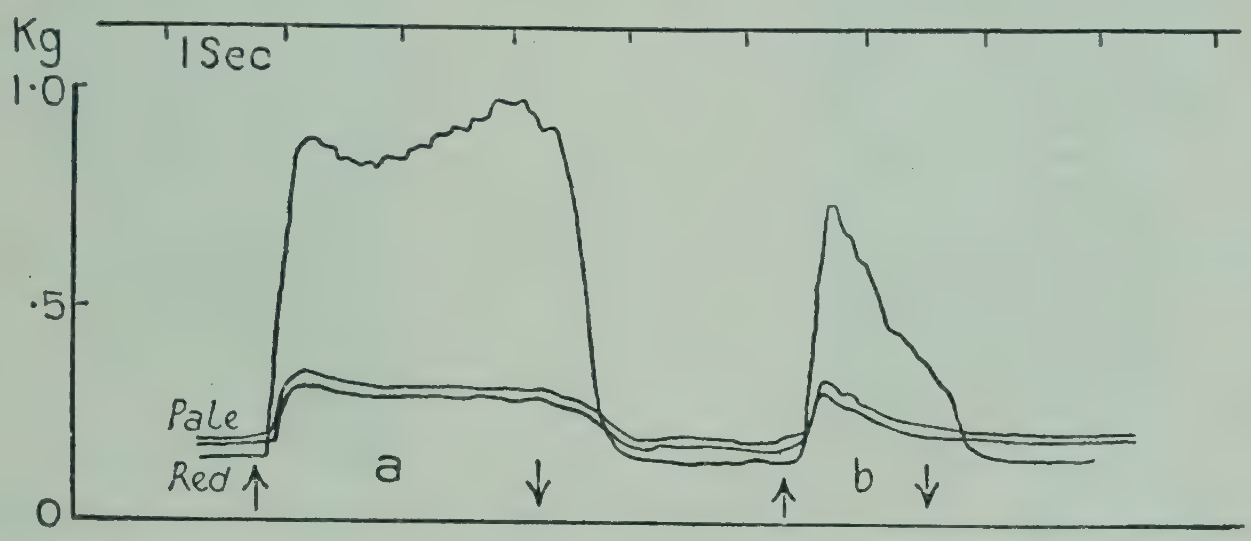

FIG. 189. Response of Pale (Short Lat. Head Triceps) and Red (Short Med. Head Triceps) Muscle to Labyrinthine and Neck Reflexes. Mid-brain preparation. ↑ dorsiflexion and ↓ ventriflexion of neck. Tracing from pale muscle shown by double line and from red muscle by single line. (CREED, *et al.* "Reflex Activity of the Spinal Cord." Oxford Univ. Press, 1932.)

B. Compensatory Pose of the Eyes. The compensatory pose exhibited by the eyes under certain conditions is really a special case of stance reflexes. In man and other animals with frontal vision it is of much less importance than in such animals as the rabbit, which have lateral vision. Like other muscles, the tonus of the eye muscles may be modified as a result of reflexes arising either from the labyrinth or from the neck. The outcome is that the eyes take up a position such that their visual fields suffer as little change as possible.

(1) *Tonic Labyrinth Reflexes on the Eyes.* In these reflexes no effect is produced by way of the labyrinth unless movements alter the relation of the head to the horizontal plane. The responses are to rotation of the head (and body) about the occipito-nasal axis (" vertical " response) and rotation around the bi-temporal axis (" rotatory " response). In the performance of these movements there is always a delicately adjusted reciprocal action of antagonistic muscles in such a manner that the eyes continue, as it were, to look at the same object in spite of the movements of the animal. Thus if the animal in the prone position is tilted so that the head moves downwards, the eyes will move upwards, and *vice versâ*.

The centres for all labyrinth reflexes on the eyes lie between the vestibular nerve entry and the nuclei for the eye muscles.

(2) *Tonic Neck Reflexes on the Eyes.* In these reactions, which are obtained after destruction of the labyrinth, when the head is moved with relation to the body, *all* the eye muscles are brought into play, and compensatory eye poses are obtained in response to alteration of the head with reference to any plane, including the horizontal. The effects are similar to those obtained with the labyrinth reflexes.

Under normal conditions the labyrinth and the neck reflexes are both present and are summated algebraically, so that, while neither reflex alone is enough to compensate fully for head movements, the addition of the two does so. The exception to this is when the movement of the head is in the horizontal plane, in which case, as already stated, there is no labyrinthine reflex set in operation.

C. Righting Reflexes. The reactions by which an animal keeps itself right side up and recovers its normal posture after it has been disturbed, are well illustrated in the familiar example of the falling cat, which always lands on its feet. The analysis of these reflexes is carried out best in thalamus animals, so that voluntary movements are eliminated. An animal takes up by means of these reactions a normal stance, which is the basis for other voluntary or reflex movements. Righting reflexes are present at birth, and are carried out by co-operation of five different groups of reflexes. When, by suitable procedure all of these are eliminated, we have the "*zero condition*," in which no righting reflexes are shown. In rabbits this is achieved by destruction of both labyrinths, and holding the animals free in the air; cats, dogs and monkeys, which use the eyes for righting reactions must also be blindfolded if the cerebrum is intact. Knowing the zero conditions we can compare the effect of introducing the responsible reflexes one by one.

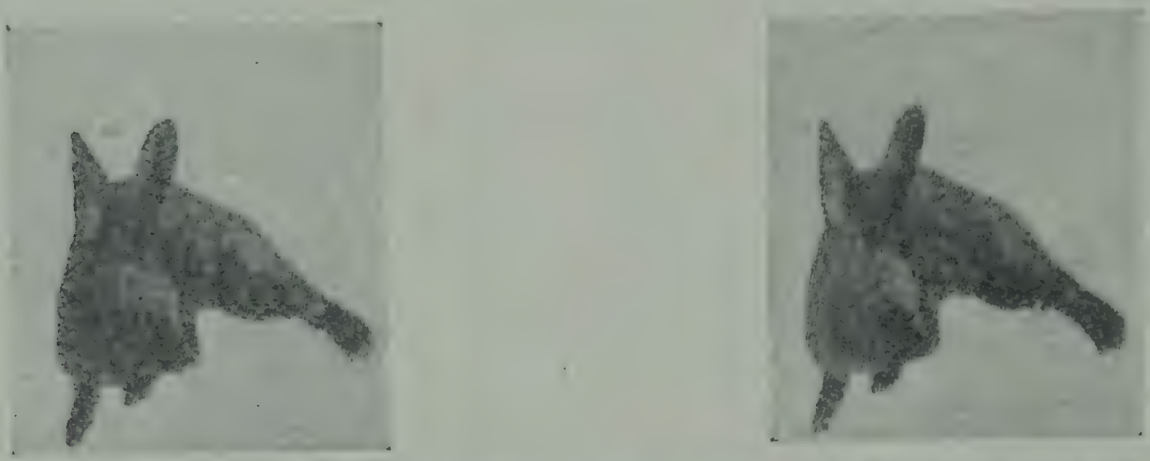

FIG. 190. Response of Thalamus Rabbit to Rotation of Pelvis when held Free in Air. The anterior part of the body retains the normal position owing to co-operation of labyrinth, and neck-righting reflexes. View with stereoscope. (MAGNUS, "Körperstellung.")

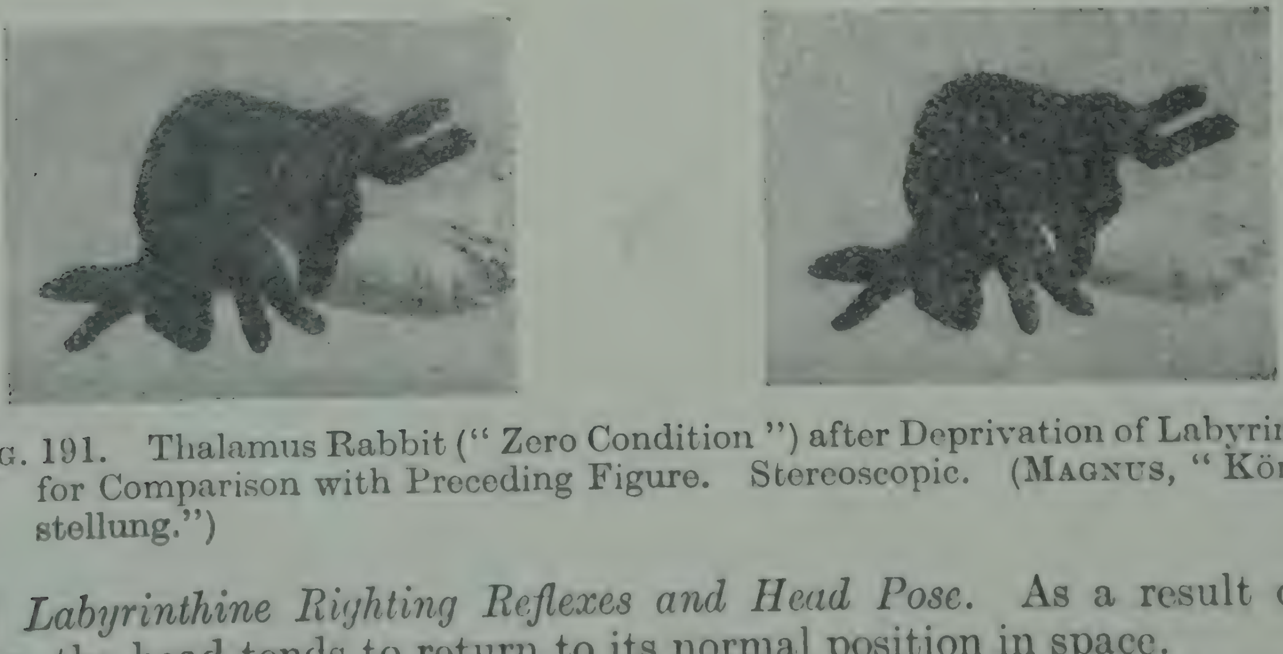

FIG. 191. Thalamus Rabbit ("Zero Condition") after Deprivation of Labyrinths, for Comparison with Preceding Figure. Stereoscopic. (MAGNUS, "Körperstellung.")

(1) *Labyrinthine Righting Reflexes and Head Pose.* As a result of these reflexes, the head tends to return to its normal position in space.

When a thalamus rabbit is held up in the air by gripping the pelvis (to avoid contact stimuli which would be introduced if the animal were allowed to lie on the ground), it is seen that the head tends to remain in the normal position when the pelvis is moved to the most various positions. This is accomplished by appropriate twisting or bending of the vertebral column (Fig. 190). After extirpation of both labyrinths the reflexes are abolished (Fig. 191).

(2) *Body Posture on the Head.* If a rabbit deprived of both labyrinths be laid on the ground, the head again tends to assume the normal pose. This is due to the operation of asymmetric stimuli arising from contact of only the lower side with the ground. Thus, if the animal is laid on its right side, contact stimuli will arise from that side, and not from the left, and these lead to orienting reactions of the head (Fig. 192). If the stimuli are made symmetrical, as by placing the animal in the lateral position and laying a board on its upper side, the head orientation vanishes (Fig. 193).

Owing to these two reflexes from labyrinth and from contact stimuli, there results a twisting of the neck when the animal is displaced, and this, in its turn, leads to the production of

FIG. 192. Thalamus Rabbit without Labyrinths laid on Right Side. The head, and then the anterior half of the body, assumes the normal pose owing to asymmetric contact stimuli. Stereoscopic. (MAGNUS, "Körperstellung.")

(3) *Neck Reflexes.* These operate in much the same way as the tonic neck reflexes, and the result of the combination of all these reflexes is that first the front and then the hind limbs follow the posture taken by the head, so that ultimately the whole animal comes to resume its normal pose. For instance, suppose an animal is laid on its left side. In consequence of labyrinthine and contact reactions, the head is turned towards the left shoulder (*i.e.* remains horizontal); this leads to neck reflexes and increase of tonus of the left fore limb, which rights the fore part of the body, then to increase of tonus in the left hind limb, by which the hind part of the body is also righted.

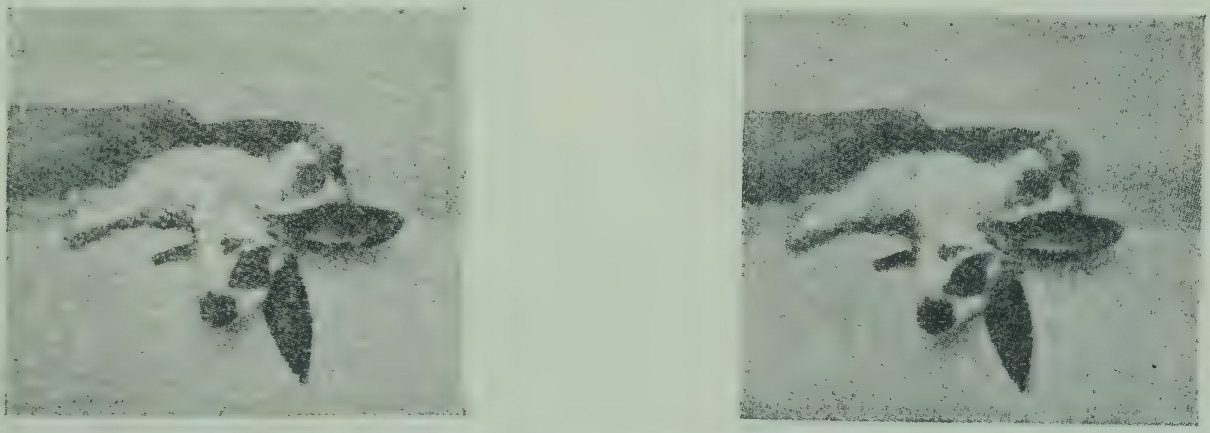

FIG. 193. The same Rabbit as last Figure laid on Side, but with Weighted Board placed on Upper Side; no Righting Reaction. Stereoscopic. (MAGNUS, "Körperstellung.")

(4) *Reflexes from the Trunk upon the Body itself.* The effect of asymmetric contact stimuli such as arise when an animal is laid in the lateral position affects not only the head, but also the body itself, so that if the head is fixed in the lateral position the body may be righted even though this entails opposition to the neck and labyrinth reflexes. In the normal animal there is thus a double reflex mechanism, which is summated to produce the total effect.

In decorticated primates lying on the side, the limbs on the under side are extended, and those on the uppermost side are flexed, and the digits in a grasping position—the "grasp-reflex."

(5) *Visual Righting Reflexes.* These reactions can be studied in cats and dogs with intact cerebral cortex after bilateral labyrinthectomy. The animals can orient their heads quite well if allowed to use the eyes, but when these are covered they revert to the disoriented position of the head, just as the labyrinthectomized rabbit does (Figs. 194 and 195).

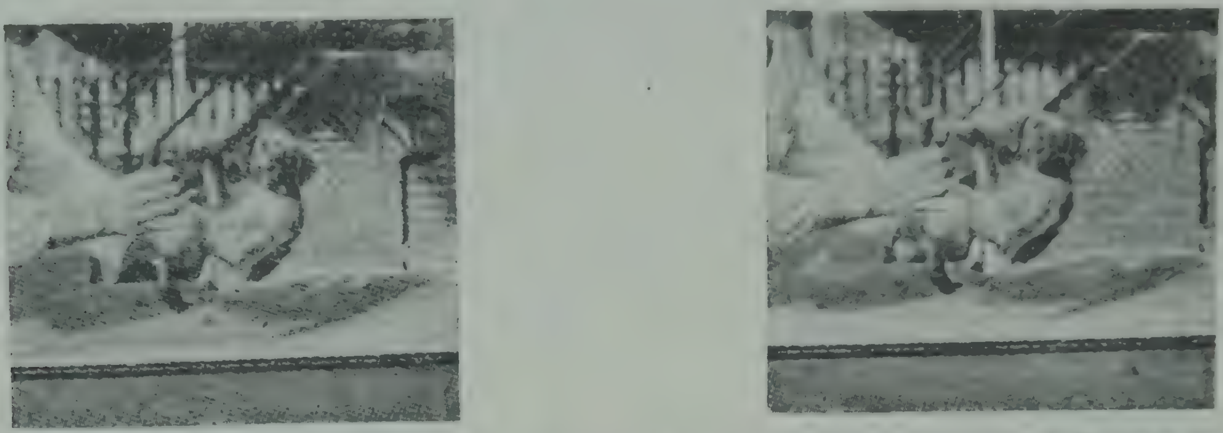

Fig. 194. Dog Sixteen Days after Double Labyrinthectomy, the Pelvis held in the Air in Horizontal Dorsal Position; Righting of Head and Thorax. Stereoscopic. (MAGNUS, "Körperstellung.")

Centres for Righting Reflexes. Visual righting reflexes are cortical. It has been shown by Rademaker, using the method of progressive section at various levels, that the other centres responsible for the righting reflexes are situated in the mid-brain and pons. The neck-righting reflexes are located in the pons, the remainder are in the ventral portion of the mid-brain at about the level of the third nerve nucleus, and probably in the large-celled portion of the red nucleus from which the rubrospinal tract arises. Destruction of the pyramidal tract, substantia nigra, or cerebellum leaves the righting reactions unchanged. Mesial sagittal section of the mid-brain causes disappearance of righting reflexes if Forel's decussation has been divided, not otherwise.

The spinal centres appear to be under the influence of higher centres of two types: medullary centres, which tend to cause over-action of the extensor muscles, and the red nucleus, which, acting *viâ* the rubrospinal tract, tends to counteract this by throwing the flexors into action. By the combined action of the two we get in the thalamus animal a normal distribution of tonus; the pyramidal tracts in the intact animal also exert a flexor effect on the spinal centres.

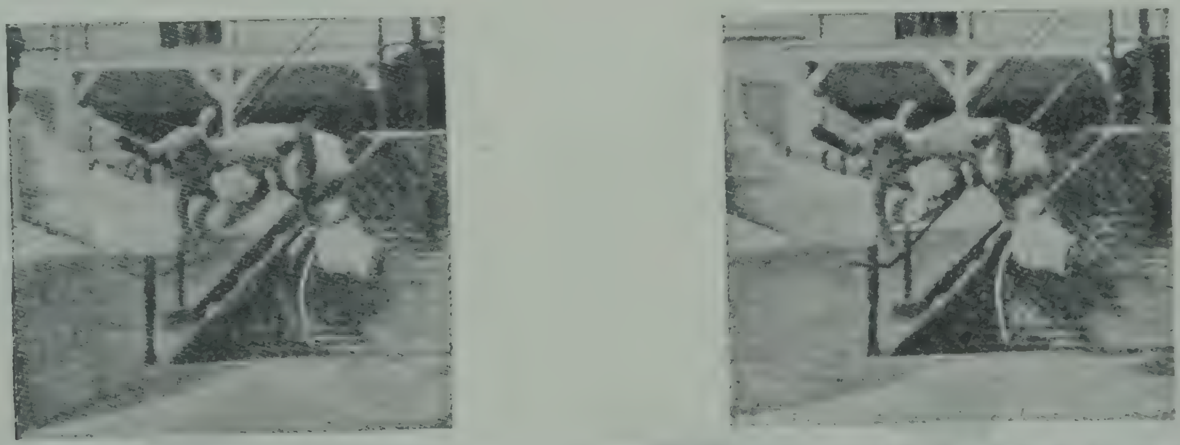

FIG. 195. The Same Dog held in the same Manner, but with the Eyes Covered; no Righting Reaction. Stereoscopic. (MAGNUS, "Körperstellung.")

II. Stato-Kinetic Reflexes

Unlike the righting reflexes, these are produced by the actual movement and not by any abnormal orientation. In so far as they arise from the labyrinth, they may be said to be due, not to movement in itself, but to an acceleration, positive or negative. This may be either angular acceleration, *i.e.* movements of rotation, or progressive acceleration when the movement is i a straight line.

A. Reactions to Rotation. (1) *Reactions of the Head.* When an animal or a man is rotated, say, to his right, the eyes tend to remain fixed on a given point, and hence the head is steadily moved to the left as far as possible, and then sharply to the right, this movement being repeated. This is called *head nystagmus*, with the rapid component in the same direction as that of the rotation. After the rotation has been stopped the nystagmus is in the opposite direction, *i.e.* in the case supposed, with the rapid component to the left.

All these phenomena may be explained as due to the effects of the rotation on the semicircular canals.

(2) *Eye Reactions.* The reactions of the eyes to rotation are similar to those of the head ; that is to say, eye nystagmus, in the same direction as the rotation, is produced. The effect on the eyes is naturally best seen when the head is fixed with relation to the body. On cessation of rotation the nystagmus is reversed.

When the head instead of the whole body is moved, the response of the eyes to the movement of rotation so produced leads to their moving in a direction towards that in which they finally become fixed by the static reflexes already considered.

B. Reactions to Progression Movements. (1). *On the Head.* These are best seen in the dog when stood on a board. When moved suddenly upwards, the head is moved ventrally and the fore-paws flexed ; when the movement ceases, the head moves dorsally, and the fore-paws are extended. On movement downwards the opposite effects are produced.

(2) *On the Extremities.* When the animal is held head downwards, the reaction to sudden downward movement is that the fore-limbs are moved in an oral direction, as in preparing the animal to take up its weight on falling to the ground.

This is called a " placing reaction." It is dependent on integrity of the cerebral cortex, and depends on impressions from eyes, labyrinth and proprioceptors.*

C. Reaction to Movements of Parts of Body. When a part of the body is moved, reflex adjustment of pose is often necessitated to maintain the balance, and the responses described above are variously brought into play. Thus, if a dog has an ulcerated foot, that leg is held in a position of flexion, and the posture and the movements of locomotion are arranged in accordance with the modified support which the body now has. This is all reflex, and depends on the constant arrival, at the centres concerned, of stimuli from the affected foot.

In general we can say that by means of the stato-kinetic reflexes the body is brought into its normal stance, which pose is maintained by the operation of the various static reflexes. It will have been noticed that the head plays an important part in deciding most of these responses. The head contains the organs of special sense, particularly the distance receptors for sight and sound, so that the head tends to be voluntarily directed towards stimuli which affect these sense organs. The proper orientation of the remainder of the body which ensues is effected by the action of the various reflexes which have been described.

CHAPTER XIX

HIGHER AFFERENT PATHS

Many of the afferent fibres of the spinal cord, in addition to furnishing collaterals which subserve the purposes of spinal reflexes, ultimately ascend to higher levels. Some, after various relays, ultimately reach the cerebrum, and convey impressions to consciousness ; others establish connections with higher reflex centres ; some do both. These various paths must now be briefly considered, together with those of the more specialised senses. Usually three neurones, primary, secondary and tertiary (or first, second and third order), are met with in the course of an afferent path from periphery to the highest centre, but auditory and visual paths have more.

I. CONSCIOUS SENSATIONS

So far as the brain stem is concerned, the main afferent tracts *en route* for the cerebral cortex are grouped together as the fillet tracts or lemnisci. These are the ***mesial lemniscus***, ***spinal lemniscus*** and ***trigeminal lemniscus***, all consisting of secondary neurones concerned with general body sensations, which end at the thalamus (on the side of the body opposite to that on which the primary neurones originate) ; and the *lateral lemniscus*, the afferent path for hearing, which consists of neurones terminating in the medial geniculate body. Third (or higher) order neurones complete the path from thalamus (or other intermediate station) to the cortex.

(1) **Tactile and Kinæsthetic Sensations.** (*a*) The Mesial Lemniscus represents the continuation of the *dorsal columns* of the cord, and therefore conveys conscious kinæsthetic and fine tactile impulses. These primary fibres, of rather large average size, pass up in the columns of Goll and Burdach, and, preserving their dermatomal lamination, end at the *nuclei Gracilis and Cuneatus* in the lower medulla, the ones from lower limbs at Gracilis, those from upper parts at Cuneatus (Fig. 196). The cells of these two nuclei give off secondary axons which cross the midline and pass upwards in the mesial lemniscus through pons and mid-brain and posterior limb of the internal capsule, still in a dermatomal order, to reach the postero-ventral nucleus of the thalamus. From this, tertiary fibres pass mainly to the sensory cerebral cortex (but some to the mesial and central nuclei of the thalamus).

(*b*) The spinal lemniscus is formed from the *two spinothalamic tracts.* The primary neurones of this path end in the grey matter of the cord, and its secondary axons, mainly small fibres, have already crossed in the cord. The fibres of the *lateral spinothalamic* tract, conveying pain and thermal sense, remain in a superficial position on the lateral aspect of the medulla, while those of the *ventral spinothalamic* tract, mediating light tactile sensations, lie more deeply. Ultimately both join the mesial fillet and terminate in the lateral nucleus of the thalamus, from which third order fibres proceed to the cerebral cortex (or mesial and ventral thalamic nuclei).

(*c*) The trigeminal lemniscus is derived from the sensory root of the Vth cranial nerve, the cell station being in the Gasserian ganglion. These primary neurones branch, forming ascending and descending " roots." These end in the sensory trigeminal nuclei, in pons, medulla and cervical cord, and from the cells of these arise the second order fibres which cross the midline at various levels and proceed with the two other lemnisci to the thalamus.

nerves also join the common fillet in a similar manner. Of the vagus fibres, for instance, about 70 per cent. are afferent, mostly unmyelinated, and with cell stations chiefly in the ganglion nodosum *; they have many important reflex functions.

---

* FOLEY and DU BOIS. *J. Comp. Neurol.*, 1937, **67**, 49.

(2) **Auditory Sensations.*** THE LATERAL LEMNISCUS is the path for auditory impulses. These arise in the cochlea and pass in by primary axons, with cells in the spiral ganglion, to form the cochlear division of the VIIIth cranial nerve. This divides round the restiform body, one branch ending in the dorsal, the other in the ventral cochlear nucleus.

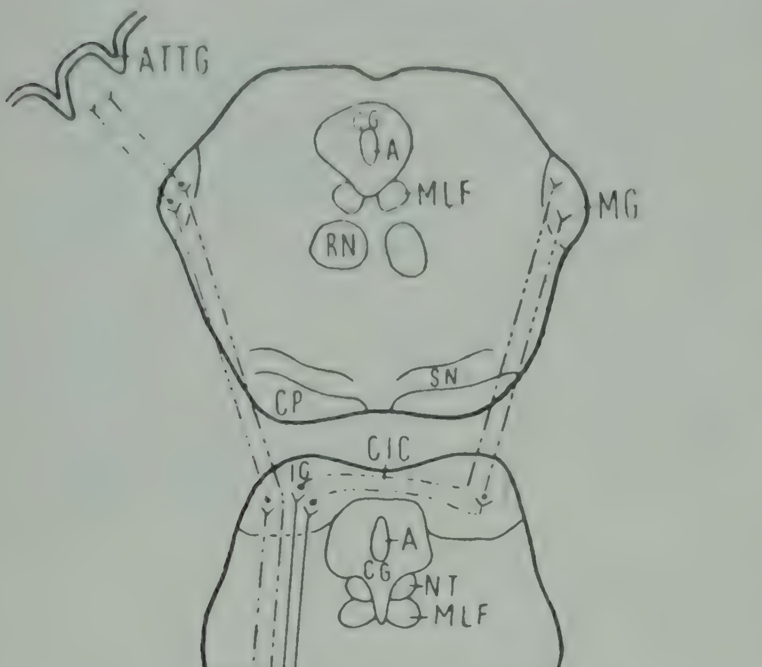

FIG. 197. Diagram of the central ascending auditory pathway in the monkey. VIIIc, cochlear nerve; CR, restiform body; DCN, VCN, dorsal and ventral cochlear nuclei; MLF, mesial longitudinal fasciculus; SO, superior olive; NLL, nucleus of lateral lemniscus; ML, mesial lemniscus; IC, inferior colliculus; CIC, commissure of inferior colliculus; MG, mesial geniculate body; A, aqueduct; CP, cerebral peduncle; ATTG, ant. tr. temporal gyrus. (After BARNES, MAGOUN and RANSON, *J. Comp. Neurol.*, 1943, **79**, 129.)

From these nuclei the fibres pass in three strands to a series of contralateral relay stations; these strands, dorsal, intermediate and ventral, cross the reticular formation, and reach the region of the superior olive (Fig. 197). On the way, some fibres of the dorsal strand end in the reticular formation. Having reached the superior olive some fibres end there in relays, and others pass up direct, with those relays, to the lateral lemniscus; many of these end in the nucleus of the lateral lemniscus, the remainder in the inferior colliculus; from here the next relay leads to the mesial geniculate body of the thalamus, and from this a final relay leads to the cortical auditory centre in the anterior transverse temporal gyrus. Some relays from the inferior colliculus cross back to the opposite inferior colliculus and so on by another relay to the other mesial geniculate body and cortex. This gives bilateral cortical representation and there are in addition some uncrossed paths from the superior olive upward which lead to the same result.

The cochlear path is thus effected by a chain of neurons with cells in cochlear nuclei, superior olive, lateral lemniscus nucleus, inferior colliculus, and mesial geniculate body, and each ear is connected to both sides.

There is a spatial projection of the different cochlear elements in the mesial geniculate body. It is claimed † that small localised lesions in the mesial geniculate body lead to loss of appreciation of particular pitches of sound, *e.g.* in the dorsal part to loss of high notes and in the ventral part to loss of low-pitched notes, *i.e.* particular fibres carry impulses aroused in discrete parts of the cochlea by particular notes. This point-to-point representation is continued to the cortex.

Auditory Reflexes. The inferior colliculus acts as a centre for auditory reflexes; from it arise the tecto-bulbar, tecto-spinal and other tracts, such as the posterior longitudinal bundle, by which auditory impressions are correlated with movements of head and eyes.

---

* For recent views *v.* BARNES, MAGOUN and RANSON. *J. Comp. Neurol.*, 1943, **79**, 129.

† ADES, METTLER and CULLER. *Amer. J. Physiol.*, 1939, **125**, 15.

Another important connection of the cochlear nerve is one *viâ* the superior olive to the oculomotor nuclei, and one direct to the VIth cranial nerve which is motor to the external rectus muscle. Hence on hearing a sound, the eye is reflexly turned to that side. In animals the incidence of sound on the ears causes erection of the pinnæ. This is effected by a reflex, the ingoing path of which consists of auditory nerve fibres, and the outcoming path of fibres of the VIIth nerve. Another auditory reflex is the contraction of the tensor tympani and stapedius muscles when sounds first fall on the ear; these muscles are innervated by a branch of the Vth cranial nerve. This reflex is bilateral even if sounds fall on one ear only. It is most marked for sounds of high pitch. Its object is to put the drum into correct tension for the perception of sounds.

(3) **Visual Sensations.** The rods and cones of the retina are visual sensory end-organs and neurones. The bipolar cells of the retina would then be the second order relay neurones, and convey the impulses to the third order neurones, or ganglion cells. The axons of these pass out from the eye as the optic nerve. Having entered the cranial cavity the nerve meets its fellow from the other eye, forming the optic chiasma, in which fibres partially decussate. The fibres thus form the optic tracts which travel round the crura cerebri and then divide to end in relation to fourth order neurones in three different places, viz. the pretectal region (a transitional area between thalamus and mid-brain), the superior colliculi, and the lateral geniculate body (Fig. 198). The first two are connected with reflex paths, the last with the transit of visual sensations to the occipital lobe.

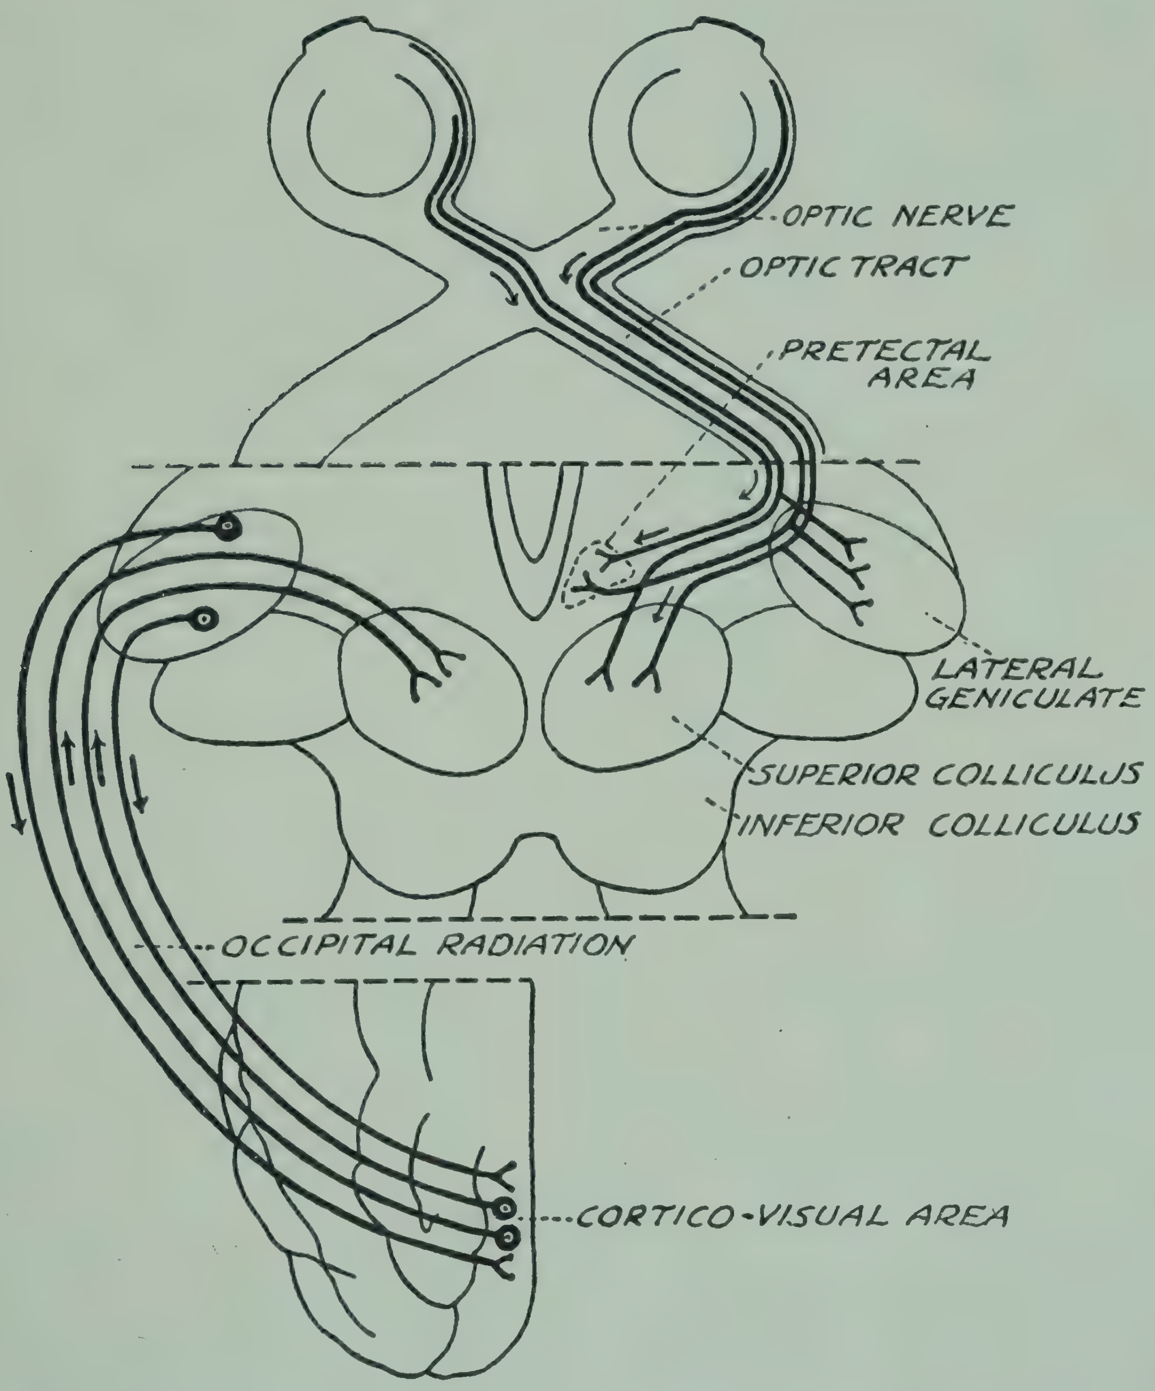

FIG. 198. Diagram of the Optic Paths. For clarity the first parts of the paths are shown in the right and the final stages on the left. (Modified slightly from BARRIS, *Arch. Ophthal.*, 1935, **14**, 61.)

The optic nerve may contain four different sets of fibres: (1) Those which convey visual impressions to the brain (coarse fibres); (2) those going to the reflex centres (fine fibres); (3) efferent fibres from the brain to the retinæ; (4) nerves travelling from one retina to the other.

The last two types, if they exist at all in mammalia, are of unknown function.

(1) Owing to partial decussation at the chiasma, the visual fibres of each optic tract are derived from both eyes, viz. from the temporal half of the retina and macula of the same side, and the nasal half of retina and macula of the opposite side; thus the right optic tract contains fibres derived from the right sides of both right and left retinæ and maculæ (Fig. 198). Each optic tract connects (for vision) with the dorsal nucleus of the lateral geniculate body (a specialised thalamic nucleus) on its own side, and, after relaying there, the impulses all pass onwards by the optic radiations to the visual centre in the occipital cerebral cortex.

By transneuronal degeneration it has been shown that there is clearly defined local representation of retinal areas in the lateral geniculate body.*

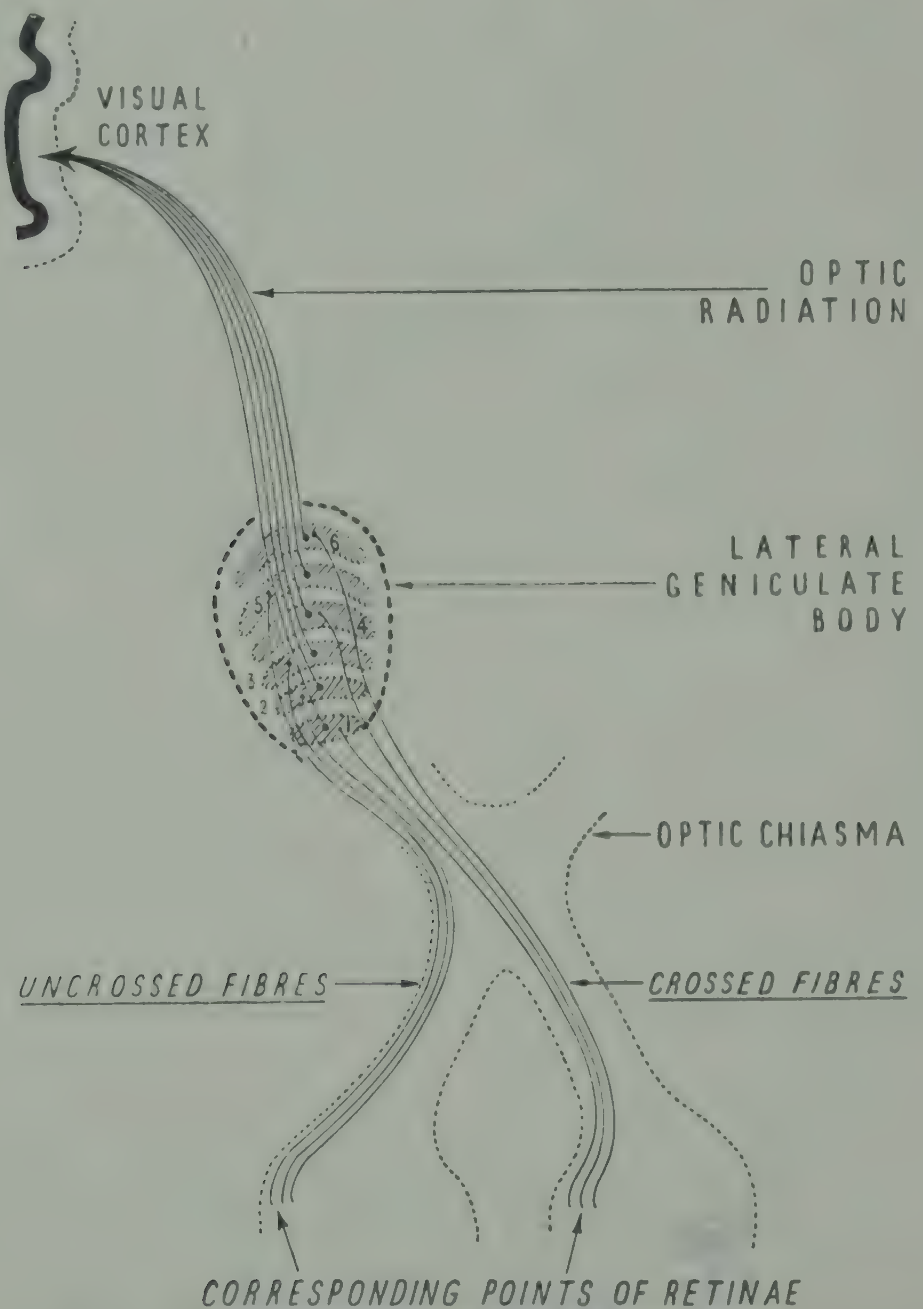

FIG. 199. To illustrate the convergence of impulses from corresponding retinal points at the visual cortex *viâ* the lateral geniculate body. (Modified from LE GROS CLARK.)

The macula has an especially large area of representation. There is a curious arrangement in the lateral geniculate body, which contains six cell laminæ. Fibres from corresponding points on the two retinæ end at vertically aligned cells in such a way that the uncrossed fibres from the temporal side of the retina end in layers 2, 3 and 5, while the crossed fibres from the corresponding points on the nasal side of the other retina end in layers 1, 4 and 6 (Fig. 199). The fourth order fibres from these cells representing corresponding points are then apparently brought to a focus at the visual cortex. It has been suggested that the 3-layer arrangement for each side may be related to colour vision.

---

* LE GROS CLARK and PENMAN. *Proc. R. S.*, 1934, **114B**, 291.

It will be seen that the occipital cortex is in this manner in connection with the halves of both retinæ of its own side, and impulses from corresponding points emerge close together. Since, as will be learnt later, each half of the retina receives light images of the opposite half of the whole visual field, this means that with vision, as with touch, each side of the brain receives impressions derived from the opposite side of the environing world.

(2) Some special afferent fibres of the optic tracts, and probably also some collaterals from the visual fibres, pass to the *superior colliculi* ; here they form the "stratum opticum" and terminate in the superficial layers : there is some degree of retinal area representation. This type of ending is concerned with reflex eye movements. It may represent a primitive vision centre.

Another reflex arc is that *viâ* the *pretectal region*, the pupillo-motor path described below.

It is of practical importance to be able to locate an injury to the visual nerve paths. Injury to an optic *nerve* causes blindness of the eye to which the nerve belongs, and exposure of the eye to light will not then elicit the pupil reflex. Injury to an optic *tract* causes blindness of the halves of *both retinæ on the same side* as the lesion, that is to say, *blindness to external objects on the opposite side* to the injury. Injury at the chiasma, *e.g.* by pituitary tumours, may only interfere with the fibres from the nasal halves of both retinæ, so causing loss of the temporal fields of vision—*bitemporal hemianopia.*

It is interesting to note that, whereas, in most other nerve paths, crossing of the fibres occurs from one side to the other as they travel to the brain, so that the left side of the brain is connected only with the right side of the body, this is not the case with the optic—or auditory—impulses. Injury to the optic radiation of the calcarine cortex will cause blindness of the corresponding halves of *both* retinæ, *i.e.* the half of each retina on the same side (and so blindness to the external world on the *opposite* side), but will not affect the pupil reflex, because the fibres concerned have already turned aside to go to the pretectal region.

EYE REFLEXES. *The Correlation of Head and Eye Movements.* These may be of two kinds, compensatory and associated. The compensatory ones take place when the head is rotated in one direction and the eyes in the opposite direction, in order still to fix the gaze on some stationary object.

The associated movements occur when the head and eyes rotate in the same direction in order to fix the gaze on an object which is moving round the observer. Both these associated movements appear to be effected *viâ* the superior colliculi. These receive not only afferent fibres from the optic tracts, but also efferent ones from the occipital cortex (Fig. 198). From the superior colliculi arise the motor tecto-bulbar and tecto-spinal tracts. Probably also co-ordination is effected through the inferior olivary bodies which connect with the oculomotor nuclei *viâ* the central tegmental tract, with the upper cervical cord by the olivospinal tract, and with the cerebellum.

The Correlation of Limb and Eye Movements. For the protection of the eyes there is an important reflex which can be initiated principally by vision, but also by the other distant receptors, such as hearing. This involves (*a*) the firm closing of the lids, and, in addition, where necessary, the raising of the arm in front of the head (or the hands in front of the eyes) ; (*b*) the flexing of the neck and spine so that the face approaches the abdomen ; (*c*) lastly, the reflex may cause the raising of the legs flexed at the knees so that they form an additional protection for the face. This reflex operates through the tecto-spinal tract.

The Pupillary Reflex. The plain muscle of the pupil is supplied by two nerves, viz. the sympathetic which causes dilatation, and the IIIrd cranial, which causes constriction. When light falls on the eye, the pupil constricts —the light reflex. This is effected by a reflex from the pretectal region, in which special fine fibres from the optic nerve terminate : from here relay fibres pass to end at the IIIrd nerve nucleus, from which axons pass out to the constrictor pupillæ muscle. There is some crossing over of neurones from side to side in the pretectal region, which explains the fact that when one eye is exposed to light the pupils of both eyes contract (Fig. 200).

In some disorders the phenomenon of the *Argyll-Robertson pupil* is encountered. In this, the pupil does not react to light, yet the IIIrd nerve nucleus must be intact, because the pupil still contracts during accommodation of the eye for near vision. The lesion is probably in the pretectal region ; destruction of the superior colliculi, which was formerly believed to be the relay station, does not affect the light reflex,* but destruction of pretectal region as well as of the superior colliculi does.†

(4) The Paths for Taste and Smell. The *nerves for taste* are the VIIth and IXth cranial, the cells of origin being in the geniculate and petrous ganglia respectively. These primary neurones end in the sensory nuclei of the VIIth and IXth nerves, from which second order fibres run, probably with the common fillet tracts of the opposite side, to the thalamus. From this, third order neurones continue to the cortical centre.

The *nerves for smell* perforate the cribriform plate and enter the olfactory bulb, of complex structure, where a relay occurs. The relaying fibres form the olfactory tracts. Ultimately the impulses reach the uncinate gyrus, the hippocampus and other structures which together form the rhinencephalon or olfactory brain.

THE THALAMUS

With the sole exception of the olfactory path, all the afferent paths which are travelling to the cerebral cortex converge on to the thalamus, which is their chief relay station. Thus, it receives optic and auditory radiations, the spinal, mesial, and trigeminal lemnisci and cerebellar fibres. It also has connections with various subcortical stations. All cortical connections are with the cortex of the same side.

The thalamus contains many nuclei, which are differently described by different authorities. In mammalian forms, it may be divided, according to Le Gros Clark ‡ into an upper and a lower level. *The upper level* is dorsally placed, and contains, among others, the lateral and dorso-medial nuclei, the supra-geniculate and centre median nuclei. These upper levels do *not* receive direct afferent fibres, and are related to the association areas of the cortex ; they also have connections with other nuclei of the diencephalon. It is probable that the more ventrally placed ones of this group also have functions in connection with visceral control, and so connect with the hypothalamus.

---

* Keller and Stewart. *Amer. J. Physiol.*, 1932, **102,** 64.

† Magoun and Ranson. *Arch. Ophth. N.Y.*, 1935, **13,** 791, 862 ; Barris. *Arch. Ophth. N.Y.*, 1935, **14,** 61.

‡ Le Gros Clark. *Brain*, 1932, **55,** 406 ; Le Gros Clark and Boggon. *Phil. Trans.*, 1935, **224B,** 313.

The lower levels of the thalamus are chiefly ventral, and receive afferent impulses from the brain stem, spinal cord and hypothalamus, and relay these to the upper level nuclei and to the cerebral cortex. They include (1) the main ventral nucleus and the medial ventral nucleus, (2) an anterior group, (3) an optic tract group, including the dorsal and ventral nuclei of the lateral geniculate body, the large-celled nucleus of the optic tract, and the pretectal nucleus, (4) the medial geniculate body.

Physiologically * there are three main groups of thalamic nuclei :

(i) Nuclei *with purely subcortical connections* (chiefly the anterior ventral groups), which do not degenerate after hemidecortication. They are the seat of primitive sensations, and probably serve to connect together the various nuclei of the diencephalon and have certain functions in visceral control.

(ii) Nuclei which are *relay stations on the afferent path* to the cortex. These are chiefly ventral, and include the geniculate bodies and the posteroventral and lateroventral nuclei.

(iii) *Association Nuclei.* These are the dorso-medial and lateral nuclei and pulvinar. They connect with other nuclei of the diencephalon (thalamus, hypothalamus and subthalamus) and also with the parietal and anterior frontal association areas of the cerebral cortex, but receive no afferent fibres from the sensory systems.

The chief function of the thalmus is undoubtedly that of receiving, modifying and relaying sensory impressions to the cortex. There is also important reciprocity between cortex and thalamus, a nucleus sending fibres to the cortex likewise receiving fibres from it. It has been shown that after receipt of sensory impulses at the cortex, an after-discharge occurs, which can be detected by a suitable amplifier, and traced back to the thalamus, but not further back.† The thalamus and cortex thus work in close collaboration, some parts of the thalamus being connected with extensive areas of cortex, and there is little doubt that the organisation of the cerebral cortex is largely effected by the intermediation of the thalamus.

Removal of parts of the cerebral cortex leads to retrograde degeneration of the thalamic relay nuclei connected with those parts. Thus it can be shown that the lateroventral parts project to areas 4 and 6 (*v.* p. 299) of the cortex and are concerned with unconscious kinæsthetic afferents, while the posteroventral parts act as relay stations for conscious sensations arriving *viâ* the lemnisci on their way to the cortex. Hence destruction of the posteroventral portion of the thalamus causes disturbances of skin and kinæsthetic sensations on the opposite side. The representation of areas is demonstrable in the thalamus, face being in the most mesial, arm and leg respectively more lateral parts of the posteroventral nucleus. There is, however, no such segregation of modalities of sensation as is seen in the cord, since the mesial lemniscus and spinal lemnisci terminate at about the same parts.

The lateral geniculates, as we have already seen, are relay stations on the visual path, and the mesial geniculates on the auditory and vestibular paths. The pulvinar serves to correlate visual and auditory impressions.

Disease of the thalamus is often accompanied by extreme hypersensitiveness in the areas represented. This is probably a release phenomenon due to severing of cortical connections. There seems little doubt that the thalamus is capable of sensation of a crude type independently of the cortex. This explains why some responses, especially to pain and temperature, may remain even after the removal of large areas of the cerebral cortex.

We have already seen that the decorticate animal exhibits a tendency to a display of " sham rage " on receipt of almost any stimulus, and this is believed to be due to the removal of the normal control of the cortex, by which such emotional expressions are toned down. It is probably in the upper levels of the thalamus that afferent impressions become loaded with an emotional quality.

II. UNCONSCIOUS AFFERENTS

The paths used for conscious impressions may also often be traversed by impulses that do not emerge into consciousness, but are concerned wholly with reflex effects. Some paths, however, are devoted wholly to the transmission of impulses which normally arouse no sensations. If, by exceptionally strong stimulation, such impressions do force their way into the field of consciousness, the sensations aroused are vague in character and lacking in local sign. The most important of these tracts are concerned with unconscious kinæsthetic impressions, related to the position and movements of the limbs, neck or trunk. Their most important destination is the cerebellum. Others lead from the viscera, and have connections with the spinal and bulbar centres. Among these paths the following are important :—

---

* Earl Walker. *J. Nerv. Ment. Dis.*, 1937, **85**, 249.

† Adrian. *J. Physiol.*, 1941, **100**, 159.

(1) **The spinocerebellar tracts** arise from the secondary neurones of the Clarke-Stilling column in the spinal cord. The large axons of these cells pass into the *dorsal and ventral spinocerebellar tracts*, chiefly of the same side and ascend through the medulla. Here the dorsal spinocerebellar tract takes a more dorsal position and forms an important part of the restiform body, or inferior cerebellar peduncle, with which it travels to, and ends in, the cortex of the vermis of the cerebellum.

Other important afferents originate from the dorsal columns of the cord, and reach the cerebellum from the bulbar nuclei, chiefly of the opposite side, *viâ* the restiform body. Among these are axons (the arcuate fibres) from the nuclei Gracilis and Cuneatus, which relay unconscious kinæsthetic impulses ascending the spinal cord.

(2) **Vestibular Paths.** As would be expected, the vestibular nerve has extensive central connections concerned with the co-ordination of motor responses. It has synapses with cells in one of the four subdivisions of the vestibular nucleus, viz. medial (Schwalbe), lateral (Deiters), superior (Bechterew), or the vestibulo-spinal nucleus. From the cells of these nuclei four main tracts arise :—

(i) *Connects with the posterior longitudinal* bundle of both sides.
(ii) The *vestibulo-spinal tract*, which descends homolaterally in the cord.
(iii) *The vestibulo-reticular tract*, which connects with motor nuclei and reticular formation, of opposite side.
(iv) *The vestibulo-cerebellar tract*, which includes some direct fibres from the vestibular nerve. It is homolateral.

In addition to these tracts leaving the vestibular nucleus, there is the cerebello-vestibular or uncinate fasciculus, which descends to the vestibular nucleus from the roof nuclei of the cerebellum of the same side.

(3) **Olivo-cerebellar Tracts.** The olivary bodies have afferent connections with the spinal cord, thalamus, etc., and send out fibres which pass up in the inferior peduncles to the cerebellum.

(4) **Visceral Afferents.** These will be considered later.

CHAPTER XX

THE CEREBRAL HEMISPHERES AND THE EFFERENT PATHS

THE cerebral hemispheres form the largest and most important part of the human brain. It is to the progressive evolution of this part that is due the rise in type in vertebrates. In development they are formed as two diverticula from the front part of an outgrowth of the first cerebral vesicle. In the lowest vertebrates these outgrowths are connected entirely with the olfactory sense organs, and we may regard the olfactory brain as a fundamental structure on which has been built up all the rest of the cerebral hemispheres. With the increasing importance of the visual sensations in the bony fishes there is still very little corresponding growth of the fore-brain, most of the fibres from the optic nerves going to the roof of the mid-brain (the optic lobes). The emergence of the cerebral hemispheres is associated with the development of nervous tissue in the roof of the fore-brain. At its first appearance this higher brain material still receives chiefly olfactory impressions. But the structure of the cerebral cortex thus laid down differs from that of the centres forming the brain stem or the olfactory lobe itself in that it provides for a very rich association of impulses between all its parts. The fibres entering the cortex break up into a fine meshwork of fibres which run tangentially to the surface and come in relation with innumerable dendrites of nerve cells situated at some little distance below the surface. We have here the first germ of an apparatus in which the nerve paths can be determined by education. In the amphibian and reptile, the cerebral cortex extends over the whole roof of the cerebral hemispheres, though even here a very large proportion of it is devoted to the association of olfactory impulses. The wider reactive powers of birds are based chiefly on an enormous development of the corpus striatum, whereas in mammals the chief development occurs in the roof of the cerebral hemispheres. With the increased entry of fibres, carrying impulses from all the other sense organs of the body, the olfactory part of the brain diminishes in importance, and in the higher mammals and man is altogether overshadowed by the newly formed structures of the cerebrum. The cortex of the olfactory brain is sometimes called the *allocortex*, and that of the remainder of the cerebrum the *isocortex*.

The whole surface of the brain is thrown by fissures into convolutions, by which means about a threefold increase of the surface grey matter is obtained. By the larger fissures the brain surface is divided into lobes. The chief lobes are (*a*) the frontal; (*b*) the parietal; (*c*) the occipital; (*d*) the temporal; (*e*) the limbic area. The chief fissures separating these are (*a*) the central or fissure of Rolando, between frontal and parietal lobes; (*b*) the Sylvian fissure between the parietal and temporal; (*c*) the parieto-occipital; (*d*) the calloso-marginal, forming the outer boundary of the limbic area. Each of the main lobes or areas mentioned above is further subdivided by numerous minor fissures.

MINUTE STRUCTURE OF THE CEREBRAL CORTEX. The cortex of the cerebral hemispheres consists of a layer of grey matter covering a deeper mass of white fibres. The white fibres are axons passing out of or into the grey matter.

Even the naked eye appearance of the grey matter, in vertical section, differs from place to place. Histologically the grey matter consists of layers of nerve cells embedded in neuroglia and nerve fibres, both medullated and non-medullated. The nerve cells vary in size and shape; one cell typical of the cerebral cortex is the *pyramidal cell*, a cone-shaped cell with one large apical process which runs towards the surface, various dendrites which are given off from the sides and lower angles of the cell, and another process (usually the axon) from the base of the cell which passes downwards giving off small collaterals in its course. Some of their axons (*projection fibres*), including those which enter the pyramidal tracts, pass by the corona radiata through the internal capsule and into the crura cerebri. Others, or their collaterals, may pass into the adjacent regions of the cortex, or by the corpus callosum into the opposite cerebral hemisphere (*association fibres*). Other neurones belong to Golgi's type II and are confined to the grey matter; they are called "*intracortical neurones*."

The structure of the allocortex (olfactory) * is totally different from that of the isocortex and cannot be considered here.

---

* LORENTE DE NÓ. *J. Physiol. Neurol.*, 1934, **45**, 381; **46**, 113.

In the isocortex, histological examination of the layers of cells and fibres shows that there are many different variations of a presumably common plan of stratification, and much labour has been devoted to an attempt to unfold this basic plan. When the whole cortex of man is systematically studied it is found that it can be divided into numerous areas, each of which has a distinctive overall structure, as judged by the thickness of the various layers of fibres and cells and by special modifications which they show from one area to another. The number of fields into which the whole cortex is thus divisible varies according to the criteria adopted by different investigators, and has been increased as a result of detailed study from an initial twenty areas * to fifty,† or even, according to some, to more than 200, all of which are presumed to have different functions.

Some of the more generally accepted structurally distinguishable areas, according to Brodmann, are shown in Fig. 201, and it is common to refer to the areas by the numbers there given.

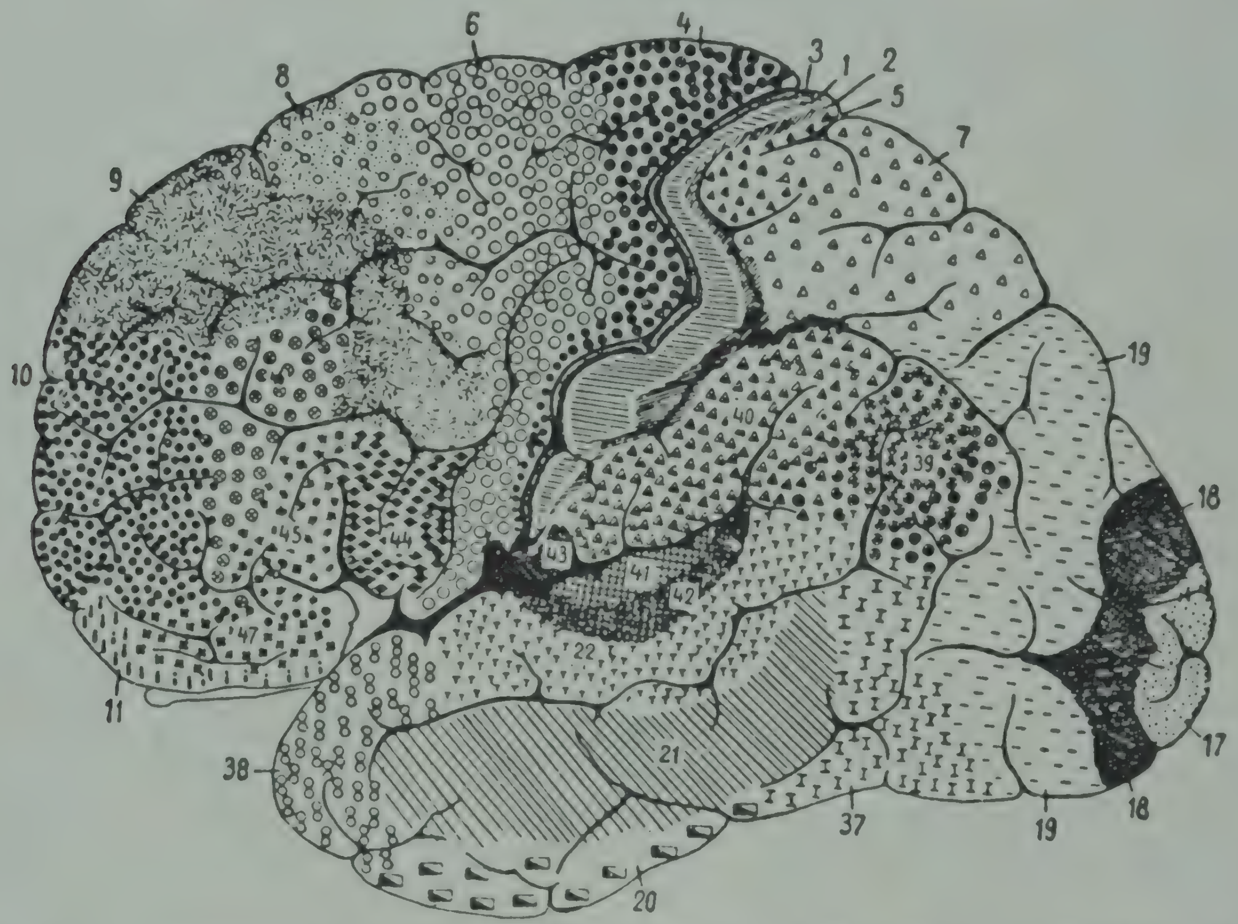

FIG. 201. Brodmann's Cytoarchitectonic Map of the Human Cortex. (From FULTON'S "Physiology of the Nervous System," Oxford Univ. Press.)

The plan of structure of the important parts, represented by the parietal, temporal and occipital lobes, generally agreed upon is that of a fundamentally six-layered stratification (I–VI) of cells of different types, layers IV., V. and VI., however, being often subdivided. The cell layers described are recognised by staining the cells for Nissl's granules, *e.g.* with methylene blue. If the medullated fibres are stained, as by the Weigert-Pal method, instead of the cells, new strata (1–6), consisting of fibres, are revealed (Fig. 202).

These six cell layers, in two laminæ, are :—

EXTERNAL LAMINA

I. The plexiform layer. It contains few cells, and is composed principally of the dendritic endings of cells belonging to deeper layers. It contains a few horizontal cells of Cajal, with processes which run approximately parallel to the surface.

II. The layer of small pyramidal and small granule cells.
III. The outer layer of medium pyramidal cells.
IV. (*a*) The layer of star pyramids. (The outer line of Baillarger (fibres) is at this level.)
IV. (*b*) The layer of stellate cells. Sometimes this layer is called the middle stellate or granule layer.

INTERNAL LAMINA

V. The inner layer of large deep pyramids. It is in this layer of the motor area that the giant Betz cells are found. (The fibre component of this layer, 5*b*, is the inner line of Baillarger.)
VI. The fusiform cell layer.

Internal to layer VI is the white matter of the cerebral cortex.

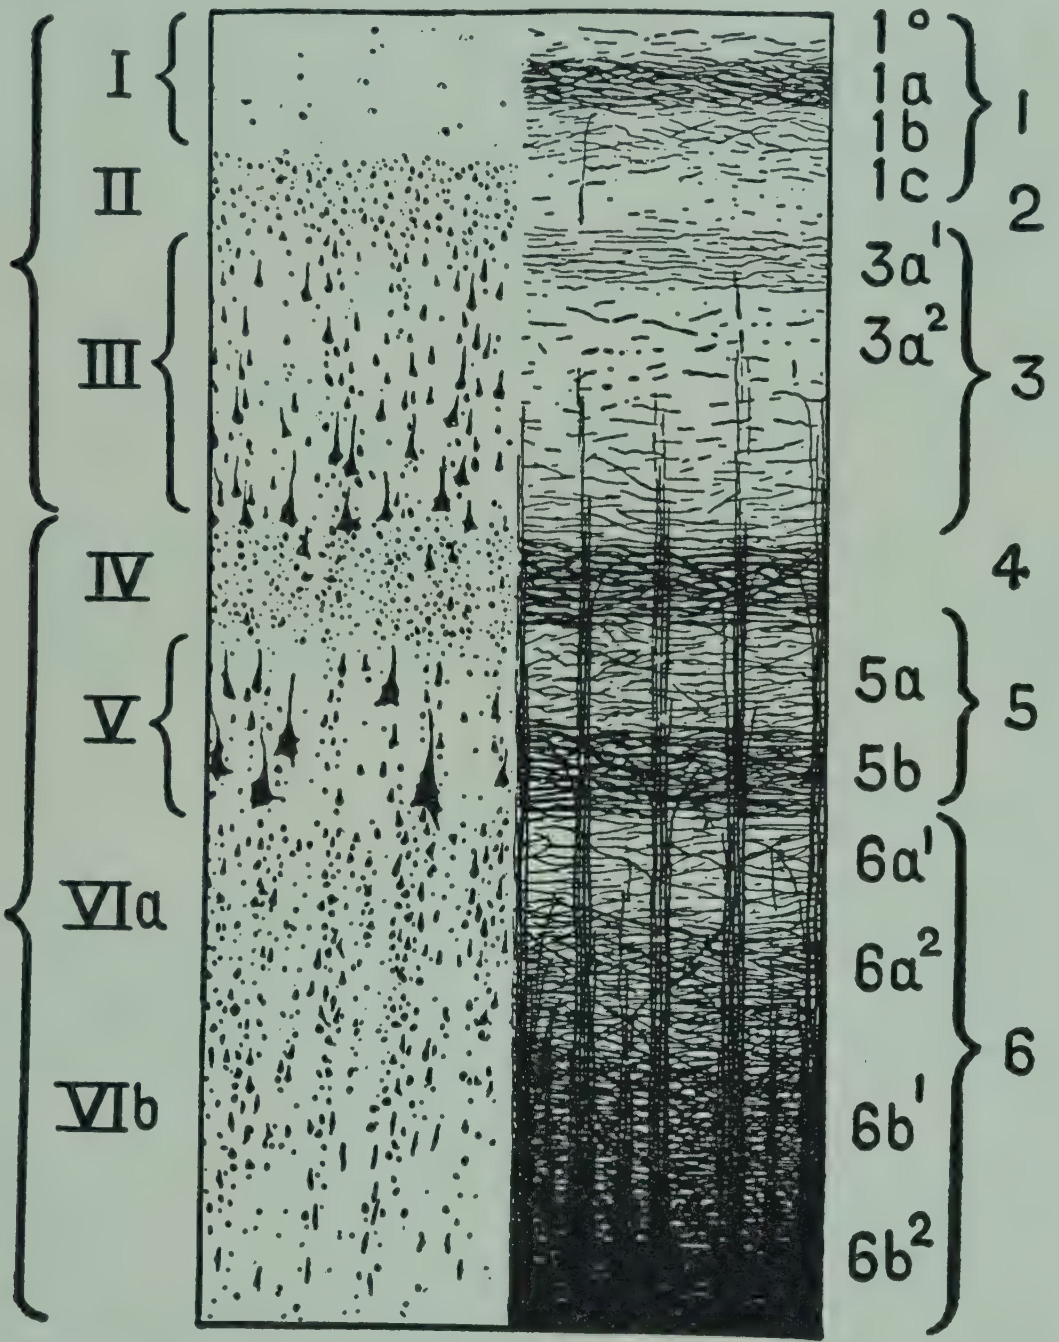

FIG. 202. Diagrammatic Representation of the Layers of the Human Cerebral Cortex according to Brodmann and Vogt. On the left the six cell layers. On the right the fibre layers, Layers 4 and 5b being respectively the outer and inner lines of Baillarger. (After ECONOMO, "Cytoarchitectonics of the Human Cerebral Cortex," Oxford Univ. Press, 1929.)

The pyramidal cells of all sizes possess, in general, three different kinds of fibre : an apical one, which runs towards the external surface, and then branches tangentially to the surface ; a basal one (axon) running towards or into the white matter, where it becomes medullated and runs a variable distance according to its function ; and a series of transverse collaterals, which run tangentially. In consequence, these tangential fibres form well-marked lines, particularly at layers IV and V. In consequence, if sections are stained by a method like Weigert's, sheaves of radial fibres will be seen running from the white matter towards the surface, giving off a rich meshwork of fibres to the intervening portions of the grey matter, while the bands of tangential fibres

FIG. 204. Types of Cerebral Cells with Intracortical Axons: axons marked *a*: 18 to 21, cells with ascending axons; 22, cell with horizontal axon; 23 to 26, cells with short axons. (LORENTE DE NÓ, in FULTON's "Physiology of the Nervous System," Oxford University Press.)

are seen running parallel to the surface. Thus we find (Fig. 202): (a.) The tangential fibre layer which corresponds to the plexiform layer; (b.) a layer of tangential fibres (4) at layer IV, corresponding to the stellate cell layer. This is sometimes called the outer line of Baillarger; (c.) an inner line of tangential fibres (5b) at layer V, corresponding to the layer of large deep pyramidal cells, sometimes called the inner line of Baillarger.

Two of the most clearly marked differences in areas are: (1) In area 4, the "agranular isocortex," a motor area, layer V is occupied by giant pyramidal cells, the axons of which enter the pyramidal tract. The largest of them are called the giant Betz cells. (2) In area 17, the visual area, the pyramidal cell layers are thin, the large pyramidal cells being very few. The lines of Baillarger are very distinct, particularly the outer, which is sometimes called the line of Gennari, a characteristic of this region.

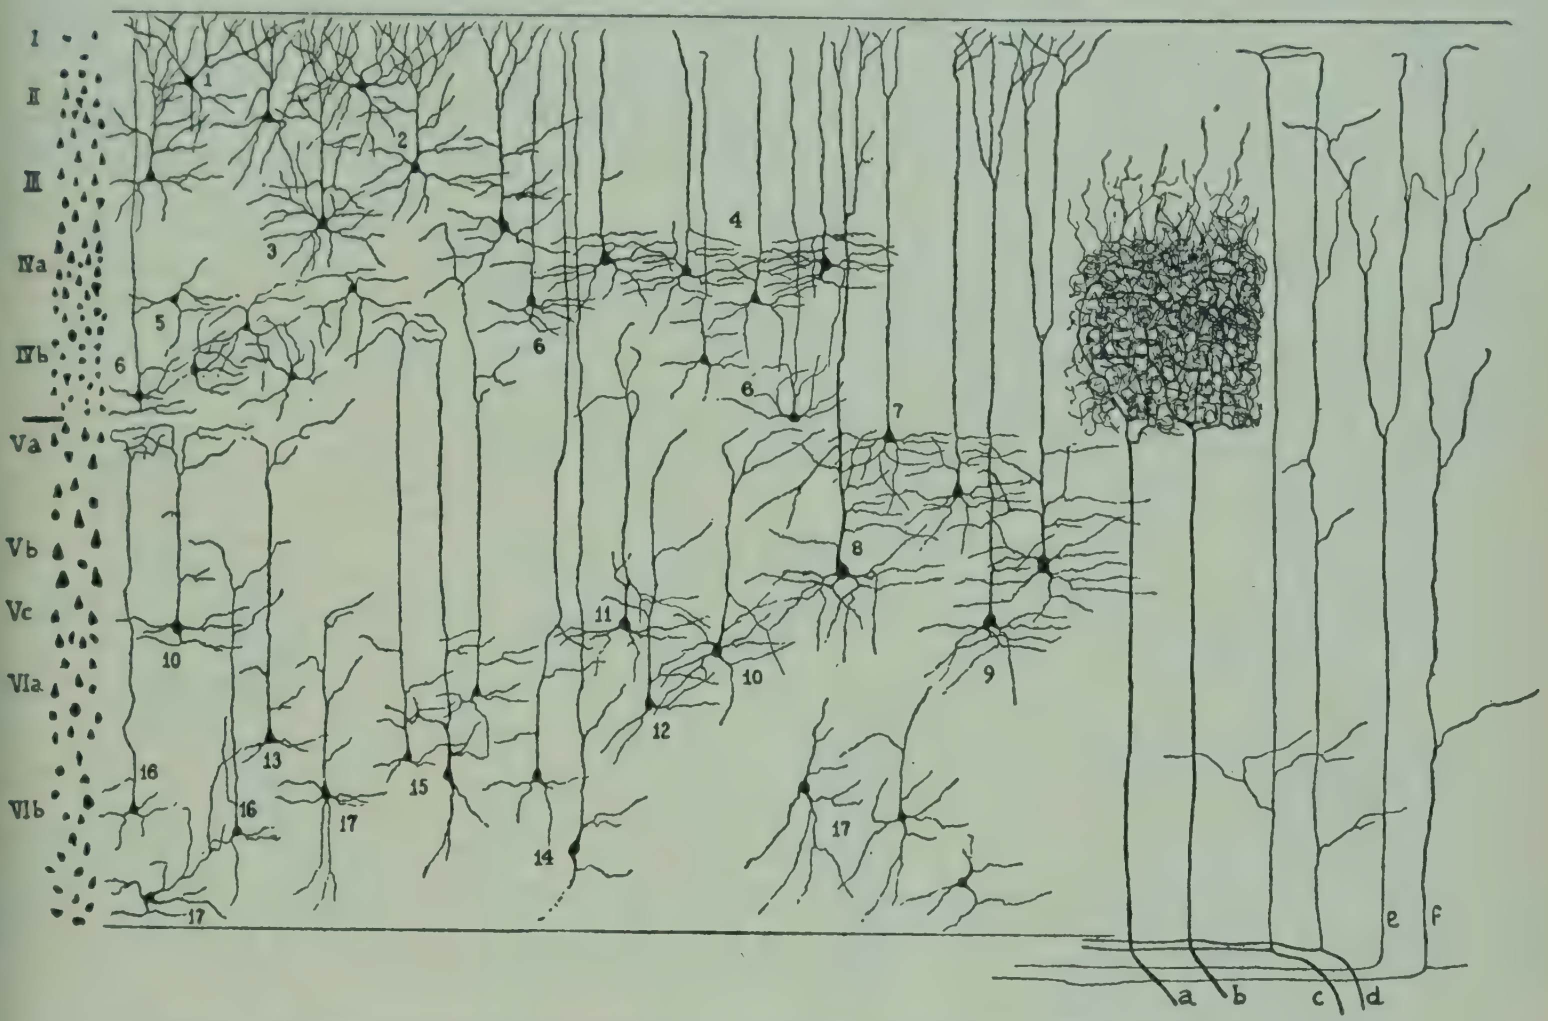

FIG. 205. Parietal Cortex of Mouse. On left a strip showing the cell layers. On right the principal afferent fibres, of which *a–d* are from thalamus, and *e, f* are association fibres. Main picture shows the relation of the chief types of descending axon cells to the cell layers, and the position of their dendritic branches. *For clarity of drawing the descending axons have been omitted*, but are shown in Fig. 203.

The cells are: 1, Pyramids of layer II.
2, 3, Pyramids of layer III.
4 to 6, Star cells and pyramids of layer IV.
7 to 11, Pyramids of layer V.
12, 13, Pyramids
14 to 16, Spindles } of layer VI.
17, Star cells

(LORENTE DE NÓ, in FULTON'S "Physiology of the Nervous System," Oxford University Press.)

Although this mapping of the cortex is valuable in stressing the varying structure of its different parts, it tells us little with regard to the functional connections of the neurones. For this purpose sections stained by Golgi's method are needed, and Figs. 203, 204 and 205 illustrate the findings thus made. It can then be realised that, as stressed by Lorente de Nó, the important point, as regards functions, is not so much the horizontal lamination as the fact that the cells are arranged in vertical chains, with synaptic connections at definite levels characteristic of each type of neurone. Seen from this standpoint we can recognise four main types of neurone in the cortex :—

(1) Cells with *axons that descend,* often into the white matter, where they form projection or association fibres (Fig. 203, 1 to 10, and Fig. 205).
(2) Cells with *axons that ascend* and ramify in other layers (Fig. 204, 18 to 21).
(3) Cells of Golgi type II, with short branching axons (Fig. 204, 23 to 26).
(4) Cells with horizontal axons (Fig. 204, 22).

It will be noticed that, with the exception of the projection and association neurones of the first group, all these neurones are intra-cortical, *i.e.* they must have internuncial functions.

Some typical neurones are shown in their proper positions in the layers, in Fig. 203 (descending axons), Fig. 204 (intra-cortical neurones, some with ascending axons) and Fig. 205 (general view of all types, and of the typical afferent fibres that reach the cortex).

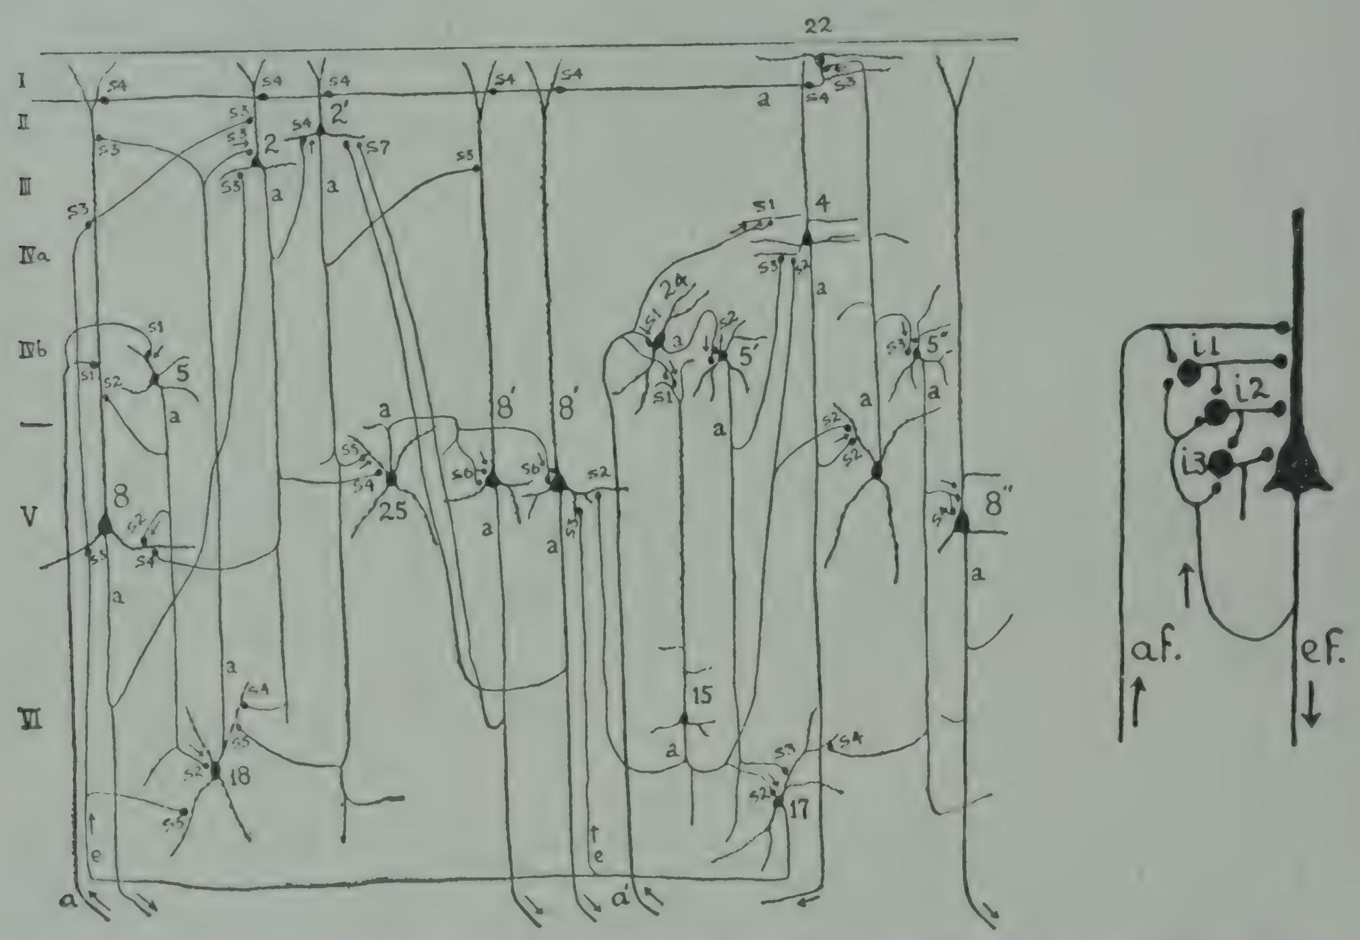

FIG. 206. Diagram of some of the Intracortical Chains of Neurones. The numbers on the cells, and the letters *a* and *e* on the fibres, are the same as in Figs. 203, 204 and 205. The axons are marked with *a*. Only a few dendrites and axonal branches have been included in the diagram. The synaptic junctions are indicated with the letter *s* (s_1, s_2, etc.) and with a thickening of the axon. It is assumed that the synapses marked with an arrow are passed by the impulses.

The small diagram at the right is a simplification of the diagram at the left. The afferent fibre *af.* activates the large pyramid, which is the origin of an efferent fibre *ef.*, and also a system of cortical internuncial cells (i_1, i_2, i_3) ; the recurrent collateral of *ef.* delivers impulses again to the internuncial system. This diagram summarises the plan upon which the cerebral cortex is built. (LORENTE DE NÓ, in FULTON's "Physiology of the Central Nervous System," Oxford University Press.)

In its general plan, as emphasised by Lorente de Nó,* the cerebral cortex appears to consist of chains of neurones, arranged in a generally vertical direction. Afferent fibres, from the thalamus or from other parts of the cortex, pass vertically upwards, and give off collaterals to all cell levels, except layers I and II. These collaterals form synaptic connections with all the types of cell, and we may speak of the afferent fibre, with all its connections as an *elementary cortical unit. In this unit the afferent impulse passes over to the*

---

* LORENTE DE NÓ. Article on Structure of Cerebral Cortex, in FULTON's "Physiology of the Nervous System," Oxford University Press, 1943.

efferent fibre. The general connections within an elementary unit, according to Lorente de Nó, are shown diagrammatically in Fig. 206.

The efferent fibres which emerge may pass, as association fibres, to other parts of the cortex, or as projection fibres to more distant parts.

A careful study of Fig. 206 and of the simplified diagram to the right of it, shows that a nervous impulse, entering the unit by an afferent fibre, makes synaptic contact not only with an efferent neurone, but also with numbers of internuncial neurones, by which reverberatory and delaying circuits are formed as by-passes, so that impulses are delivered over and over again to most of the cells, in the manner previously outlined. These trains of impulses not only result in more prolonged bombardment of the neurones, but, as a result of facilitation, may open up synapses not previously permeable.

So an entering impulse may, for instance, pass first to layer IV, thence down to layers V and VI and again up to layers II and III, finally emerging from a layer characteristic for the particular area.

It should be noted that all these arcs are superposed on the direct one from afferent to efferent, as *e.g.* from fibre *a* to cell 8 in Fig. 206. Further, there are various possible closed-chain circuits, as *e.g.* 8–2, 18–8, etc.; in the figure *a*, *a′* are afferent fibres, 8, 8′ and 8″ are effector neurones; the others (including 4 and 17, which give association axons *e*) are internuncial neurones. Some of the by-path arcs are confined to one layer, *e.g.* 25–8′, while others are long and span several different layers, *e.g.* 18–2. In the higher animals there are proportionally more of the short-axon connections, which confer greater delicacy and range of paths.

LOCALISATION OF FUNCTION IN THE CORTEX

The demonstration by Fritsch and Hitzig in 1870 and by Ferrier in 1874 that stimulation of certain areas of the cortex led to rather accurately predictable movements on the opposite side of the body, and the discovery by Ferrier that fibres of the optic nerve ultimately ended at the occipital cortex, led to the conclusion that there is in the cerebral cortex a topographical differentiation of function. Subsequent detailed study over several decades confirmed this, and fitted in well with histological studies showing that the structure of the cortex likewise differed from place to place. Ultimately, it was expected, the cortex would be mapped out like a mosaic, each small area having one function, projicient or receptor, and one function only.

Fig. 207. Diagram of the Chief Cortical Areas in Man, according to Foerster and Penfield. (Slightly modified from *Ztschr. f. d. ges. Neurol. u. Psych.*, 1930, **125**, 475.)

This conception was too simple and went too far; it accords neither with experimental facts nor with clinical observations. Localisation of a kind there certainly is, but known facts cannot be adequately explained unless it is realised that there is also considerable overlap. So far as the accepted motor areas are concerned, for instance, they are those which respond to threshold stimulation; the area mapped out as the motor area for the hand, for instance, is that which on the feeblest stimulation gives movements of the hand alone. It is in reality only predominantly a hand area, for on stronger excitation other movements result as well,* and these happen even when the cortical area is isolated from neighbouring areas. Moreover, on excision of a given motor area, movement in the part of the body it is supposed to govern is only transitorily abolished and is restored later, though perhaps with some clumsiness. Sensory areas similarly spread more widely than was formerly supposed.

Nevertheless, the accuracy of the localisations of function in the areas of lowest thresholds is undoubted.

Some areas are predominantly the site of origin of efferent projection fibres concerned with movements—the *motor areas*, while others, the *sensory areas*, are more intensively concerned with the reception and appreciation of sensory impulses. Others serve associative functions.

The functions and situation of these areas have been revealed by the study of the results of several different methods :—

(1) Anatomical and histological, by which it has been found that the different pathways to and from the cortex are connected with cortical areas that have characteristic structures. (2) The results of experimental or surgical removal, and of destructive disease, of various areas of the cortex. (3) The results of local electrical or chemical excitation (*e.g.* by application of strychnine) or of irritative disease, of the areas. (4) The *positive* electric potential changes in the cortex which result when sensory stimuli are applied to the appropriate receptors in deeply anæsthetised animals : under anæsthesia the sensory centres receive impulses in the usual way, but these do not reach the upper layers and so do not produce the widespread negative potential in the cortex which is the case in conscious animals, so the exact place of their arrival can be found.†

The functions of the chief of these areas of predominant function and their relation to the areas on the structural map are briefly as follows (Fig. 207, but not all areas are shown) :

The Frontal Lobe. Area 4 is subdivided into areas 4γ, 4a and 4s. Areas 4a and 4γ, the latter being the Betz cell area, are motor. In man, area 4γ occupies only the anterior lip of the Rolandic fissure. The axons of the Betz cells, and other cells of area 4, enter the pyramidal tract, and pass down, *viâ* interneurones, to the motor neurone pools in the brain stem and spinal cord.

Area 6, the so-called "*pre-motor*" *area*, occupies the greater part of the precentral gyrus. Its posterior part, adjoining area 4, is also motor, and sends fibres into the pyramidal tract. It also has other motor projections, but these are largely concerned with the extra-pyramidal system, and with the musculature of the mouth and respiration. Its lower parts (44 and 45) sometimes called Broca's area, are concerned with speech.

Area 8 is also largely extra-pyramidal and concerned with *eye movements*.

Area 9 *to* 12 is the prefrontal area or frontal association area, and is probably largely *associative* in function.

The Parietal Lobe. Area 3, 1, 2, the "post-central" area, is chiefly sensory, receiving most of the projections from the thalamus, for *cutaneous and general kinæsthetic sensitivity. Areas* 5 *and* 7 are also mainly sensory.

All these areas also contribute to the pyramidal tract.

The Temporal Lobe, Areas 41–42, receive the auditory radiations and are sensory for hearing.

Area 22 is an *auditory association* area.

* Walshe. *Brain*, 1943, **66**, 104; Murphy and Gellhorn. *Arch. Neurol. Psychiatr.*, 1945, **54**, 256.

† Adrian. *Lancet*, 1943, **245**, 33; *Brain*, 1943, **66**, 89.

The Occipital Lobe is entirely visual in function.

Area 17, the true *visuo-sensory* or "striate" area, receives projections from the lateral geniculate body and also sends fibres to it.

Area 18 is *visual associative.*

Area 19 is a visual area connected chiefly with the thalamus. Stimulation causes eye movements as a secondary effect.

Associative Functions of the Cortex. *The Pre-Frontal Area.* The earlier investigations on localisation led to a belief that it would ultimately be possible to allocate a precise function to every part of the cortex. This has proved not to be the case, and it must be admitted that large areas of the cortex do not possess such readily demonstrable functions, but might exercise general functions of some kind. Thus, large parts of the frontal lobes (areas 9 to 12) are quite unresponsive to electrical stimulation, and these areas on one side (notably on the right side) may be removed surgically without very evident effect. Removal of parts of the frontal lobes, or division of the thalamic connections of the lobes (frontal leucotomy) is an operation for relief of incurable anxiety states, and is often successful. Removal of the greater part of the areas 9 to 12 on *both* sides does, however, lead to general mental impairment and a change in personality.* Emotional reactions are changed, and the key to this change is perhaps in the important connections between the hypothalamus and the frontal cortex. Also, in children, disease of the pre-frontal area causes arrested mental development.

It has been suggested that these lobes play an important part in forming our habits of thought and behaviour and, in later life, in utilising the emotional drive to exertion and enterprise.† It seems, therefore, that these portions of the frontal lobes possess associative functions which are, however, probably shared by other areas of the cortex, so that they cannot, so to speak, be regarded as the seat of the "organ of mind." The association areas deal more or less as a whole with the complex processes that are interpolated between receipt of an impression and any consequent motor response.

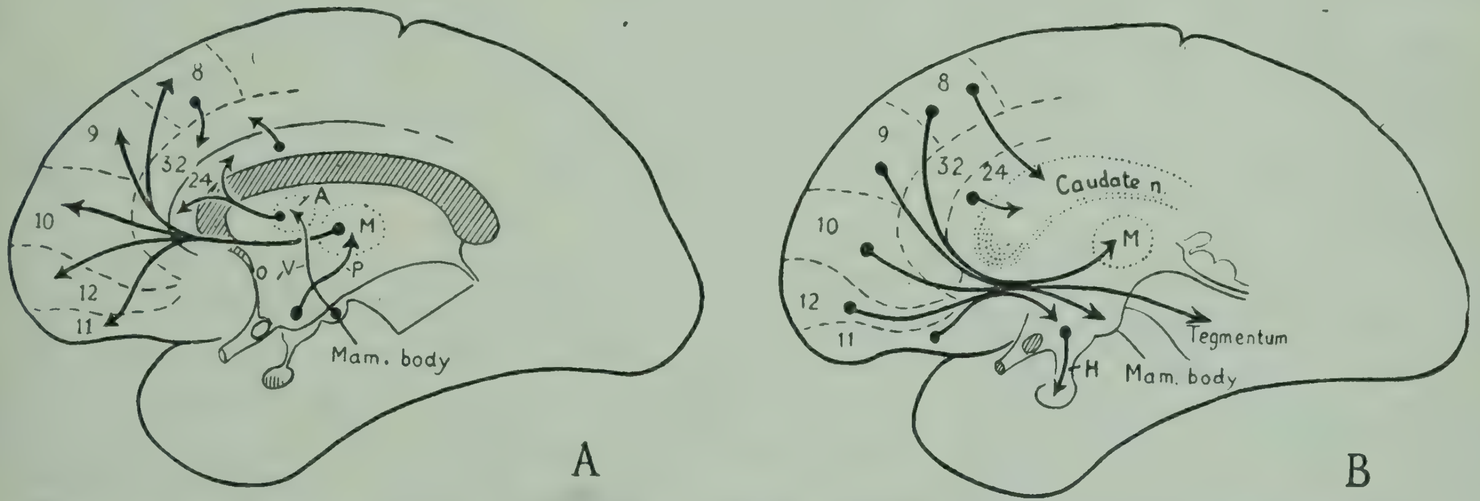

FIG. 208. Right cerebral hemisphere, medial aspect, showing (A) main afferent, and (B) main efferent connections of frontal lobes. Cortical areas are numbered. A, anterior, and M, dorsomedial nucleus of thalamus; P, fibres from hypothalamus; V, mamillothalamic tract (of Vicq D'Azyr); H, tract from hypothalamus to posterior lobe of pituitary. (LE GROS CLARK, *Lancet*, 1948, **254**, 353.)

Long association tracts passing backwards connect area 8 in the frontal lobe with area 18 in the occipital, and tracts also connect the frontal and temporal lobes. The frontal lobes are also receiving areas from various thalamic nuclei, of which some are relays from the hypothalamus: as shown in Fig. 208, these connections are both afferent and efferent.

It would seem that the frontal areas are important receiving areas from the hypothalamus, and thalamus; they are also efferent stations connected with various sub-cortical centres.

SENSORY AREAS IN THE CORTEX

The different types of afferent fibres that reach the cortex travel to definite areas according to their functions. It is curious that, for each locus of each sense there appears to be a double representation on either side: these are called, *e.g.* visual areas I and II, etc. The chief of these areas are in the parietal, temporal and occipital lobes.

To begin with general body or somatic sensations. These we have traced up from their origin on the opposite side of the body *via* the spinal, mesial and trigeminal lemnisci to the thalamus, at which level there appears to be a crude recognition of the particular quality of the sensation, coloured by an affective quality (*i.e.* a definitely painful or pleasurable property). Impulses are relayed on from the thalamus to the cortex of the parietal lobe, which they reach by passing through the internal capsule and corona radiata. The receiving area concerned is sometimes called the somæsthetic area.

The Somæsthetic Area. Its chief part includes the posterior lip of the fissure of Rolando and the greater part of the post-central gyrus lying posterior to it (areas 1 to 3). This post-central area has often been subjected to direct electrical stimulation in human subjects * with the result that sensations of numbness, pressure, touch or warmth were felt on the opposite side of the body, the actual place depending on the part of cortex stimulated. Thus, stimulation of the upper part of the area gave sensations in legs or feet; of the middle part sensations in trunk or arm, and of the lower part, sensations in face and head. More detailed examination has shown that the cortical representation closely follows the arrangement of the spinal dermatomes. Thus the order of sequence for the lower limb was hip, knee, ankle, toes (pre-axial surfaces), ankle, knee, hip, perinæum (post-axial aspects).† There was no special localisation of different types of sensation, but only representation of places stimulated.

According to some, sensation is also caused by stimulation of the corresponding parts of the anterior lip of the Rolandic fissure,‡ although, as we shall see later, this area (4 and 6) is also definitely motor. The explanation may be that what is represented here is proprioceptive sensibility from the muscles. Powerful excitation of the posterior parietal areas 5 and 7 may also produce sensation.

Another method of studying these areas in animals is by the local application of strychnine to the cortex.§ This causes an excitatory condition to spread out over the cortex from the place of application, and the animal responds by paying attention, *e.g.* by scratching, to the part of the body represented. The results are generally in agreement with those obtained on man. Yet another method is to record the potential changes on the surface of the brain when the skin is stimulated by any mechanical means, or when the dorsal roots are stimulated electrically, and to note from which regions characteristic waves can be recorded. This method shows that in addition to the areas in the upper part of the post-central gyrus (3, 1, 2) the dermatomal areas are also represented on the upper bank of the Sylvian fissure (area 7b). These areas are called somatic areas I and II respectively; they are reached by separate routes; somatic area II is also an extrapyramidal motor area.

Ablation of the areas concerned, or of parts of them, leads to loss of the finer grades of discrimination in sensation in the part represented ‖; but not to any complete loss of sensation. There is also clumsiness and inaccuracy in the movements of the parts concerned, and there is evidence that some of the cutaneous part of the sensations is bilaterally represented.

According to Head and Holmes the chief function of the somæsthetic area is the integration and critical examination of the crude sensory phenomena that are submitted from the thalamus. It thus has discriminative functions enabling us to form opinions regarding (1) relative *intensities* of sensations, *e.g.* of warmth ; (2) *spatial relationships, e.g.* the position of limbs, the exact locality of a skin stimulus ; (3) *similarities and differences* such as are arrived at by a synthesis of all the sensations involved. Thus we realise by touch similarities (or differences) of size, weight, texture. This is sometimes called *stereognosis*.

The size of an area on the cortex is not proportional to the area of skin from which it receives impulses, but rather to its delicacy and importance : thus, in man the areas which represent hands, lips, tongue and face are relatively large, and those for leg and trunk small : in the pig, the snout, in horse the nostril, and in sheep the lips are the areas where representation is most minutely cared for, and accordingly these areas are relatively large.*

The Auditory Centre. We have traced the fibres from the auditory nerve as far as the *medial geniculate body.* From this a new relay starts and, passing *viâ* the posterior limb of the internal capsule forms the *auditory radiation,* which ends in the auditory cortex in areas 41, 42. Not only is this sense served by the part of the cortex visible on the external surface of the temporal lobe, but also by cortex concealed from view (the gyrus of Heschl) in the depths of the Sylvian fissure. The cortex is divided physiologically into two parts, the audito-sensory area, and the audito-psychic area.†

The *audito-sensory* area (41 and 42) is largely hidden in the Sylvian fissure. A small part, however, is seen at the superior lip of the temporal lobe. Here the stimuli from the cochlea are interpreted as sensations of sound which vary in pitch, loudness and quality. The audito-sensory area is marked histologically by all its layers being very rich in both cells and fibres ; particularly is this the case with the outer layer of large pyramidal cells, which are both large and numerous. So also are the stellate cells in the layer just internal to this. These features are typical of the audito-sensory area. When sections are stained to show nerve fibres they exhibit a well-marked band running parallel to the external surface, *the line of Kaes.* The vestibular nerve has more important relations to the cerebellum, but it also has cortical connections with the temporal auditory area.

Electrical stimulation of the auditory area of one side in conscious human subjects gives rise to subjective noises in both ears ; and, because both sides are equally represented, a temporal lesion on one side, though it may cause some impairment of hearing, does not cause deafness.

There seems to be a spatial representation in the auditory cortex of the different parts of the cochlea. Thus, a low-pitched sound, which causes excitation of the receptors at the apex of the cochlea, or electrical stimulation of the fibres from that region, has been shown to produce electrical changes, signifying the arrival of nerve impulses, in the posterior part of the audito-sensory area.‡

The more peripheral portions of the auditory area in the lower two temporal gyri (area 22) form the *audito-psychic* area. Histologically, the cells found are small and there is no line of Kaes. This is an associative centre which is concerned chiefly with the appreciation of the significance of the sounds.

* ADRIAN. *Lancet*, 1943, **245**, 33.

† BREMER and DOW. *J. Neurophys.*, 1939, **2**, 308.

‡ WOOLSEY and WALZL. *Amer. J. Physiol.*, 1941, **133**, 498.

Stimulation causes auditory hallucinations and movements of the head to the opposite side. A special part of the superior and middle temporal convolutions on the left side (in right-handed people) is concerned with the understanding of speech, since failure of speech, or to understand spoken words, results from lesions in that situation (see Aphasia, Chapter XXVI).

The Visual Centre.* The cortical centre for vision is the "area striata" situated on the walls of the calcarine fissure (area 17). The visuo-sensory area on section shows to the unaided eye a conspicuous white striation known as the *line of Gennari* (fibre layer 4), which lies roughly midway between the two boundaries of the grey matter. It is formed by the interlacing dendrites of large stellate cells which replace the external layer of large pyramidal cells found in other parts of the cerebral cortex. This layer of large stellate cells is broad and is the most conspicuous feature of the visuo-sensory cortex. Other noteworthy features are the solitary giant pyramidal cells of Meynert, which are found forming a row of widely separated cells in the internal layer of large pyramidal cells.

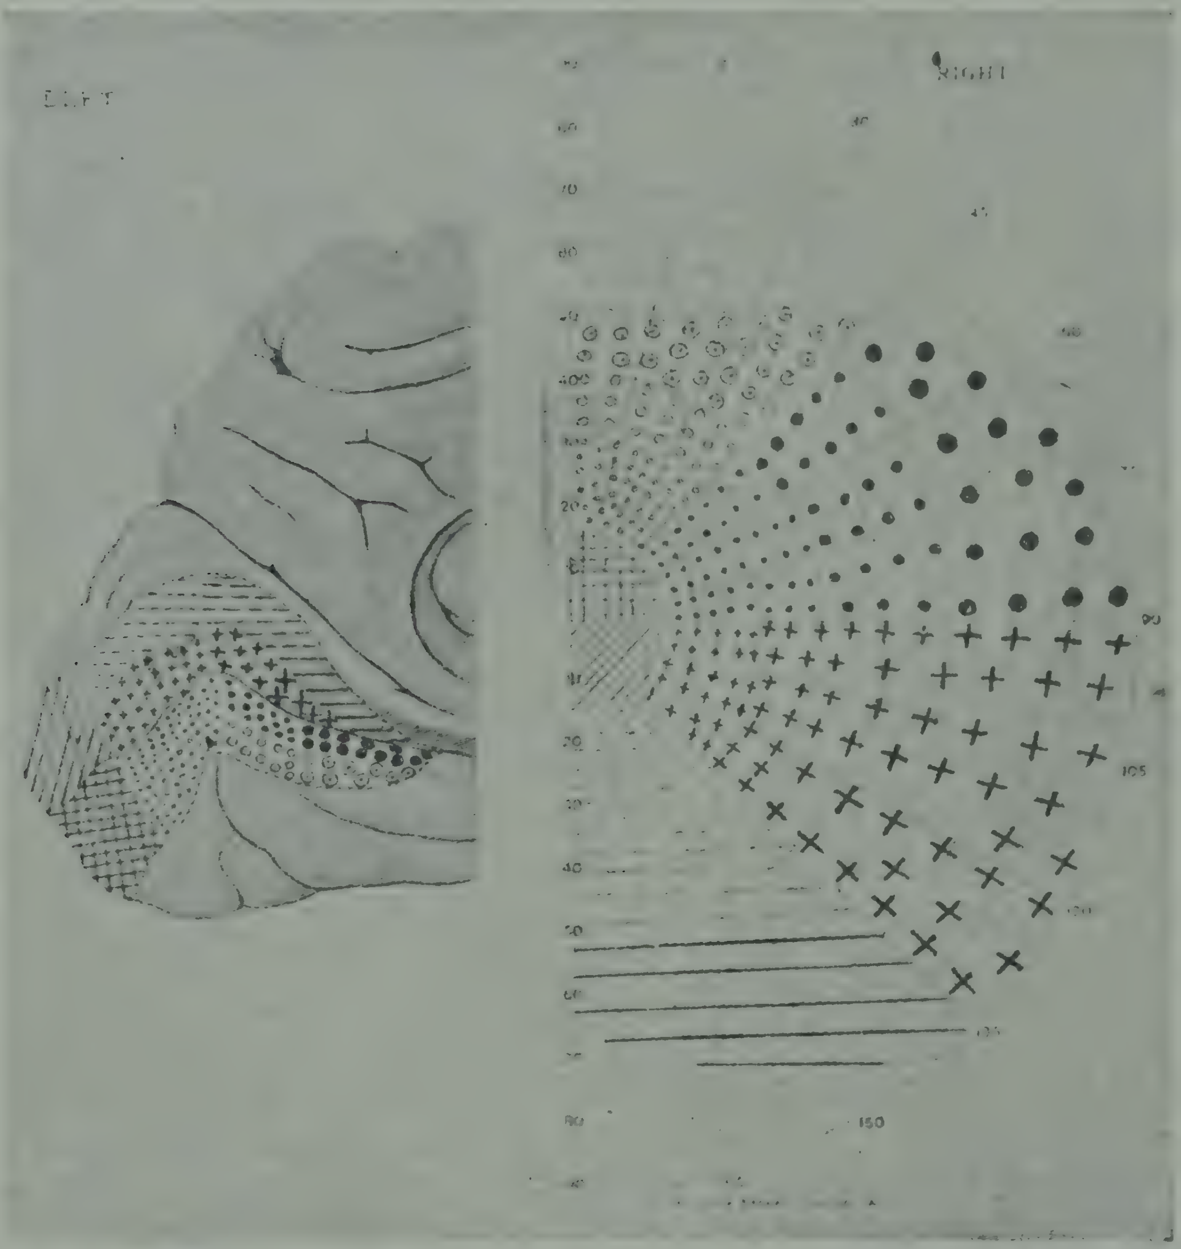

FIG. 209. The Relationship between the Field of Vision and the Calcarine Cortex. (After GORDON HOLMES.†)

To this area the fibres from the lateral geniculate body pass *viâ* the optic radiations (Fig. 198, p. 287) but exactly how they terminate is uncertain. The visual cortex on each side receives impulses from its own side of both retinæ, so that it is concerned, like most other cortical centres, with impressions arising from the opposite side of the surrounding world. There is fairly accurate spatial representation of retinal surfaces on the visual cortex (Fig. 209). Thus the upper quadrants of the peripheral retinæ are connected with the parts of the cortex above the calcarine fissure and the lower quadrants with parts below it. The macula is separately represented near the posterior occipital poles.

---

* GORDON HOLMES. *Proc. R.S.*, 1945, **132B**, 348.

† HOLMES and LISTER. *B. Med. J.*, 1919, ii, 193.

The histological delineation of the visual centre has been confirmed by the study of the electrical changes in the cortex when light falls on particular retinal localities in anæsthetised animals * and the projection of retinal areas on the cortical surface has been confirmed. It seems certain from these observations that when an image falls on the retina, a related image in the form of a pattern of electrical impulses is formed on the visual cortex.

Visual sensation is located in area 17, which is sometimes called the visuo-sensory area. Sensations of light and movements of the eyes result from stimulation of almost any part of the cortex surrounding the calcarine fissure. If the upper surface of the left calcarine zone be stimulated, both eyes move downwards and towards the right, as though light fell on the upper left quadrant of the retina from a source in the lower right quadrant of the visual field (Fig. 209). Excitation of the lower part causes movement of the eyes up and to the right for the converse reason ; while between these two parts there is an intermediate zone, most marked on the mesial surface, stimulation of which evokes a purely lateral deviation of the eyes to the left. Destruction of area 17 on one side causes *homonymous hemianopia*, *e.g.* if the right visual area is ablated there is loss of function of the right half of both retinæ which means blindness in the left half of the visual fields of both eyes.

The adjacent areas 18 and 19 and part of the posterior parietal area are concerned with the association of visual and other impulses. Here visual and tactile, and to a lesser extent auditory, impressions are correlated and synthesised to give proper visual perception and appreciation. A person born blind and having sight restored when adult is unable to understand the meaning of visual sensations until, by a process of re-education, these have been compared with the familiar tactile and auditory ones. Lesions in areas 18 and 19 in man result in disturbances of visual appreciation, so that written or printed words may lose their significance. Stimulation of area 19 causes visual hallucinations, and movements of both eyes to the opposite side.

Taste Centre. It now seems certain † that the cortical centre for taste is not, as long supposed, near to that for smell, but is represented on the cortical surface ; the nerves of taste (VII and IX) and those for somatic sensation from the face have a closely similar path. These nerves are fine and probably non-medullated. They pass to the nucleus of the *tractus solitarius*, from which relays pass by the mesial lemniscus to the posteroventral nucleus of the *thalamus*, and thence to the cortical area near to that receiving somatic sensory impressions from the face, *i.e.* about the lower end of the post-central gyrus.

Smell Centre. This is situated in the uncus and the anterior part of the hippocampal gyrus near to the auditory centre. Hence lesions in the temporal lobe often result in conjoint deficiency in hearing and smell. But the hippocampus is not entirely olfactory in function, and the central connections of this sense are still obscure.‡

MOTOR AREAS OF THE CORTEX

The areas of the cortex, the stimulation of which results in co-ordinated movements, are called *motor areas*. The most important ones are in area 4 and the posterior part of area 6, which are motor areas proper. Area 4 in man occupies the anterior lip of the fissure of Rolando, and area 6 most of the remainder of the precentral convolution. The areas extend on to the mesial surface of the hemisphere.

‡ Brodal. *Brain*, 1947, **70**, 179.

Other Motor Areas. Movements can be excited by stimulation of various other cortical areas in addition to the precentral ones described above. The chief of these (Fig. 207) are :—

(1) Various areas in the lower part of area 6 cause movements of mouth, larynx, arrest of breathing, etc.
(2) The so-called "frontal eye-field" (area 8) causes conjugate deviation of eyes and head to the opposite side.
(3) Area 19 in the occipital region gives constriction of pupil, and, if strongly stimulated, conjugate deviation of eyes to opposite side.
(4) The post-central area (3–1–2) in the parietal lobe yields movements similar to those obtained from corresponding levels of area 4. These results in man are accompanied by sensations in the parts served, and are perhaps due to irradiation to area 4.
(5) Area 5 of parietal lobe and area 22 of temporal lobe may also cause adversive movements of head and eyes, also probably a secondary effect of sensory stimulation.

Of these areas, the frontal eye field is the most definitely related to voluntary movements, since ablation of that area leads to impairment of eye movements. The other areas are perhaps largely reflex in function, and concerned with postural reflexes, and such automatic acts as respiration, pupillary constriction, vocalisation, etc.

The following facts show that on cortical stimulation the seat of the excitation is in the grey, and not in the white, matter :—

(1) A smaller strength of current is required to excite the grey than the underlying white matter.

(2) Inexcitability of the grey matter can be produced by painting it with cocaine.

(3) The latent period between stimulation and movement is longer when the grey matter is excited than when a stimulus is applied to the white matter.

There is evidence that the stimulus acts directly on the pyramidal cells of layer V of the cortex, or on the endings of the afferent nerves to it.

Stimulation of Motor Centres. The earlier stimulation experiments were made on the lower mammals, in which the anatomical relations are somewhat different and need not be considered here, but valuable information was obtained from them, and was extended and applied in experiments on monkeys and apes.* Ultimately many experiments have been carried out on the human subject,† and these have confirmed the inferences drawn from the work done on the apes. In man the localisation, though not punctate in precision, is fairly well defined, especially in area 4.

If a part of the precentral convolution be stimulated with a weak faradic current, movements are produced on the *opposite* half of the body, the site of the movements depending on the locality of the spot stimulated.

We may say broadly that, by stimulation of the precentral convolution at a series of points from above downwards, we get movements in that order of the leg, arm and face ; though, as is shown in the diagram (Fig. 207), within these larger areas smaller areas can be distinguished for definite co-ordinated movements of the smaller parts of the body. Those portions of the limbs, such as the fingers and thumbs, which execute delicate movements have larger areas of representation in the cortex than those whose movements are less precise. This means that the number of muscle fibres in a motor unit is smaller when the muscle is capable of delicately adjusted movements, and hence a larger cortical area, with more motor pyramidal cells, is needed to innervate it and its associates.

Representation is not of muscles, but of movements, *i.e.*, the movements obtained by excitation of the motor areas resemble in every respect the co-ordinated movements observed during the normal activity of the animal, and involve the reciprocal innervation of antagonistic muscles. The movements are organised by co-ordination of muscular contractions in both time and space. Never do we find simultaneous contractions of antagonists, even where two opposing centres are excited simultaneously ; one reaction is prepotent, as is the case with reflexes.

* Grünbaum and Sherrington. *Proc. R. S.*, 1901, **69B**, 206 ; 1903, **72B**, 152 ; Leyton and Sherrington. *Q. J. Exp. Physiol.*, 1917, **11**, 135.

† Bidwell and Sherrington. *Brit. Med. J.*, 1893, (ii) 988 ; Penfield and Boldrey. *Brain*, 1927, **60**, 389.

Thus the movement of opening the jaw, excited from the cortex, involves a relaxation of the normal tone of the masseter muscle. Flexion of the leg demands relaxation of the extensor muscles. As in the spinal reflexes, this relaxation can be abolished under the systemic action of strychnine or of tetanus toxin. Excitation of the cortical centre for the movements of the jaw then causes contraction of both closers and openers of the jaw, *i.e.* the stronger masseter muscles predominate, so that the jaw is firmly closed.

The part played by muscular relaxation in the response to cortical stimulation is also well seen in the eye muscles. Stimulation of the centre for eye movements on area 8 of the frontal lobes on the right side causes " conjugate deviation " of both eyes to the left. This movement involves contraction of the right internal rectus and left external rectus and a simultaneous inhibition of the tone of the right external rectus and left internal rectus. If all the nerves of the right eye be divided except the VIth, which supplies the external rectus, this eye looks permanently towards the right side, *i.e.* a right external strabismus or squint is produced. On now exciting the right cortex, *both* eyes still move towards the left, although the right internal rectus is paralysed. The movement of the right eye stops at the middle line, however, and is brought about simply by a relaxation of the tone of the right external rectus muscle. (Sherrington.)

This movement of both eyes on stimulation of one side of the brain shows that the function of each hemisphere is not entirely unilateral with regard to the muscles of the body. As a rule, the response to excitation of the motor area for limbs is only contralateral. In the case of those movements, however, which are normally carried out by co-operation of the muscles of the two sides, such as the movements of the trunk, neck, and eyes, stimulation of the motor area in one hemisphere evokes a movement involving the muscles of both sides of the body, *i.e.* the cortical representation is one of movement rather than one of muscles. Also, where an action is carried out by similar contractions of corresponding muscles on the two sides, the movement itself is bilaterally represented in the cortex. Types of such reactions are found in closure of the mouth, contractions of the abdominal muscles, extension or flexion of the trunk. It seems that under such circumstances there is a free communication between the lower motor centres of the two sides, since the bilaterality of the response is not altered by extirpation of the cortex of the hemisphere opposite to that which is being stimulated.

A certain antagonism is evident between the action of the cerebral hemispheres and that of the lower centres. Whereas in the decerebrate animal there is increased tonus in the extensor muscles, stimulation of the cortex produces flexion more easily than any other movements.

The *kind* of response to excitation is never predictable ; the same point may at one moment give flexion and at another extension. Moreover the response can vary according to the immediately preceding history of the area stimulated. Sub-threshold stimuli may be facilitated and so rendered adequate by preceding weak stimuli.* When a point is repeatedly stimulated for short periods, the resultant movement becomes larger and larger (" primary facilitation ") ; moreover, the area of cortex from which that movement can be evoked grows in size, and spreads into neighbouring areas that previously gave other responses. This is called the " deviation of the response," and is due to an irradiative facilitation (" secondary facilitation "). It probably means that a given movement, although represented by large numbers of pyramidal cells in the usual " area " of representation, is also represented by cells in other areas, *i.e.* there is considerable overlap. Such deviated responses may occupy large areas of the cortex.†

Under some conditions, cortical stimulation is followed by a period of *subnormal* excitability. This is called " extinction."

Stimulation of points in area 6 in man gives movements in the same parts as is obtained by excitation of the adjacent portions of area 4, but stronger stimuli are needed, especially at the rather diffuse anterior edge of the motor area. Stimulation of area 6 greatly facilitates the responses from area 4 ; it seems likely, therefore, that the cells responsible for motor representation become more sparse as we pass forwards in area 6, and finally vanish along an indefinite boundary line. If the pyramidal tract has been divided, or area 4 destroyed, it is claimed that strong excitation of area 6 still produces general adversive movements, *i.e.* rotation of head, eyes and trunk to opposite side.

---

* Graham Brown. *Q. J. Exp. Physiol.*, 1916, **10**, 103.

† Graham Brown and Sherrington. *Proc. R. S.*, 1912, **85B**, 250.

It is claimed by Fulton, Foerster and others that area 6, which they call the *pre-motor area*, is not only connected *viâ* area 4 with the major projections of the pyramidal tracts, but also has other connections, the so-called extra-pyramidal paths, with the spinal motor neurones. Others, *e.g.* Walshe,* regard area 6 as a region for synthesis of movements executed *viâ* the pyramidal system, and therefore as a higher level of motor control. The movements are more precise and more nearly confined to one muscle the nearer the stimulated point lies to the central fissure, *i.e.* the closer to area 4. As area 6 is approached the movement tends to become that of a whole limb.

Cortical Epilepsy. When electrical excitation at any strength above the minimum effective stimulus is applied to the motor area of the cortex, the movements evoked tend to persist for a short time beyond the duration of the stimulus. This is readily understood to be due to the same causes as produce after-discharge in spinal reflexes, viz. deviation of impulse along delay-circuits. On still further increasing the strength of the current, the contraction spreads to adjoining muscles, and finally may affect all parts of the body, giving rise to an epileptiform convulsion. The same effect may often be caused by weak stimuli if the irritability of the cortex be raised in consequence of previous repeated stimulation. The fit consists of two parts. The first effect of the stimulation is a strong tonic contraction ; this outlasts the stimulus for some time, and then gives way to a series of clonic contractions, repeated at first at intervals of from six to ten per second, but gradually getting slower as the fit dies away.

The main phenomena of a "convulsion beginning unilaterally," due to irritation of any portion of the motor area, were described by Hughlings Jackson in 1864, before the experimental proof of cortical localisation had been brought forward by Fritsch and Hitzig. They may occur in the human subject as a result of irritative lesions of this part of the cortex, such as that due to the presence of a tumour or a spicule of bone pressing on the brain. They commence in one of three predominant foci, viz. thumb, angle of mouth, or hallux. Jackson showed that in this condition the convulsive movements follow a certain order or "march." Thus, if the thumb area be the seat of stimulation, the fit begins by a contraction of the thumb muscles, then spreads to the muscles of the hand, fore-arm and shoulder of the same side, and then to the face, trunk and leg. If it begins in the toe, the order would be up the leg and trunk and down the arm. The same "march" is observed in artificial stimulation of the motor area, and the explanation is similar in both cases, viz. the excitation spreads by the overlapping of cortical fields, and "deviation" follows in a predictable sequence.

Suppressor Strips. Certain areas of cortex on excitation lead not to muscular movement, but to the *suppression* of any contralateral movement. The chief of these is called area 4s, which is a narrow band between areas 4 and 6. Other suppressor strips are 2s, 8s and 19s. These are instances of the complex relations between one part of the cortex and another. The mode of action of the strips is discussed later.

Ablation of Motor Areas. The results of ablation of the motor areas are more serious in man and the higher apes than in lower mammals. In the cat or dog, for instance, removal of the motor areas on one side results in nothing more than a transitory paralysis and spasticity of the musculature on the opposite side of the body.† The effect is greater and lasts longer on the fore limbs, but in a few days the paralysis nearly disappears and only a little weakness and loss of skilled movements remains. The spasticity is an extensor rigidity and lasts somewhat longer than the paralysis. Bilateral removal of the accredited motor areas is also not followed by lasting paralysis and we may take this to mean that the more diffuse and less excitable motor centres are brought into function.

In the higher apes ‡ and in man § the results are more serious and long-lasting. Thus, if the left arm area (4b) is removed from a chimpanzee, after having its situation verified by electrical stimulation, there is at first loss of reflexes, and complete and flaccid paralysis of the right arm. After a period which varies from days to weeks there is a progressive partial return of function from the shoulder downwards, the hand never recovering its finest movements completely. If the arm area on the right side is removed at this stage no effect is seen on the left arm. These observations have been interpreted by some as showing that there is some other motor centre and some path other than the pyramidal tract by which movements are controlled. Opinion is not unanimous on this, however.

† Laughton. *Amer. J. Physiol.*, 1928, **85**, 78.

‡ Ferrier. *Phil. trans.*, 1875, **165**, 433 ; Leyton and Sherrington. *Q. J. Exp. Physiol.*, 1917, **11**, 135 ; Grünbaum and Sherrington. *Proc. R. S.*, 1903, **72B**, 152.

§ Foerster. *Brain*, 1936, **59**, 135.

When in man, or one of the apes, the whole of the precentral motor area (*i.e.* areas 4 and 6) are removed on one side, the affected limbs on the opposite side are paralysed, and their reflexes are at first depressed; in a few days, however, spasticity may develop and extensor reflexes become exaggerated.[*] Voluntary power returns partially in a few days, but is lost again, and permanently, if the motor areas of the opposite side are removed. The posture of the animal then resembles that of the decorticate or thalamic preparation. The effects of removing area 6 (the "premotor" area) alone is also stated to be to cause spasticity and exaggerated extensor reflexes, with involuntary grasping movements of the hands.

These results are capable of at least two explanations. According to Walshe[†] the precentral motor areas comprise both area 4 and area 6, of which area 6 represents a higher level of function, largely associative in character. Spasticity only develops when the pyramidal tract is almost or completely severed from the whole area. Fulton, on the other hand, regards area 4 as the principal area of origin of the pyramidal tract, and area 6 as not only contributing to the pyramidal tract directly, and also indirectly by association with area 4, but also regards both areas, but chiefly area 6, as having other important connections with lower centres. These are called the extra-pyramidal paths and will be referred to later.

Other words indicate position of fibres for movement of parts or fibres for sensations indicated. These fibres mostly pass vertically to plane of paper. (SAMSON WRIGHT. "Applied Physiology," Oxford University Press.)

EFFERENT (OR CORTICO-FUGAL) PATHS

Two types of projections leave the cortex to proceed to lower centres, viz. the pyramidal and allied tracts which proceed to motoneurone pools in the bulb or spinal cord; and "extra-pyramidal" projections, which pass in the first instance to sub-cortical stations.

I. **The Pyramidal or Cortico-spinal Tract.** As we have seen (p. 226), this tract is of mixed origin, from areas 4 and 6, from the parietal lobe, and possibly from sub-cortical regions.

The "upper neurone" fibres of the pyramidal tract pass by the corona radiata through the internal capsule, mid-brain, pons, medulla and spinal cord, to end mainly in relation to contralateral dorsal horn cells, from which impulses pass *viâ* intermediate column cells to motoneurones of the ventral horn of the cord.

The *internal capsule* is a band of fibres lying between the lenticular nucleus laterally and the thalamus and caudate nucleus medially. The position of the various motor and sensory fibres in the internal capsule is shown in Fig. 210. The motor fibres occupy the genu and the anterior two-thirds of the posterior limb, the fibres in order from before backwards being eyes, head, shoulder, arm, hand, trunk, leg, foot.

Sp., Vestibulo-spinal tract.

The motor fibres pass on as a compact mass (Fig. 211), forming the middle portion of the descending main pathway which passes through the crusta of the mid-brain ventral to the substantia nigra. Retaining the same situation, they reach the pons. They are here split up into discrete bundles by the cross passage of the pontine fibres. On leaving the pons and entering the medulla they form into two bundles once more. At the lower part of the medulla the main mass of fibres decussates to reach a more lateral position (the motor decussation), forming the lateral cortico-spinal or crossed pyramidal tract (about 10 per cent. of its fibres are not crossed however). A remnant of fibres, which is called the anterior cortico-spinal, or direct pyramidal tract, is left behind, close to the anterior fissure. Both direct and crossed pyramidal tracts descend in the cord in these two situations, turning in at different levels to relay at dorsal horn cells, the crossed ones to cells of the same side, the uncrossed ones to cells of the opposite side. In this way, fibres that have originated in the motor area on the one side of the brain ultimately innervate anterior horn cells which send fibres to muscles on the other side of the body.

Although the pyramidal tract is regarded as the principal motor path, section of the tracts at the level of the pyramids does not result in complete motor incompetence in lower animals. In the cat, for instance, Liddell found automatic movements normal, but skilled movements, *e.g.* walking along a ladder, impaired. If the motor cortex is also removed skilled movements are quite impossible. In man (*v.* p. 233) the effects of pyramidal section are more serious and complex.

Various collateral paths are formed from the pyramidal tracts. The chief of these are to the nuclei pontis, from which fibres pass in the middle peduncle to reach the cerebellum on the opposite side. Other branches of the tract cross in the mid-brain, pons and medulla to reach the motor nuclei of cranial nerves on the opposite side.

II. **The Extra-pyramidal System.** The evidence obtained from ablations of the precentral cortex in man and the higher apes, together with some clinical evidence, points to there being other efferent paths besides the pyramidal tracts by which the cortex is connected with lower motor centres. Thus, the eye movements controlled from area 8 in the second frontal convolution, and the complex movements of body and limbs obtained from area 6 of the precentral area, are obtainable after section of the pyramidal tracts. These so-called extra-pyramidal tracts still remain somewhat obscure, but those for the trunk and limbs appear to have important connections with the basal ganglia. The chief extra-pyramidal projections, some of them non-medullated, are to :—

(1) *The reticular formation* of the brain stem, from all four lobes, but chiefly from areas 4, 6, and 3, 1, 2.

(2) *The substantia nigra, red nucleus* and other grey matter of the brain stem.

(3) *The corpus striatum*, especially from the cortical suppressor bands to the caudate nucleus.

(4) *The thalamus* from all four lobes.

(5) *The hypothalamus.*

Some will relay at more than one of these stations.

The simplest of them is the path from the frontal eye field, called the *cortico-nuclear* tract. The fibres pass in the anterior limb of the internal capsule, with the fronto-pontine fibres, thence in the mesial fifth of the crusta of the mid-brain, from which fibres pass dorsally to the oculomotor nuclei of the opposite side. There is little difference, beyond anatomical detail, between this path, or paths to bulbar motor nuclei, and the pyramidal path.

The other cortical projections have a more complicated pathway and function. They arise from the motor areas, which all include some extra-pyramidal projections, in addition to pyramidal ones, *e.g.* from the precentral areas, and especially from area 6.

Thus after section of the pyramidal tracts, a flaccid paralysis results, and stimulation of area 4 then gives movement, or, more usually, an inhibition of any postural tonus.[*] Impulses passing along the extra-pyramidal projections seem especially to exert a modifying influence, which may be either inhibitory or facilitating, upon the lower motor neurones, rather than themselves to excite those neurones. This may be demonstrated by eliciting a movement, either reflex or by cortical excitation, at regular intervals, and then studying the effect on that movement of applying stimuli to the reticular formation of the brain stem, or other cell stations on the extra-pyramidal path. As shown in Fig. 212, the result of such stimulation is to abolish, or to enhance, the movement, according to the region stimulated (Fig. 213). The most common result is inhibition, but by hypothalamic stimulation facilitation can be obtained.[†]

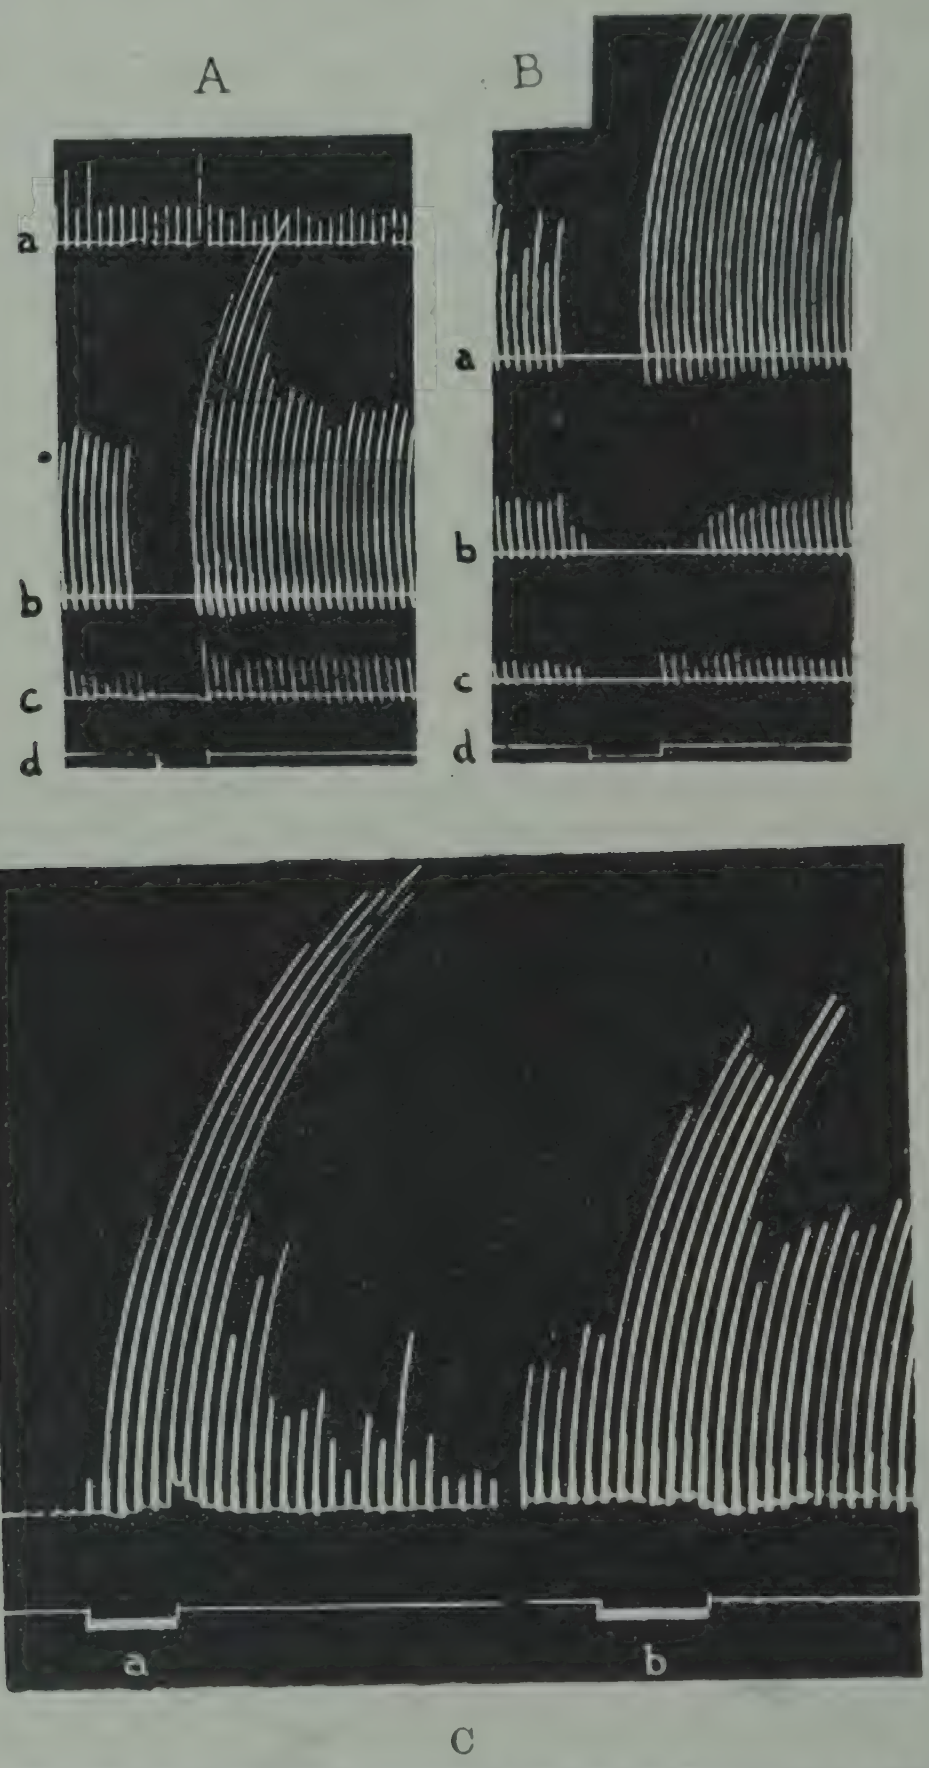

Fig. 212. A, B, Effects of stimulation of reticular formation of brain stem on flexor reflex (a), knee jerk (b), and blink reflex (c) evoked at 2 sec. intervals. Bulbar stimulation at line (d). C, Effects of stimulation of hypothalamus on response to cortical motor response (a) and patellar reflex (b). The experiments were on monkeys. (Magoun. *Quart. Bull. N.U.M.S.*, 1946, **20,** 180.)

It is probable that the extra-pyramidal path is interrupted by one or more relays, and finally ends at the motor cells of the lower motor neurone, as diagrammatically suggested in Fig. 213. The reticulo-spinal, tecto-spinal and rubro-spinal tracts are examples of large bundles of fibres having extra-pyramidal functions. The reticulo-spinal tracts convey both facilitatory and inhibitory impulses, the former lying more dorsally, and arising from cells higher up in the brain stem than the latter.* The suppressor strips and area 6 are important cortical areas from which extra-pyramidal paths originate, and some of these fibres have relays in the reticular formation, etc., and are inhibitory in action; but probably most other cortical areas contribute to the system. Damage to area 6, according to this view would result in spasticity by leaving the lower motor neurone in a state of release.

[†] Magoun and Rhines. *J. Neurophysiol.*, 1946, **9,** 165.

Kinnier Wilson † pointed out that destruction of the corpus striatum in man may give rise to a condition (Parkinson's disease), characterised by tremor and weakness in the execution of willed movements and increased tonicity of the muscles. He therefore ascribed to these bodies, or rather to the sensori-motor mechanism which has its chief meeting-place in their nuclei of grey matter, a steadying effect on the motor system.

The condition of hypokinesia, or weak movements can be reproduced experimentally in monkeys by lesions in the globus pallidus or hypothalamus; we may suppose then that in Parkinson's disease it is the facilitating pathway that has been eliminated, leaving the lower motor neurone unduly inhibited.

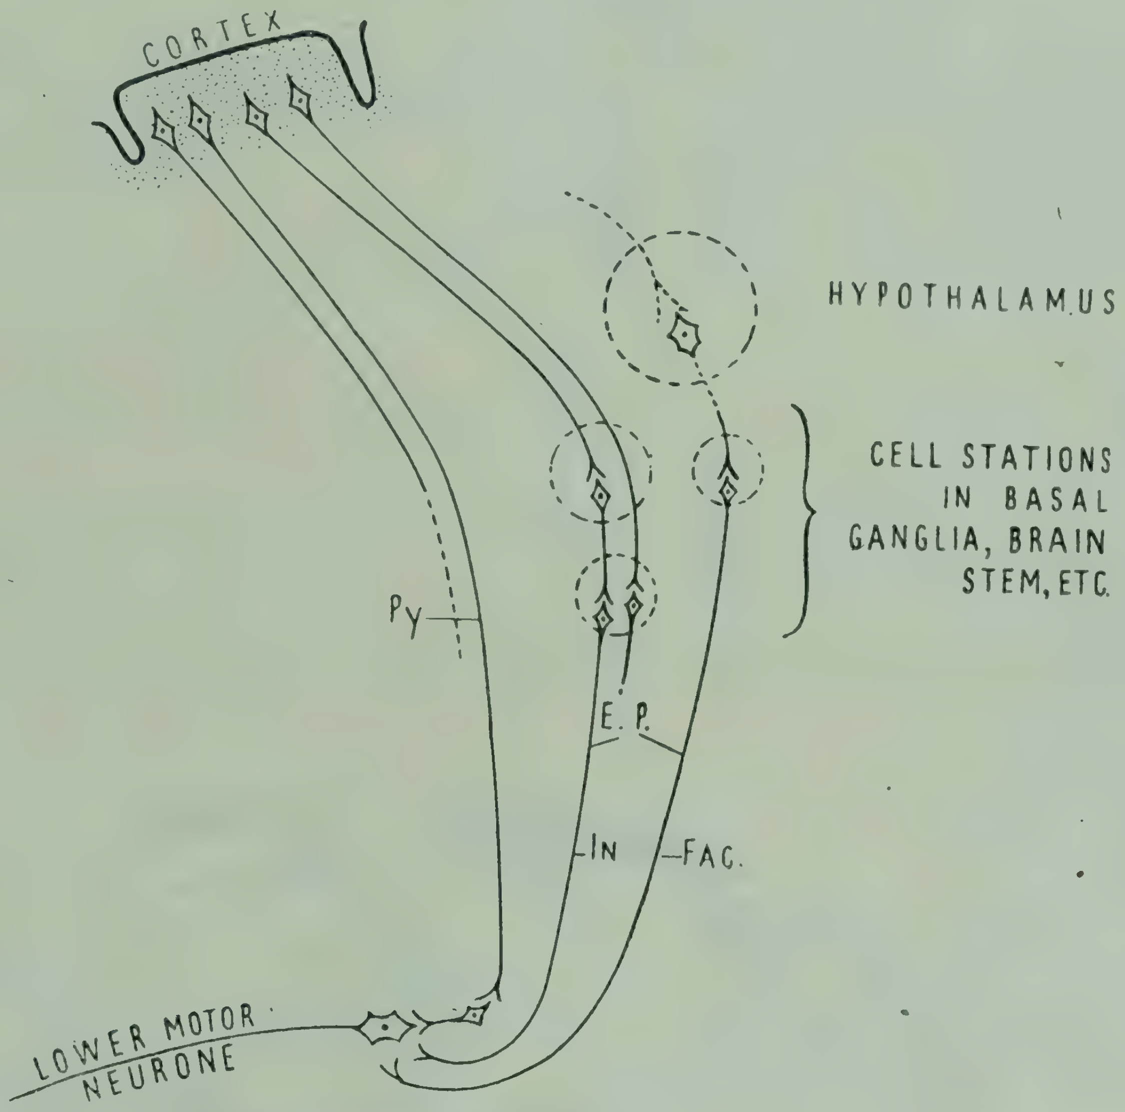

FIG. 213. Diagram of Pyramidal and Extra-pyramidal projection systems. *Py*, pyramidal; *E.P.*, extra-pyramidal. *In*, path producing inhibition of lower motor neurone; *Fac*, path producing facilitation.

It will be seen that there are important connections with the basal ganglia.

Functions of the Basal Ganglia. The basal ganglia include:

(1) The corpus striatum.
    (i) Caudate nucleus.
    (ii) Lenticular nucleus.
        (*a*) The putamen.
        (*b*) The globus pallidus.
(2) The claustrum.
(3) The amygdaloid nucleus.
(4) The body of Luys.

The relations of the lenticular nucleus are shown in Figs. 210 and 215.

The basal ganglia receive important afferent connections from the cortex, but these were missed for a long time because they are non-medullated.‡

‡ GLEES. *J. Anat.*, 1944, **78**, 47.

Attempts to produce effects by stimulation also failed, until it was realised that the results of stimulation were inhibitory and not motor. If any movement due to cortical action is in course, *e.g.* as a result of stimulating area 4, stimulation of the caudate nucleus or globus pallidus will at once arrest it. As has been stated above, such a result can be got by the action of extra-pyramidal systems which can inhibit the lower motor neurone, and part of the effect is to be explained in that way. But the inhibitory action is also one upon the cerebral cortex itself. Light was thrown on the functions of the basal ganglia when, in studying the action of the suppressor strips already referred to, Dusser de Barenne and McCulloch * followed the action potential which resulted when the strip, *e.g.* area 4s, was stimulated, *e.g.* by local strychnine application. They found that as a result of this the caudate nucleus became active; this then passed on impulses to the globus pallidus and this again to the thalamus. From the thalamus, the impulses passed back to the related motor area, *e.g.* area 4, which was thereby inhibited (Fig. 214). In this manner the basal ganglia could play an important part in regulating and controlling muscular responses,

* DUSSER DE BARENNE and MCCULLOCH. *J. Neurophysiol.*, 1941, **3**, 311.

but they no doubt have other important functions, and very flexible and varied connections. Electroneuronography is such a sensitive method that it tells us whether *any* neurones connect in a given way rather than whether a given path is a quantitatively important one, and so exposes to the risk of finding what we look for.

The motor projection areas 4 and 6 also have connections, *e.g.* with putamen and globus pallidus, and *viâ* these with the substantia nigra, nucleus of Luys, and hypothalamus, and other extra-pyramidal stations, but it is not yet known whether these connections mediate any controlling influence on the cortex in the way that the caudate nucleus does.

The balance of probability seems to be that muscular responses are controlled in a variety of ways—by reflected action on the cortex, by action through extra-pyramidal projections on the lower motor neurone, and, of course, through spinal reflex mechanisms, such as the stretch reflex.

Lesions of the Motor Paths in Man. The pyramidal path comprises three neurones. The first, called the *upper motor neurone*, starts in a pyramidal cell of the cortex and ends at the second, an intercalated neurone in the dorsal horn of the cord, which passes on to a motor neurone in the ventral horn, and this third, or *lower motor neurone*, comprises the spinal motor neurone and its axon enters one of the motor nerves. It has long been recognised by clinicians that the effects of section of the upper and lower motor neurones differ greatly. Lower motor neurone lesions, *e.g.* by cutting the motor nerve, or by destruction of the motor nerve cell bodies, as in the results of poliomyelitis, produce permanent flaccid paralysis and subsequent wasting of the muscles.

Lesions of the upper motor neurone as a rule produce quite other results. If the lesion is in the cortex the result will depend upon its position and extent. These have already been considered ; the main point is that at least partial recovery occurs, but spasticity appears and persists if the lesion is extensive.

Mere section of the pyramidal tracts apparently leads only to a flaccid paralysis,* whereas destruction of the motor path in the internal capsule by a hæmorrhage results in a spastic condition. The commonest site for lesions of the upper motor neurone in man is in the internal capsule, the cause being thrombosis in, or rupture of, the small arteries that supply it (apoplexy). The result, if on one side, is a paralysis of the muscles of the opposite side, the situation depending on the actual site and extent of the lesion. Often it is a general paralysis of one side (hemiplegia), the right-sided paralysis due to a left-sided lesion being accompanied by loss of speech. Respiration and other involuntary movements, *e.g.* some postural reflexes, are little affected, and muscles that act on both sides, *e.g.* eyes, trunk, etc., suffer only slight loss of function.

At first, in hemiplegia, the paralysed muscles are flaccid, but after a stage of shock has passed off, certain muscles become spastic. By spasticity is meant stiffness, highly active reflexes and a tendency to a clonic response on sudden stretching. The knee-jerk is more sustained than normal, a Babinski plantar reflex is obtained, there is often ankle-clonus, and characteristic limb attitudes, at first of extension in legs and flexion in arms, later of spastic flexion, also in legs. These are similar to the ones described under decerebrate rigidity (p. 274), and the explanation is no doubt similar, viz. that the rigidity is due to release from some higher control.

It is difficult to see why the upper motor neurone lesion should give a state of tonus so different from that resulting from lower motor neurone lesions, unless we admit that there is also damage to neurones other than those of the pyramidal tract but which also play upon the final common path of the lower motor neurones. This is generally admitted for the condition of decerebrate rigidity, and in totally decorticate animals, etc., where quite complex motor reflexes can be carried out. We must suppose, therefore, that the spasticity is the result, not of the interference with the pyramidal path, but of damage to the extra-pyramidal paths which run near to them, and which normally inhibit that overaction of lower reflex centres, which in its most developed form is recognised as decerebrate rigidity.

The Part played by Afferent Impressions in the Co-ordination of Muscular Movements. As a result of the carrying out of muscular movements, impulses are set up in the proprioceptive structures, including those of muscles. These secondary afferent impulses in their turn affect the excitability and the activity of the motor neurones, and are important in regulating the movements, whether these be aroused reflexly or volitionally.

When, in a mammal, a contraction of the quadriceps extensor is induced by a single shock applied to the intact ant. crural nerve, the curve obtained shows a relaxation time much slower and more prolonged than when the cut nerve is similarly excited, or when the posterior roots alone are divided. The contraction of the muscle, when its afferent path is intact, seems to develop reflexly in the muscle itself a condition of tone which damps down the relaxation. In the dog, after section of the afferent nerves of one hind limb, this limb is not at first used for walking ; it is kept more or less flexed at hip and knee, and later, when it is employed in walking, it is lifted too high with each step. After division of the afferent fibres of both limbs, these appear as if they were affected with motor paralysis. At first during walking, the fore limbs simply drag the hind limbs after them, though later, as the hind limbs are drawn along, they make alternate movements and may ultimately afford a certain amount of support to the body.

Still more striking effects are observed in complete deafferentation of the fore limb in monkey or man. The limb is never used in climbing, nor in the taking of food. That the peripheral motor mechanism is intact is shown by the fact that stimulation of the appropriate area of the cerebral cortex in such animals elicits at once a movement of the hand or limb. It seems, however, impossible for the cortex to *initiate* such movements in the absence of all afferent impulses arriving from the limb.

In these phenomena of sensory paralysis we are dealing with the effects produced by the deprivation of two distinct classes of afferent impressions, viz. those from the skin and those from the deep structures and muscles. The phenomena due to these two factors may be studied separately. Cutaneous insensibility of a limb of an animal causes very little disturbance of locomotion, the alternate movements of which seem to be regulated by the stimulation of deep structures and muscles. If, in the monkey, all the afferent brachial roots except the last cervical, which supplies cutaneous sensations to the whole hand, be divided, the monkey uses the arm and hand both in climbing and in taking food. A marked ataxy of the movement is, however, observed. Whereas the normal monkey, in taking grains of rice out of the observer's hand, exhibits perfect precision of movement, the monkey with only cutaneous sensibility remaining grasps clumsily with the whole hand, and the arm sways as it is put out, often missing the object aimed at altogether. These effects are due to the loss of sensations from the deep structures and muscles. Division of the afferent nerves from the muscles gives rise to a condition of tonelessness, and the passive mobility of the joints is greater than usual, so that the hip with the limb extended at the knee may be flexed to an abnormal extent.

The disturbance of co-ordination resulting from the cutting off of afferent muscular impressions is well seen in cases of tabes dorsalis (locomotor ataxy) in man, and to a slighter extent in cases of peripheral neuritis affecting chiefly the sensory nerves of muscles. The ataxic gait of such a patient is characteristic. There is no loss of power in the muscles, but there is loss of control. The patient is unaware of the position of his limbs and has to guide his walk by visual impressions : even then the movements are inco-ordinated. The contraction of every muscle is exaggerated, so that in walking the leg is first raised too high and then is brought down on to the ground with a stamp.

Such a patient may show "static ataxy," *i.e.* he is unable to stand with his feet together and his eyes shut. The afferent impressions from the skin of the feet, and from the muscles, appear therefore to be necessary also for the maintenance of static equilibrium. As the disease progresses the loss of control becomes more and more pronounced. The impressions are wanting which should cut short the contraction of a muscle when it has attained its optimum and which should inhibit the antagonists during the contraction and induce activity of the antagonists in successive alternation to those of the other muscles. In such a patient, therefore, walking finally becomes impossible, and, with well-nourished muscles and a motor path which is intact, he is condemned to pass the rest of his days in bed.

CHAPTER XXI

FUNCTIONS OF THE CEREBRAL CORTEX

From the evidence which has been reviewed it may be inferred that parts of the cerebral cortex act as final receiving stations for the afferent impressions from all parts of the body, including the organs of special sense, while other parts act as stations of origin for motor and other efferent impulses. A simple view of one of its functions would be that it acts as a centre in which, as in the spinal reflex centres, afferent impulses are reflected outwards as motor impulses. But we know also that the cerebral cortex is the seat of all the higher activities of the mind. In particular the frontal areas are concerned with these associative functions. The study of these belongs to the province of psychology, which employs methods different from those of physiology for its approach. Accompanying the passing-over of impulses from the afferent to the efferent side of the cerebral arc, it would seem that the state which we call consciousness is engendered. The states of consciousness glide continually from moment to moment in an unbroken stream of experience, consisting of a sharper focal content with a fringe of slighter definition, and leaving behind it a trace which we know as memory. By a process of attention we can single out parts of the stream of consciousness for closer focussing.

There seems but little doubt that our conscious experiences are the result of complex integrations of sensory impressions, which are assessed by being checked and compared with traces of previous experiences. Around each specific sensory receiving area is an associative zone, the function of which is believed to be concerned with the perception of the sensations aroused. Thus the visual sensory area is the area striata, Brodmann's area 17, and its stimulation leads to the production of sensations of light. Around it are areas 18 and 19, where these sensations are tested and integrated with tactile or other sensations so that out of the process visual perceptions are arrived at. Stimulation of these areas leads to hallucinations of definite objects, *i.e.* the sensation is intellectually classified and recognised.

There are various objective methods by which the physiology of cerebral activity may be studied, and they are of different significance. Among others, we have the study of reaction times, electroencephalograms, animal behaviour, conditioned reflexes, and the varied phenomena of disease.

Reaction Time. In studying reaction times we measure the time interval between the application of a stimulus and a voluntary response. The greater the complexity of the reaction, the longer will be the period which elapses between the stimulus and the response. Especially is this the case when the complex meshwork of neurones of the cerebral hemispheres is involved. The determination of the *reaction time* gives information as to the time relations of the psychical processes which are the representation in consciousness of the physiological changes occurring in the neurones of the central nervous system.

In most methods the application of the stimulus is arranged so as to close the circuit of a current which flows through an electro-magnet activating a lever which writes on a rapidly moving blackened surface. The reaction of the subject is arranged so that the movement activates a key by which the same current is opened. We thus obtain a tracing showing the moment of application of the stimulus and the moment at which the reaction takes place. If, *e.g.*, the sensory impression is to be from the skin, the current may be made to pass through the primary circuit of an induction coil, and wires be taken from the secondary coil to some part of the surface of the skin. In this case the signal may be started by opening the circuit, and the subject of the experiment will respond by closing the circuit by means of a spring key directly he feels the shock caused by the break of the primary circuit.

The average reaction times in man obtained with the different senses are as follows :—

Sight.	Hearing.	Electrical Stimulation of Skin.
0·19 to 0·22 sec.	0·12 to 0·18 sec.	0·12 to 0·20 sec.

The two figures given for each case are the extremes obtained in different series of observations.

The times vary according to the condition of the person who is the subject of the experiment. They are lengthened by fatigue ; they are shortened up to a certain point by continued practice. Within limits also they are shortened by increase of the strength of the stimulus.

Reaction time applies only to movements carried out in response to isolated stimuli, or to stimuli repeated at irregular intervals. When the stimuli are rhythmic the lost time applies only to the first one or two of the stimuli. The observer is conscious of the interval elapsing between the physical event and his reaction, and anticipates the later stimuli so that his reaction becomes synchronous with the stimulus. This synchronism of stimulus and reaction characterises all rhythmic movements, such as dancing or the playing of an orchestra.

Dilemma. When the subject is required to distinguish between alternative stimuli, the reaction time is considerably longer. Thus, the wires from the secondary coil may be connected by a switch to two pairs of electrodes which are applied, one to the right and one to the left half of the body. It is agreed beforehand that the subject shall react, say, only to stimulation of the right side. The switch is removed from the observation of the subject and the stimulus is applied irregularly to one side or to the other. It is found that the additional neural processes involved in determining whether the stimulus is on the right side, and therefore should be followed up as agreed, adds considerably (on an average 0·06 sec.) to the length of the reaction time. It is possible to complicate the dilemma to almost any extent. Thus the experiment may be so arranged that either a red or a white disc appears, and the subject has to react with the right hand to the red disc and with the left hand to the white disc. In such an experiment the reaction time was found to be 0·154 sec. longer than the simple reaction time. A still more complex process would be involved in the experiment in which a word was spoken, and the subject had to speak some other word which had some association with the word which formed the stimulus, *e.g.* horse—mammal ; paper—pen, etc. In such an experiment the reaction time was found to be as long as 0·7 to 0·8 sec.

Electrical Activity of the Cortex. When the cerebral cortex of an anæsthetised animal is led off by two electrodes placed on its surface and connected with a suitable amplifier and recording oscillograph, potential waves may be recorded.* These are roughly divisible into large slow waves, at 1–4 per sec., and superimposed smaller waves. These waves are the resultant of large numbers of short waves in individual neurones, the response of each unit probably varying in duration according to conditions, from 0·1–0·01 sec., but of uniform size. Increasing or reducing the anæsthesia may alter the magnitude of the waves : injury causes a rapid series of waves, the frequency of which gradually dies down from 100 to about 40 per sec., and which appear to be due to synchronous pulsation in large groups of neurones (Fig. 216).

The cause of the synchronisation, and of the wave-character of the cortical potentials is largely a matter for speculation. It has been suggested that chemical environmental conditions, or polarisation changes in the cells, may be the explanation. Thus, a layer of nerve cells, oriented with axons centrally directed, is normally polarised with the axonic ends positive : this could behave like a polarised nerve membrane and local depolarisation could spread over the surface as a wave.†

The arrival of afferent impressions at the cortex results in the starting off of trains of potential waves which radiate from the special sensory area concerned. Thus, if light falls on the eye, rhythmic discharges spread out from the area striata,* and so on. There is, as we have seen, a point-for-point representation of the receptor surface on the cortical area which receives the impulses, and it is also found that the time-distribution of the electrical changes in the cortex is related to those in the receptors. The world around us, and our own body sensations, are thus translated into a spatially and temporally distributed pattern of electrical potential changes, and it is these patterns which are woven into our state of consciousness, and which brings us all the information we can get about the universe around us. It is not certain whether these waves are initiated in the afferent terminal fibres or in internuncial cells affected by them. They show fluctuations according to the general background of cortical activity on which they impinge. The rhythmic potential waves of this background tend to be increased locally on arrival of an afferent stimulus and this effect resembles that of direct electrical stimulation of the cortex.†

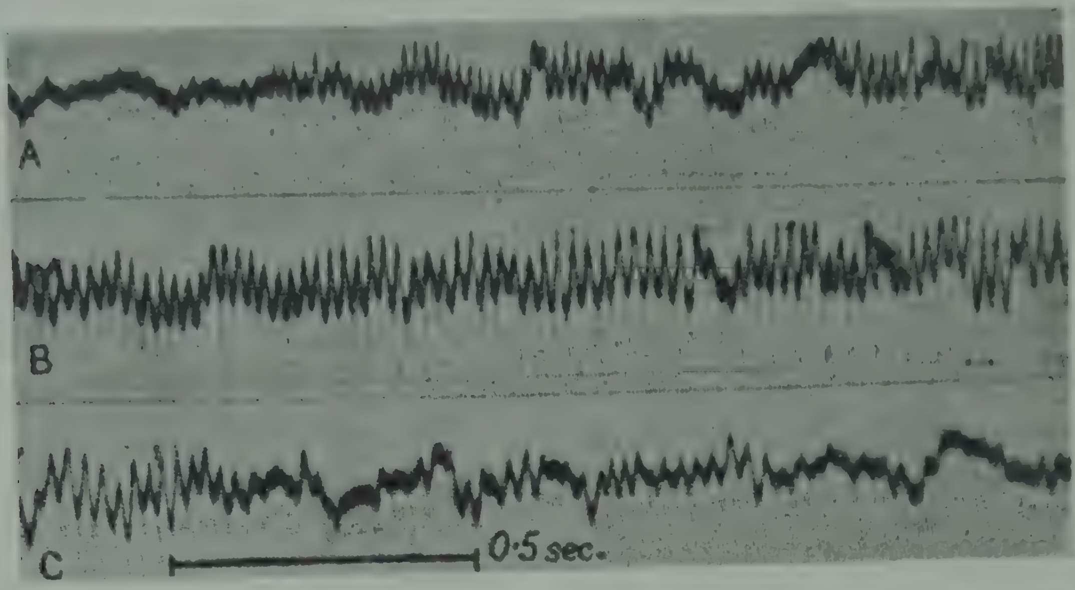

FIG. 216. Injury Discharge from Cortex of Anæsthetised Rabbit, punctured with fine Wire. A. Beginning, frequency = 64 per second ; B. Middle, frequency = 44 per second : C. End, frequency about 40 per second. (ADRIAN and MATTHEWS, *J. Physiol.*, 1934, **81**, 440.)

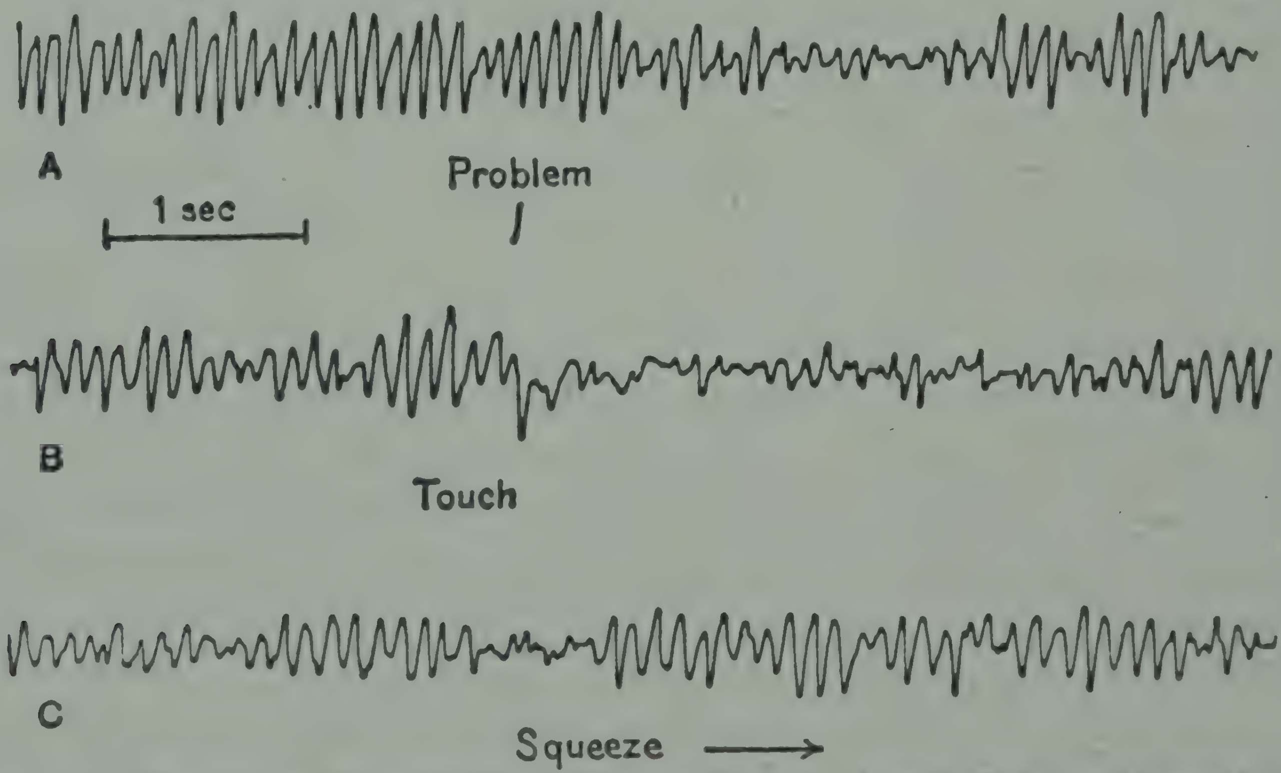

FIG. 217. "Berger" rhythm from Human Scalp. A and B show depression of waves by non-visual activities. At A, a mental arithmetic problem. At B, a touch on nose with cotton wool. C. Squeezing pliers tightly shows that muscular efforts do not affect rhythm greatly. (ADRIAN and MATTHEWS, *Brain*, 1934, **57**, 355.)

Electric stimulation of the cortex usually starts waves which radiate out

---

[†] ADRIAN. *Proc. R. S.*, 1939, **126B**, 433.

over the cortex, the size of wave and the extent of spread increasing by facilitation as the stimuli are repeated. As the stimuli are repeated at the same spot, also, it is found that the point from which the waves begin tends to drift to other positions as other neurones, by facilitation, become more excitable. After further repeated stimuli, in fact, the whole cortex may be involved and may be driven as by a pacemaker, from the area of origin, and at its rhythm. If two centres compete in the emission of cortical waves, the regular rhythm may break down into small, rapid and irregular oscillations. Centres of inhibition may also be set up and the inhibitory influence may likewise irradiate widely over the cortex. This is especially well shown in certain areas, called suppressor bands (*e.g.* in areas 8s, 23s, 24s), stimulation of which abolishes spontaneous electrical activity over the entire cortex.

Severe injury or convulsant drugs cause the pulsations to spread widely over the cortex and in different directions, and large irregular waves are often seen.

Somewhat different potential waves (electroencephalograms) can be detected when electrodes are applied to the human scalp.* It is the practice to lead off from frontal, parietal, temporal and occipital regions on each side. The potentials are very minute (less than 50μV.) and need great amplification. The important feature is frequency, not amplitude of waves. The chief are the *alpha waves* (Fig. 217). These occur at about 10 per second; they usually arise in the visual area of the occipital lobe.† They are present when the eyes are shut or when, with uniform visual fields, there is no attempt to see detail, and are reduced or abolished whenever the central field of vision has any detail, or in any mental state, visual or otherwise, which demands attention. It is significant that the latent period for disappearance of the α waves on opening the eyes is about 0·4 second, *i.e.* it is longer than the motor reaction time. Adrian and Matthews regard these waves as due to spontaneous rhythmic activity arising simultaneously in groups of neurones in an area of visual cortex when this is not engaged in definite function.

Sometimes waves at about 25 per second also appear. These, the *beta waves*, possibly originate in the sensori-motor areas. They tend to be inhibited by tactile stimuli. In sleep there are sometimes intermittent "bursts" of waves at 14 to 15 per second, which are called "spindles," and in deep sleep a slow random rhythm, the *delta waves*, at about 6 a second.

It is probable that these various rhythms are not due to the effects of afferent impulses arriving at the brain, but represent a tendency on the part of groups of nerve cells to emit regular synchronous potential waves.

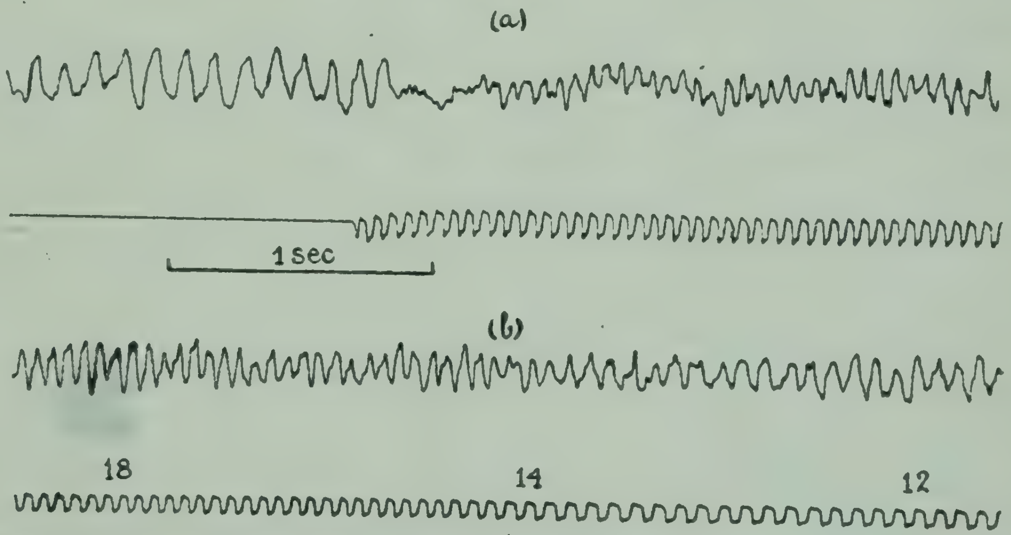

FIG. 218. Occipital Electroencephalograms from Man (*a*) Upper trace, EEG; lower trace, record of photo-electric cell, showing rate of flicker. Eyes were opened as flicker began. (*b*) Tracings as in (*a*): rate of flicker reduced from 18 to 12 per sec., and the EEG record follows it. (ADRIAN. *Lancet*, 1943, **245**, 33.)

This property is seen in almost any isolated portions of grey matter. Thus the isolated medullary centres of the goldfish show potential waves at a rate corresponding to that of the normal respiratory movements,* and portions of the frog's brain, especially the olfactory lobes, also show characteristic rhythms when isolated.†

---

* BERGER. *Arch. f. Psychiatr.*, 1929, **87**, 527; 1933, **102**, 454; KREEZER. *Amer. J. Psychol.*, 1938, **51**, 737.

† ADRIAN and MATTHEWS. *Brain*, 1934, **57**, 355.

In the brain *in situ*, moreover, it was found by Bremer ‡ that section across the mid-brain did not cause the cortical rhythms to disappear, although all afferents except olfactory and optic were removed thereby. These facts are of great importance inasmuch as they indicate that even in absence of stimuli from without, the cells of the cortex are not inactive, but tend over whole areas to fall into synchronous rhythms, the corresponding foci in the two hemispheres being also synchronous. There are some indications that mutual reinforcement by the cortex and the thalamus is largely responsible for maintaining the spontaneous rhythm.

If stimuli are given in a rhythmic manner, as by the exposure of the eyes to a flickering light, a community rhythm of the cells is very readily established, and corresponds with the rate of the flicker (Fig. 218).

ANIMAL BEHAVIOUR. Another objective method of investigation is by the study of the behaviour of animals as affected by conditions such as the extirpation of cortical areas. The methods mostly depend on the use of tests which involve the learning of something. Thus rats can learn to traverse a maze in response to a particular stimulus, *e.g.* light, or monkeys can acquire skill in unfastening latches, etc. After removal of the entire cerebral hemispheres nothing can be learnt, and even complex behaviour generally classed as instinctive, *e.g.* nesting of birds, may be lost. It is often supposed that when a habit has been acquired by voluntary effort, it ultimately becomes a reflex in which only the lower centres are concerned. The truth of the matter seems to be that cortical and sub-cortical processes react considerably one upon the other, and that many apparently cortical responses are really mediated by sub-cortical structures, though removal of the cortex does nevertheless modify or abolish such responses. Examination of animals in an ascending evolutionary scale shows that the cortex takes over to an increasing extent the functions of older structures, so that conclusions based on lower species are not necessarily applicable to higher ones.

One of the most striking results of animal behaviour experiments is the demonstration by Lashley that the effects of removal of cortical areas can be counteracted by training or retraining. Thus, rats can be trained to enter an illuminated alley and avoid a dark one. If, after training, the striate areas are removed the rat fails to pass the test and will never spontaneously recover the ability. Removal of up to 60 per cent. of other parts of the cortex leaves the ability unimpaired. Animals with striate areas destroyed can, however, be trained as quickly as normal rats to pass the test, and retraining of those who lost the ability by removal of the striate area also restores the ability. Such experiments, and similar ones on auditory centres, show that the idea of a simple path from receptor to cortex is quite inadequate.

Similar vicariation of function is shown in the motor paths of the cortex, and it has been found possible to train movements after removal of the motor centres primarily concerned with them, or after destruction of pyramidal tracts.

It may be concluded from experiments along these lines that there is less precision of localisation of functions in the cerebral cortex than the earlier work on localisation led us to expect, and that there seems to be a certain amount of mutual dependence between parts of the cortex. While there are certain fairly precise fields of local representation, or of special function there appear also to be wider and less precisely defined areas between which there is some latitude with respect to function. It is a surprising fact tha both frontal lobes can be removed in man without producing any very profound change (p. 301).

CONDITIONED REFLEXES

Pavlov introduced a method for investigating the functions of the higher centres, which is capable of very wide applications. It is applied to perfectly normal animals, and affords objective means of observation of the effects and interaction of sensory stimuli. Nevertheless, the conclusions drawn have not been universally accepted.

THE UNCONDITIONED AND THE CONDITIONED REFLEX. All reflex activities can be divided into two large groups: the *inborn*, and the *acquired* reflexes.

The inborn reflexes are characteristic of the central nervous system of any whole class of animals: they are transmitted by heredity, and their formation is therefore independent of the conditions under which any individual animal may live. Their strength may vary in the course of the animal's life: some of them do not appear until a definite age is reached, some disappear in senility, but in each case always to reappear in the next generation. To express the permanently stable character of these reflexes and their slight dependence upon surrounding conditions, Pavlov gave to the inborn reflexes the name of *unconditioned reflexes*. All spinal and bulbar reflexes are unconditioned reflexes: the knee-jerk, the stepping reflex, the secretion of saliva caused by administration of food, the flying reflex of birds, most of the postural, vascular and lower sexual reflexes, are included in the group of unconditioned reflexes. Some of these reflexes may be extremely complex and involve a series of successive reflexes, or be of an elaborate integrative nature, forming chains of reflexes following one another and presenting different groupings. What are generally known under the rather ill-defined name of "instincts" are probably nothing but a very complex integration of these inborn or unconditioned reflexes.

The acquired reflexes are peculiar to a single individual animal and may be entirely absent from the rest of the individuals of the same class. They are acquired in the course of the animal's existence, as a result of adaptation to changes in the surroundings. The organism at birth presents merely greater or lesser possibilities for the formation of these reflexes, but their actual formation depends only on the conditions under which the individual animal lives. They disappear more or less quickly when the conditions of the animal's life become so changed that it has no more use for the previously acquired reflexes; instead of the lost ones it forms new reflexes. Hence the name given to them of *conditioned reflexes*. However, it is important to remember that the conditions of life among individuals of the same class of animals may be identical in many respects; therefore it is not surprising that, besides possessing all the inborn unconditioned reflexes, these animals will also have many conditioned reflexes in common. The following example may serve as an illustration. Meat when placed in the mouth of any dog causes a reflex secretion of saliva and a reflex act of deglutition. It is common knowledge that salivation will also be produced if meat is only shown, or given to smell. The latter reflex will be found just as universally amongst the carnivorous animals as the former. Food therefore, besides its property of causing these reflexes when directly stimulating the taste, can cause a similar effect through the optic and the olfactory nerves. Only by means of special experiments was it possible to show that secretion caused by the application of the stimulus to the taste buds is based on an unconditioned reflex, while that excited by the *stimulation of the visual and olfactory* receptors is a conditioned, *i.e.* acquired, reflex, and is common to all *carnivorous animals only because the conditions of their life are identical in respect of their food.*

The Formation of Conditioned Reflexes. Conditioned reflexes never originate spontaneously. They only develop in association with another previously established reflex. In the simplest case, conditioned reflexes are based upon an inborn reflex and, since conditioned reflexes are not hereditary, we must look upon all conditioned reflexes as being an associative development of the inborn reflexes which ultimately lie at their root. Endless numbers of conditioned reflexes can be based upon one single unconditioned reflex. Conditioned reflexes of the second, third and higher orders can be developed in association with the primary conditioned reflexes, thus forming a complicated collection of nervous activities which are governed by education, experience and adaptation to the secondary conditions. The higher the organization of the animal's nervous system the greater the number and complexity of the conditioned activities it presents.

The experimental study of conditioned reflexes has dealt up to the present mostly with the simplest kind of reflexes which are developed in association directly with the unconditioned reflexes (conditioned reflexes of the first order). When a stimulus which is quite neutral, in that it does not by itself originate any kind of reflex activity of the animal, is repeatedly used during the execution of an inborn reflex (this latter of course in response to its proper stimulus), it loses its neutral character and acquires the property of bringing about by itself the same result as the inborn reflex. The hitherto neutral stimulus is transformed into a *conditioned stimulus*: it acquires the properties of the stimulus which initiated the reflex, and this can now be set into operation by the new accessory stimulus.

An example will illustrate the point. It is well known that food or acid when placed in an animal's mouth causes a reflex secretion of saliva, which in a dog with a salivary fistula can be collected and measured. This secretion is an inborn reflex, and does not require the presence of the cortex, since it can be observed after decerebration, or even on a bulbo-spinal preparation. Now if a second stimulus, say a sound (or any other stimulus), is applied to the animal simultaneously with feeding, and this combined stimulation is repeated several times, we find that the sound acquires stimulative properties and, when used alone without feeding, causes a secretion of saliva. A new reflex has thus been formed and a new nervous association established. That particular sound in respect of the salivary gland becomes a stimulus. Any other effector organ of the animal besides the salivary gland, or any sort of stimulus, can be used for the establishment of conditioned reflexes. On account of the comparative simplicity of measuring the reflexes the salivary glands have been most used as effectors. Conditioned reflexes have been established and studied also in the case of striated muscles, respiration, vasomotor system, pupil, deglutition, excretion of milk, contraction of the bladder, and intestinal and gastric secretion. It has been found possible to establish reflexes to visual, auditory, tactile, thermal, kinæsthetic, and olfactory stimuli.

Rate of Development of Conditioned Reflexes. Experiment shows that the development of conditioned reflexes is comparatively rapid. For example, a conditioned reflex was developed between the showing of food and the sounding of a note of 637·5 vibrations per second. The table on p. 325 shows that the reflex has been established by the thirty-first repetition.

Such a conditioned reflex as the above might be established within a few days, by repeating the combined stimuli of food and sound many times per day. When once such a conditioned reflex has been established, evidence of its persistence may be obtained for many years afterwards. If, however, the experiments be discontinued before it has been fully established the effects

51	69	2

will be of a temporary nature. Suppose, for example, the above experiment had been discontinued on the ninth day, then, if tested on the fifteenth day, with no intermediate experiments, the probability would have been only a small secretion of saliva, indicating that the effect hitherto produced was fading away. If, on the other hand, the trials were continued until the fifty-first experiment, then a considerable effect might be obtained many months later. This forms the basis of "ingrained habits."

Laws of Conditioned Reflexes. Since the phenomena connected with conditioned reflexes are almost always investigated by means of some easily observed reflex act, such as salivation, the idea is apt to arise that conditioned reflexes only concern phenomena of this type. Such an idea is, of course, entirely erroneous. Such reflexes are chosen because by their use the observer has a simple and objective indication of what is happening in the animal's nervous system.

Summation. If, by means of separate applications, conditioned reflexes have been set up for two different kinds of stimuli, then, on subsequently applying both of them together, a greater effect may be produced than either would give alone. For example, suppose a conditioned reflex be set up by giving food and by sounding a whistle, and also in another series of experiments, carried on at the same time, by giving food and stimulating the back electrically, then, if subsequently the electrical stimulation is given and the whistle sounded together, the number of drops of saliva will be found to be the sum of those given by either stimulus alone.

Irradiation. Suppose that a conditioned reflex be established for a carefully-marked area of skin, and that by testing this area the strength of the conditioned reflex be measured. If now a slightly different area of skin be stimulated, it will probably be found that there is still a flow of saliva, though a smaller one than that obtainable if the correct spot had been stimulated. As spots farther and farther away from the correct one are tried, the number of drops decreases. A spreading of effect of this kind is called irradiation.

Specificity. Suppose that, having established a conditioned reflex for a particular gong, a gong of different pitch be sounded, then there may be either no flow of saliva or quite a considerable flow, according as the difference in pitch between the two gongs be perceptible or not. This phenomenon is called specificity.

Discrimination. Suppose that a series of gongs of different pitch are obtained and that two of them be experimented with in the following manner. The sounding of gong A is always accompanied by the giving of food, whereas the sounding of gong B is not. Then, on subsequently testing the animal for the existence of a conditioned reflex for these two gongs, it is possible to tell whether the animal has been able to distinguish between their pitches or not. Thus, if both of them are accompanied by secretion of the same number of drops of saliva on the average, then quite clearly they have sounded alike to the dog. By first testing with gongs which are very different in pitch, but in subsequent experiments using gongs which are closer and still more close, it is possible to ascertain precisely at what point discrimination ceases. Since very great care has to be taken to see that it is really nothing but the pitch which is the criterion that determines the dog's behaviour, tuning forks or organ pipes emitting pure tones will be preferable to gongs, and it would be necessary to be sure that no other quality changed at the same time, which would enable the animal to differentiate between them. Thus, one organ pipe might emit a slight high-pitched hiss when it was sounded. This might be quite inaudible to us but easily discerned by the dog. We should think that the dog was discriminating between the tones by their pitches, while in point of fact it was discriminating by the hiss in one of them.

REINFORCEMENT. Suppose that an animal in which a particular conditioned reflex has been established be not experimented with for several months, it will probably be found that the strength of the conditioned reflex has fallen somewhat from the value it had when the experiments ceased. This phenomenon is called decay. Experiment shows that a very few applications of the conditioning factors suffice to restore the reflex to its original value. This phenomenon is called reinforcement.

LINKING. Suppose that an animal with a conditioned reflex established between salivation and the sounding of a gong is experimented with for a few days by sounding a gong and a whistle at the same time. Then on subsequently testing the animal with the whistle it will be found that the conditioned reflex has a strength far greater than could be accounted for by the few times that the sound of the whistle and the feeding have been associated. What apparently has happened is that the conditioned reflex established for one sound has in great measure been transferred to the second. This phenomenon is called linking.

EXTINCTION. Suppose a conditioned reflex to have been established between the salivary reflex and the blowing of a whistle. Then, if for a number of times in succession the whistle be blown but no food given, it will be found that the strength of the conditioned reflex quickly dies away. This phenomenon is called extinction.

Delayed and Trace Reflexes. It is clear that the fundamental experiments with the modifications just described can be elaborated in a number of different directions. One of these consists in varying the time that is allowed to elapse between the application of the conditioned stimulus and the subsequent unconditioned stimulus. For example, the sounding of a note and the giving of food may occur simultaneously, or any number of minutes may be allowed to elapse between the sounding of the note and the giving of the food. If they occur together the conditioned reflex is called *simultaneous*. If a short time is allowed to elapse between the two, they are called *delayed*, and if the time is longer they are called *trace reflexes*. Now, as one would expect, delayed reflexes take longer to establish and are more liable to fade than simultaneous reflexes, and the same is still more true of trace reflexes.

Now it is clearly possible to vary in the opposite direction the time relations between the sounding of the gong and the giving of the food, namely, to give the food first and then to sound the gong. Experiment shows that unless the time be very short the establishment of a conditioned reflex becomes difficult or impossible. This is because the animal, as the result of repeated associations of the sounding of the gong and the giving of food, forms an association between the two, that is to say, the mechanism which sounds the gong is in some way connected with that which produces the food. If, on the contrary, the food is given first, so far as the animal is concerned subsequent events happening to the gong are of little or no interest.

Inhibition. EXTERNAL INHIBITION. Suppose that between the time of sounding the gong and the giving of food an additional unexpected stimulus be introduced, such, for example, as playing a gramophone record. Then it is found that this extra stimulus has a marked depressant effect on the strength of the conditioned reflex. The first application of this unexpected stimulus has a more powerful depressing effect than subsequent ones, as the following table shows :—

Strength of visual conditioned reflex . . . = 100 per cent.
Effect of gramophone, 1st application . . . = 10 ,,
,, ,, 2nd ,, . . . = 50 ,,
,, ,, 3rd ,, . . . = 65 ,,
,, ,, 4th ,, . . . = 85 ,,
,, ,, 5th ,, . . . = 90 ,,
,, ,, 6th ,, . . . = 94 ,,
,, ,, 7th ,, . . . = 100 ,,

This effect is known as external inhibition. Experiments of this nature make it clear that considerable pains have to be taken to eliminate the entry of unintentional external inhibition when initiating or testing the strength of conditioned reflexes. It has been found necessary to design special rooms (Fig. 219) provided with automatic means of giving the animal food at the required instant of time and for supplying the various forms of stimulation, gongs, whistles, etc., etc., so that adventitious stimuli of an unwanted kind are avoided so far as possible.

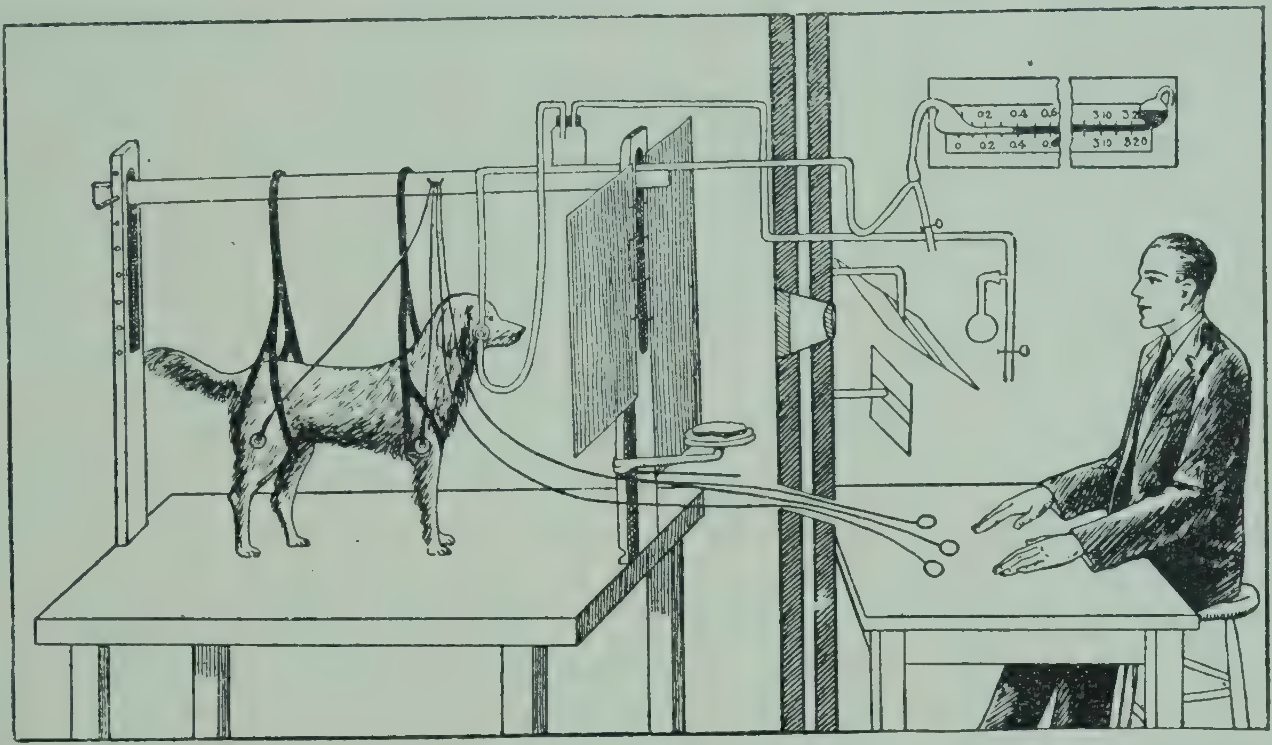

FIG. 219. Operator with various controls outside the cell observing animal inside the chamber by periscope. (PAVLOV.)

INTERNAL INHIBITION. Besides the type of inhibition described in the previous section, other varieties of inhibition are met with, some of which can be classed as internal inhibitions. For example, as the result of careful training a conditioned reflex may be set up for an organ pipe producing a note of 256 vibrations per second, whereas another similar pipe, producing a note of 244, is ineffective. In this case discrimination of the pitches of the two pipes has enabled the animal to react correctly to one and to inhibit the effects of the other. This is one type of internal inhibition.

EXPERIMENTAL NEUROSIS. Some of the dogs used in experiments involving rather fine and difficult discriminations showed signs of neurological stress, and ended in a neurotic state. They became highly excitable, bad-tempered, and generally unstable. Long treatment often restored them to apparent normality. It is of interest that it is just those mental processes which are concerned with discriminations which result in strain and fatigue in man.

EFFECT OF EXTERNAL STIMULI ON INTERNAL INHIBITION. We have already seen that adding an extra stimulus of an unexpected nature immediately before or after a stimulus to which a conditioned reflex has been set up may result in marked inhibition in the strength of the conditioned reflex. We must now consider the effects of putting an additional unexpected stimulus just in front of a stimulus to which internal inhibition has been established. For example, having caused the animal to discriminate between a tone of 256 to which he salivates, and another of 244 to which he does not, let us investigate what will happen if, just prior to sounding the pipe of 244, an unexpected additional stimulus is given to the animal. The result is that the animal salivates as if it was responding to the tone of 256 vibrations per second, and this clearly indicates that the internal inhibition may be temporarily removed by this unexpected extra stimulus.

SEAT OF INHIBITION. We must now consider whether the external inhibition which we have been considering develops primarily in the cortical area to which the normal stimulus goes, or whether it is associated more firmly with the cortical area to which the unexpected stimulus travels. Several observations seem to suggest that the inhibition arises within the cortical area to which the end organ concerned in the conditioned reflex connects. Suppose, for example, that as the result of repeatedly stimulating an area of skin and giving food, the conditioned reflex has been set up, and that a loud noise has been used to inhibit the conditioned reflex. Then experiment seems to show that the inhibitory after-effect will be much more marked in the cortical area representing the skin than in the cortical area representing hearing. The following experiment makes this clear. Suppose that a conditioned reflex has been set up for a particular area of skin, and that this has been inhibited by a loud sound so that the stimulation of skin only means to the animal to "expect food," whereas the loud sound and the stimulation of skin together mean "no food." Now, during a subsequent period another skin stimulus is used at the same spot for establishing a new reflex, for example, the contraction of a particular muscle instead of the secretion of saliva. Then, for the first time that the loud sound is applied at the same time as stimulation of the skin, there will be found to be inhibition of the movement of the muscle, just as there was inhibition of the flow of saliva. This clearly indicates that the association is between areas of cortex and not between the final paths used for the reflexes in question.

Conditioned Reflexes of Higher Orders. It is clear that by using conditioned reflexes in various combinations, sometimes using the same stimulus for two different reflexes, sometimes using a stimulus which has been used to inhibit one reflex to bring about the operation of a second one, we can link up conditioned reflexes in a very complicated way, only being limited by lack of time or of our own ingenuity. One example may be given. Suppose that a stimulus A be associated with the giving of food so that a conditioned reflex has been set up. Suppose that another stimulus B has been used to inhibit it, so that A and B together signify that no food is coming. Suppose now that for several times in succession the inhibitory stimulus B is associated with a third stimulus C which the animal has not previously experienced. Then on trying A and C together it will be found that C inhibits just as effectively as B did.

Removal of or Damage to Cortical Areas. Dogs which have survived the experimental removal of their cerebral cortex suffer a complete loss of the ability to form conditioned reflexes. Local damage only causes a temporary effect on conditioned reflexes if the damaged areas are of small size. Further, the damage appears to affect inhibitory stimuli more than excitatory ones. If, on the other hand, extirpation of the whole of the cortical area corresponding to a particular sense organ has been carried out, then many, but not all, of the effects previously produced by stimulating this sense organ are lost. Such conditioned responses as are retained are probably effected by sub-cortical mechanisms.*

Heredity of Conditioned Reflexes. One experiment to test this was performed as follows : Five puppies were removed from their mother and were fed entirely on milk. The first puppy had a conditioned reflex established between the giving of food and the sound of a metronome ; the second puppy to the stimulation of the skin by an induction coil; the third to the smell of camphor; the fourth to the appearance of a red light; and the fifth to a white light, which periodically went on and off. The conditioned reflexes developed quickly, and on testing were found to be quite stable. When the puppies were several months old they were shown a number of different objects, amongst them being pieces of meat and other foods which their ancestors had been acquainted with. No salivary activity was observed in the puppies. It did not matter whether the animals were merely shown the objects in question or were allowed also to smell them. The results were the same. Meat and rubber corks alike were indifferent to them. We see, then, that the salivary reflex to sight or smell, which might be supposed to be a hereditary characteristic possessed by all dogs, is in point of fact an acquired conditioned reflex.

Relation of Conditioned Reflex to Neurology. The main mass of neurological science has been built up on the basis of the neurone doctrine and its experimental interpretation by Sherrington. Conditioned reflex physiology has a large literature, and is clearly of great significance. But it has developed independently and has a special nomenclature, the relation of which to the tenets of general neurology is undefined. It is evident, for example, that the association between the conditioned and unconditioned stimuli on the one hand, and the effector path on the other hand implies a plasticity not so far revealed in the lower nerve centres. An attempt to harmonise these two fields of knowledge has been made by Konorski. He suggests that new synaptic connections can be established reversibly, and that these can be either excitatory in action, or, as in internal inhibition, inhibitory.

SLEEP

All higher animals have, during each day, one or more periods of rest in which there is a general reduction in the activity of the central nervous system, but especially of the cerebral cortex. The reduced, or delta, electric waves in the cortex are evidence of this. Adult human beings normally have one such sleep period in the twenty-four hours.

The need for, or onset of, sleep is announced by subjective feelings of drowsiness, dryness of the conjunctivæ, difficulty in keeping the eyes open, and general muscular relaxation.* When sleep sets in, the muscular relaxation increases, and before awakening, tonus returns. Many methods have been used for recording the movements made during sleep; the closing of electric contacts by movement of the bed springs, the use of smoked drum and lever, or cinema photography of the sleeper. Kleitman, Cooperman and Mullin † used a combination of some of the above methods with a machine which added together the vertical displacements of the centre of the bed springs. They also recorded the rectal temperature. Although most people make some movement every few minutes, little time is occupied by movements during sleeping, usually less than half a minute per hour. More time is spent in movement towards morning. There was no observable connection between rectal temperature and movement.

During sleep the knee-jerk disappears, but various superficial reflexes remain, and a positive Babinski sign is always obtained on stroking the sole of the foot. Urine secretion is reduced, and sometimes also gastric secretion and movement, but hunger contractions of the empty stomach may be increased. Vasomotor reflexes are conspicuous. The eyes are usually directed upwards, but any position may be taken up by either eye. The pupils are contracted, but contract still further to light. The heart rate is slowed, largely because of the general inactivity of the body, and the arterial blood pressure is lowered about 10 to 20 mm.* There is some dilution of the plasma and increase of blood volume.† Basal metabolic rate is reduced, but the respiration rate may be lowered, raised or unchanged.

---

* KLEITMAN. *Amer. J. Physiol.*, 1923, **66**, 67.

† KLEITMAN, COOPERMAN and MULLIN. *Amer. J. Physiol.*, 1933, **105**, 574.

The depth of sleep may be measured in a number of ways. One way is to take a record of the blood pressure, and to ascertain by experiment how loud a sound is necessary to cause a noticeable change in this. It is found that there are wide individual variations, but often sleep increases in depth until, two or three hours after the onset of sleep, it reaches its maximum. After this it decreases until about six hours after the onset of sleep, and then stays approximately uniform. Just before the time to wake up is reached, it becomes very light. Deep sleep is dreamless, and when dreaming does occur it is probably the result of some afferent impressions ; these are not subjected to the normal critical examination in the cortex, and so are usually grossly misinterpreted.

Prolonged sleeplessness in man leads to no very conspicuous objective changes, except as regards the results of certain psychological tests. Thus arithmetical problems are less accurately solved, and it is generally agreed that the driving of a motor car would be less reliable. In later stages it becomes difficult to stand erect, and hallucinations may occur. In order to keep awake after a certain time continuous muscular activity is essential. When very prolonged, sleeplessness leads to collapse and death. In such cases chromatolysis and shrinkage of cells in the frontal areas of the cortex are found.

As the result of experimental work on sleep, several hypotheses have been advanced to explain it. One of these, due to Pavlov, ascribes the phenomenon to a spread of internal inhibitory processes. If, for example, an animal has been trained to expect food half an hour after an auditory stimulus has been given (a trace reflex) and that this time interval be made longer and longer, the animal tends to go to sleep during the intervening period. When the time interval of the experiment is over the animal wakes up and exhibits the normal salivary reflex.

Kleitman regards sleep as a reversible inactivity of the highest cortical centres, which is due to a functional break between it and the lower parts. The highest levels are least organised and most sensible to fatigue. The break is due to a reduction in the number of afferent impressions, especially in the proprioceptive ones dependent on muscular tone. Hence muscular relaxation, whether voluntary or due to fatigue, is a necessary condition for it. This view receives important confirmation in the experiments of Bremer, who found that when nearly all afferent impressions were removed from the cerebral cortex in cats by section of the mid-brain, the head showed all signs, including the slow electric waves, of deep sleep. The diurnal alternation of wakefulness and sleep is probably a conditioned phenomenon.

Since the volume of the brain increases in sleep ‡ there can be no possibility that sleep is primarily due to cerebral anæmia, as often supposed. Some vascular phenomena may be related to it, however, since increase of pressure in the carotid sinus may under certain conditions induce sleep.§

Most neurologists now incline to the view that some special " centre " is concerned in the production of sleep, but opinions diverge as to the mode of its action. According to one school, led by v. Economo * the centre, near the tuber, could cause active inhibition of various higher centres, and this has been called a "sleep centre." Hess † was able to induce immediate sleep at any time in cats by stimulation of an area lying between the subthalamus and the thalamus, and near to the bundle of Vicq d'Azyr.

§ KOCH *cit.* SCHWEITZER. Die Irradiation autonomer Reflexe. 1937 (Basel, Karger).

Others have thought it to be more appropriate to assume a "waking centre" the depression of which would cause sleep. Ranson ‡ indeed found evidence for such a "centre." He produced sleep, and sometimes catalepsy, in monkeys by bilateral lesions in the lateral hypothalamic area near the mammillary bodies, and similar results have been reported as a consequence of hypothalamic lesions in man. This is explained as due to the loss of the emotional drive which normally emanates from the hypothalamus, so that a stage of quiet and relaxation results. It is the converse of the state in the decorticate animal (p. 233) where the hypothalamic activity is uncontrolled and leads to extreme excitability and "sham rage." It was also found by Demole § that injections of 2 mg. of calcium chloride into the region of the tuber cinereum caused sleep lasting several hours. It could be reversed by injection of KCl. In pathological conditions of hypersomnia any lesions present are usually in the region lying between the corpora mammillaria and the third nerve nucleus.

Examination of the results of hypothalamic lesions in rats led Nauta to the conclusion || that there are in the hypothalamic region two neural mechanisms closely connected with sleeping and waking, and which may for convenience be called the sleeping and waking "centres." The "waking centre," in the caudal hypothalamic region, exercises a tonic influence on the cerebral cortex during the absence of external stimuli ; it is closely related to the sympathetic centres. This centre can be inhibited by a "sleep centre" situated in the preoptic region and related to parasympathetic centres. Sleep then occurs when this centre becomes active, provided that external stimuli at the time are not too powerful.

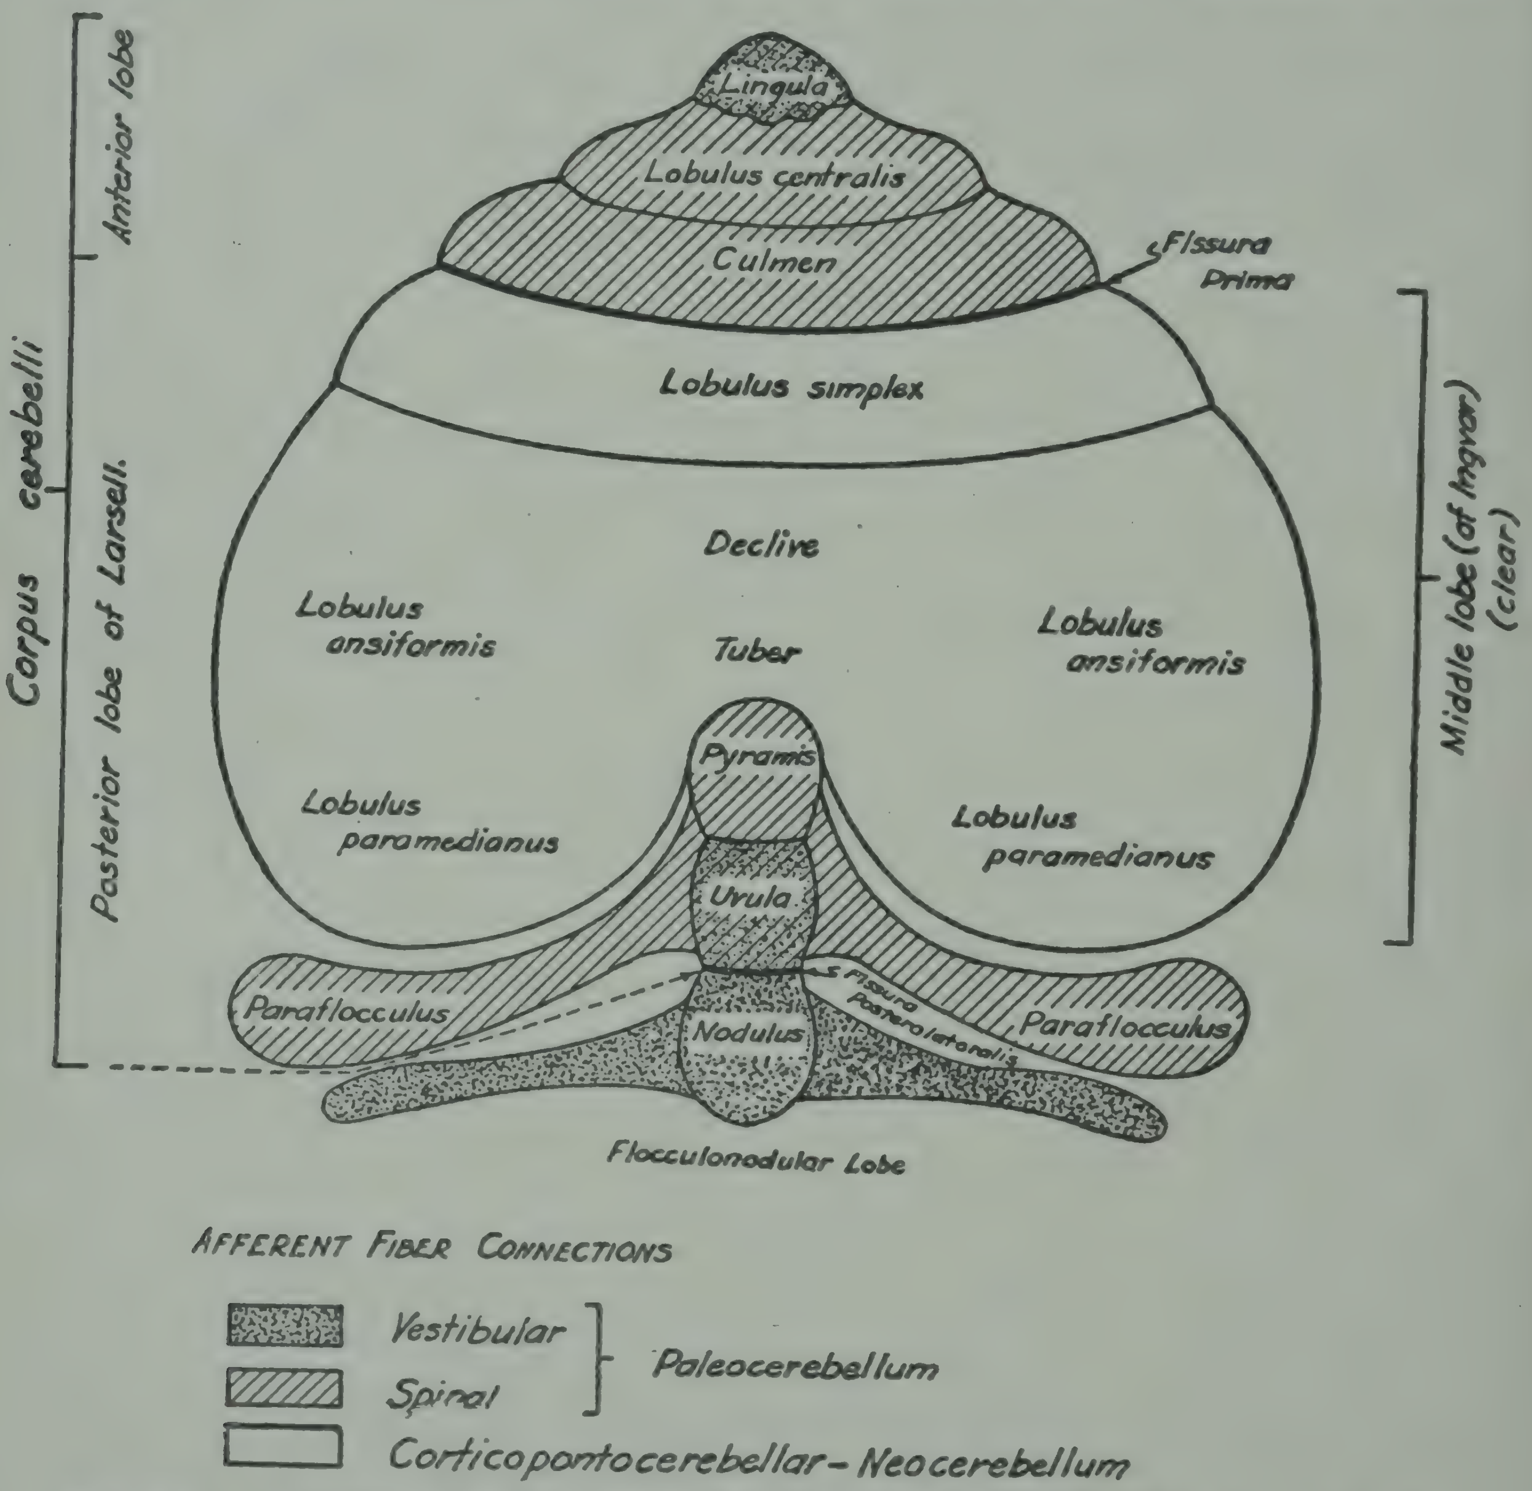
CHAPTER XXII

THE CEREBELLUM

MORPHOLOGY

MANY attempts * have been made to systematize the anatomy of the cerebellum, with the result that the terminology is at present in a chaotic state. The cerebellum consists of a central part or vermis, and two lateral hemispheres. The vermis on the upper aspect is called the superior vermis and that on the inferior aspect the inferior vermis (nodule to tuber in old terminology). According to Larsell,† whose subdivisions we shall use, the cerebellum consists of two main divisions :—(1) a smaller *flocculo-nodular*



Anterior lobe
Corpus cerebelli
Posterior lobe of Larsell.
Lingula
Lobulus centralis
Culmen
Fissura Prima
Lobulus simplex
Middle lobe (of Ingvar) (clear)

lobe, consisting of the flocculi, the nodulus and their peduncles, and (2) a larger *corpus cerebelli*, the two being separated by a fissure (not very conspicuous in man), the postero-lateral fissure.

The corpus cerebelli is again subdivided by the fissura prima, which runs transversely, into an *anterior lobe* and a *posterior lobe*, each further subdivided into smaller lobules by smaller fissures. Other folds run in such a way as to seem to divide the organ into a number of transverse laminæ. Ingvar recognises a middle and a posterior lobe in the corpus, but Larsell considers both as posterior lobe (Fig. 220).

FIG. 221. Transverse Section of a Cerebellar Folium. (GRAY'S "Anatomy.")

The anterior lobe, the posterior part of the posterior lobe, and the flocculonodular lobe are the phylogenetically old parts, and hence may be called the *palæocerebellum*. They represent the original cerebellum as a structure developed chiefly in connection with the vestibular centres of the medulla. Their fibre connections as shown in Fig. 220 are vestibular and spinal. The anterior, and larger, part of the posterior lobe (= Ingvar's middle lobe) is greatly developed in higher animals and especially in primates: it is the *neo-cerebellum* and is chiefly connected, *viâ* the pons, with the efferent tracts from the cerebral cortex. The cerebellum connects with the rest of the central nervous system by means of three pairs of peduncles: the *superior peduncles* or brachia conjunctiva, the *middle peduncles*, which form the pons, and the *inferior peduncles* or restiform bodies. The cerebellum is covered with a grey cortex, within which is white matter.

The Cerebellar Nuclei are the three pairs of roof nuclei, viz. the *Nn. fastigii, globosus,* and *emboliformis* and the lateral *nucleus dentatus*, the last-named being the largest. Part of the dentate nucleus is connected with the palæocerebellum and part with the neocerebellum. All the nuclei are placed deeply and separated from the cerebellar cortex by the white matter. The general plan of connections is that the afferent fibres to the cerebellum go chiefly to its cortex: from this, fibres relay to the cerebellar nuclei, and from these again fibres pass out to other parts of the central nervous system, chiefly by the superior peduncles.

Histology of the Cerebellum. The cerebellar cortex is thrown into laminæ or folia by the transverse arrangement of the smaller fissures. Its substance shows three layers, and their structure is identical over the whole cortex. Outermost is the molecular layer, next a layer of Purkinje cells, and on the inside a granular layer. Beneath this is the white matter.

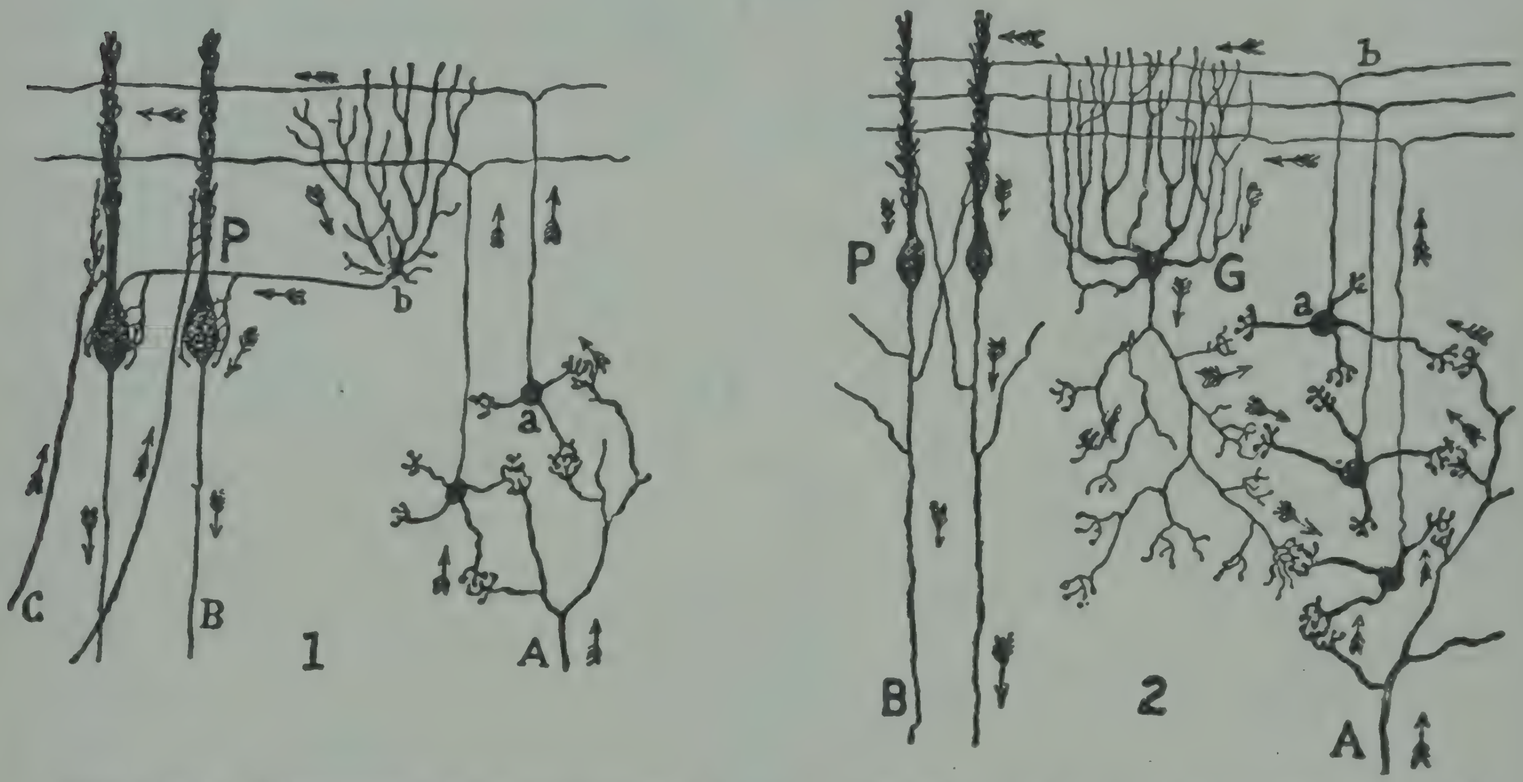

FIG. 222. Diagrams of Cajal showing two possible Paths for the Impulses carried by the Moss Fibres to the Cerebellar Cortex; the arrows indicate the direction of transmission of the impulses. 1. The unidirectional arc, and 2, the recurrent arc through the Golgi cells (G). A, moss fibre; B, axons of Purkinje cells; C, climbing fibres; a, granule cells; b, basket cells; P, Purkinje cells. (From LORENTE DE NÓ. *Arch. Neurol. Psych.*, 1933, **30**, 245.)

Starting at the deepest layer, the *granular layer*, this consists of small "granule" cells with short dendrons and long axons; the latter ascend to the molecular layer, where they bifurcate, the two branches then running parallel to the surface and parallel to the folia, *i.e.* transversely across the cerebellum (Fig. 221). Golgi type II cells are also found in the granular layer.

The *Purkinje cells*, of the next layer, have large bodies with freely branched dendrons that extend throughout the molecular layer and make synapses with the parallel axons of the granule cells (Fig. 221). The dendrons of the Purkinje cells are spread out in a plane which is right angles to that of the folia. Their axons pass to the cerebellar nuclei.

The *molecular layer*, in addition to the ascending axons of the granular cells, and their horizontal branches, contains small stellate cells and the so-called *basket cells*, the dendrites of which run at right angles to the folia, *i.e.* sagitally. They send out collaterals which end by basket-like arborisations round the bodies of Purkinje cells, so that several of these can be affected by one basket cell.

The *afferent fibres* entering the cerebellum go mainly straight to the cortex and are of two types :—(1) the *moss fibres* which end in the granule layer, and (2) *climbing or tendril fibres* which connect only with the Purkinje cells or their dendrons.

The moss fibres are derived chiefly from the spino- and olivo-cerebellar fibres and it will be seen that the arrangement of cerebellar neurones is such as to diffuse impulses from these widely over the cerebellum in a transverse direction by means of the parallel fibres, and also in a sagittal direction by the Purkinje cells and the basket cells by which these latter are associated.

The climbing fibres on the other hand, derived mainly from pontine and vestibular sources, carry impulses that are less widely diffused. From the climbing fibres they reach the Purkinje cells and the axons of these lead straight down to the cerebellar nuclei. Since some collaterals from the axons of these Purkinje cells are recurrent, there are no doubt opportunities for self-re-exciting circuits by which discharges are reinforced and prolonged. Similarly, the Golgi cells provide further opportunities for the reinforcement of impulses (Fig. 222). The histological evidence then, suggests that in the cerebellum incoming impulses are widely diffused and may also be augmented before their final emergence.

CONNECTIONS OF THE CEREBELLUM

The cerebellum receives the major part of the proprioceptive impulses from all sources, and acts as an important centre for their co-ordination. Its efferent fibres make connections with the motor system at all levels of the central nervous system. If any clue to its functions may be discerned in these connections, it is that the afferent connections of the palæocerebellum (roughly speaking, the vermis in older nomenclature) are vestibular and spinal, while those of the neocerebellum (the lateral lobes) are with the cortico-spinal and cortico-pontine projections.

The following are among the most important of its numerous connections (Fig. 223).

A. Afferent Connections

By the Inferior Peduncle

(1) *Vestibulo-Cerebellar Tracts.* From the vestibular nerve, and nuclei *viâ* the inferior peduncles to

(*a*) the flocculo-nodular lobe and part of the vermis of the anterior and posterior lobes (Fig. 220).

(*b*) the roof nuclei (chiefly fastigii).

(2) *Arcuate fibres* arising from cells of the nuclei gracilis and cuneatus, enter the inferior peduncle, and pass probably to the palæocerebellar cortex (not very important).

(3) *Olivo-cerebellar tract* fibres arise in the olive, cross over and pass up by the inferior peduncle to the cortex of the palæo- and neocerebellum.

(4) *Spino-cerebellar tracts.* (*a*) The *dorsal* spino-cerebellar tract fibres, with a contribution from the Vth cranial nerve, ascend by the inferior peduncle to reach the posterior parts (Culmen) of the anterior and the lobus simplex of the posterior lobe of the same side.

Exploration of the cerebellar cortex by micro-leads has shown that when the limbs are stimulated, or passively moved (most effective being pressure on the pads of the feet, with dorsiflexion of digits, as in standing), nervous impulses arrive at the mesial regions of the anterior lobe of the cerebellum *, impulses

FIG. 223. Diagram showing the principal connections of the Cerebellum. Afferent fibres blue, efferent fibres red. Cerebral efferent fibres black.

A.L., anterior lobe; D.C., dorsal cerebellar; Dent. N., dentate nucleus; Flocc, flocculo-nodular lobe; F.P., fronto-pontine fibres; Frontal, frontal cerebral cortex; I.P., inferior peduncle; L.N., lenticular nucleus; Motor, motor cortex; M.P., middle peduncle; N.C., N, G, nuclei and cuneatus gracilis; P, pyramidal fibres; P.L., posterior lobe; R.B., restiform body (blue fibres); Rb.S., rubrospinal fibres; Ret. Sp., reticulo-spinal fibres; R.F., formatio reticularis; R.N., red nucleus; Roof. N., roof nuclei; S.P., superior peduncle; Temp., temporal cortex; T.P., temporo-pontine fibres; V.C., ventral cerebellar; Vestib. Nerve and Nucl., vestibular nerve and nucleus from the hind limbs reaching the oral part, those from the forelimb the culmen, and those from the vibrissæ and face the lobus simplex (Fig. 224). There is thus, as in the cerebral cortex, a rough local representation of the proprioceptive regions projected on the cerebellar cortex, in order leg to face from "above downwards." The areas involved are larger when the proprioceptive regions to which they correspond are more important. Thus, the size of the culmen, which receives from the front limbs, grows progressively greater as we pass from pig to Shetland pony, and finally to man.

BY THE SUPERIOR PEDUNCLE

(*b*) The *ventral* spino-cerebellar tract passes up to the superior peduncle, and then turns back to enter the anterior lobe and roof nuclei of the same side.

BY THE MIDDLE PEDUNCLE

(5) *Cortico-cerebellar tracts.* Fibres from the cortico-pontine projections (= fronto-pontine and temporo-pontine) and branches from the cortico-spinal (pyramidal) tracts relay in cells of the *nuclei pontis*, axons from which conduct to the cortex of the neocerebellum of the opposite side. This is shown by the results of electrical exploration of the cerebellar cortex, while the cerebral motor cortex of the opposite side is stimulated.* Impulses are then observed to arrive at situations which show an orderly marshalling of local representation; the impulses reach more lateral regions of the anterior lobe than those conveyed from the spino-cerebellar tracts (Fig. 225). The greater part of the cortex of the posterior lobe seems to receive but few impulses from this source, or from the spino-cerebellar tracts.

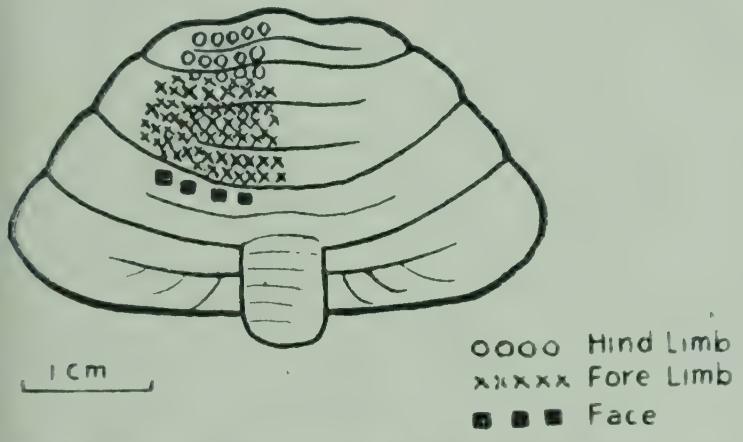

FIG. 224. Receiving areas for Spino-cerebellar Impulses in the Cerebellar Cortex of the Monkey. (ADRIAN, *B. M. J.*, 1944.)

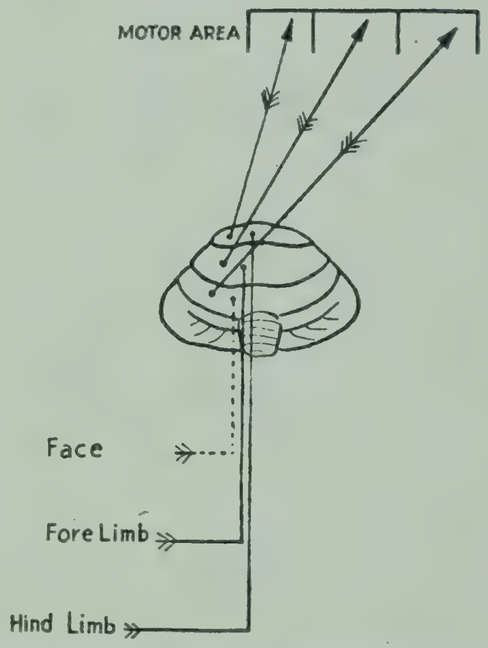

FIG. 225. Spino-cerebellar and Cortico-ponto-cerebellar Projections to receiving areas in Anterior Lobe and Lobus Simplex of the Cerebellar Cortex. (ADRIAN, *B. M. J.*, 1944.)

B. Efferent Connections. Fibres leaving the cerebellar cortex do so in two stages :—

I. FROM CEREBELLAR CORTEX to DEEP NUCLEI.

II. FROM DEEP NUCLEI to EXTRA-CEREBELLAR STRUCTURES. The chief paths outwards fall into three groups :—

(1) *Cerebello-tegmental tracts* which lead from the deep nuclei to tegmental motor nuclei of the reticular formation in the brain stem :—

(*a*) Fibres from roof nuclei *viâ* inferior peduncle to vestibular nuclei, posterior longitudinal bundle, reticular formation, reticulo-spinal tract, etc.

---

* HAMPSON. *J. Neurophysiol.*, 1949, **12**, 37.

(*b*) Russell's tract from roof nuclei to vestibular nuclei, posterior longitudinal bundle, etc., of the opposite side (Fig. 226).

(*c*) From roof nuclei and dentate nucleus (palæo-cerebellar part) by *superior peduncles*, fibres cross to the opposite side, and after sending collaterals to nuclei in medulla, pons and mid-brain, end in the large-celled part of the red nucleus. From these the rubro-spinal tract originates and this then crosses back again to the same side.

(2) *Cerebello-rubro-thalamic and cerebello-frontal tracts.* From the dentate nucleus (neocerebellar part) *viâ* the superior peduncles to the opposite side, and on to the small-celled red nucleus; relays from here, together with direct fibres from cerebellar peduncles, pass on to relay in the thalamus, or pass directly to the frontal and temporal cerebral cortex.

The efferent tracts thus fall, like the afferent ones, into two systems, one putting the palæocerebellum into relation with the motor and correlation centres of the brain stem and spinal cord, and one putting the neocerebellum into relation with the cerebral cortex.

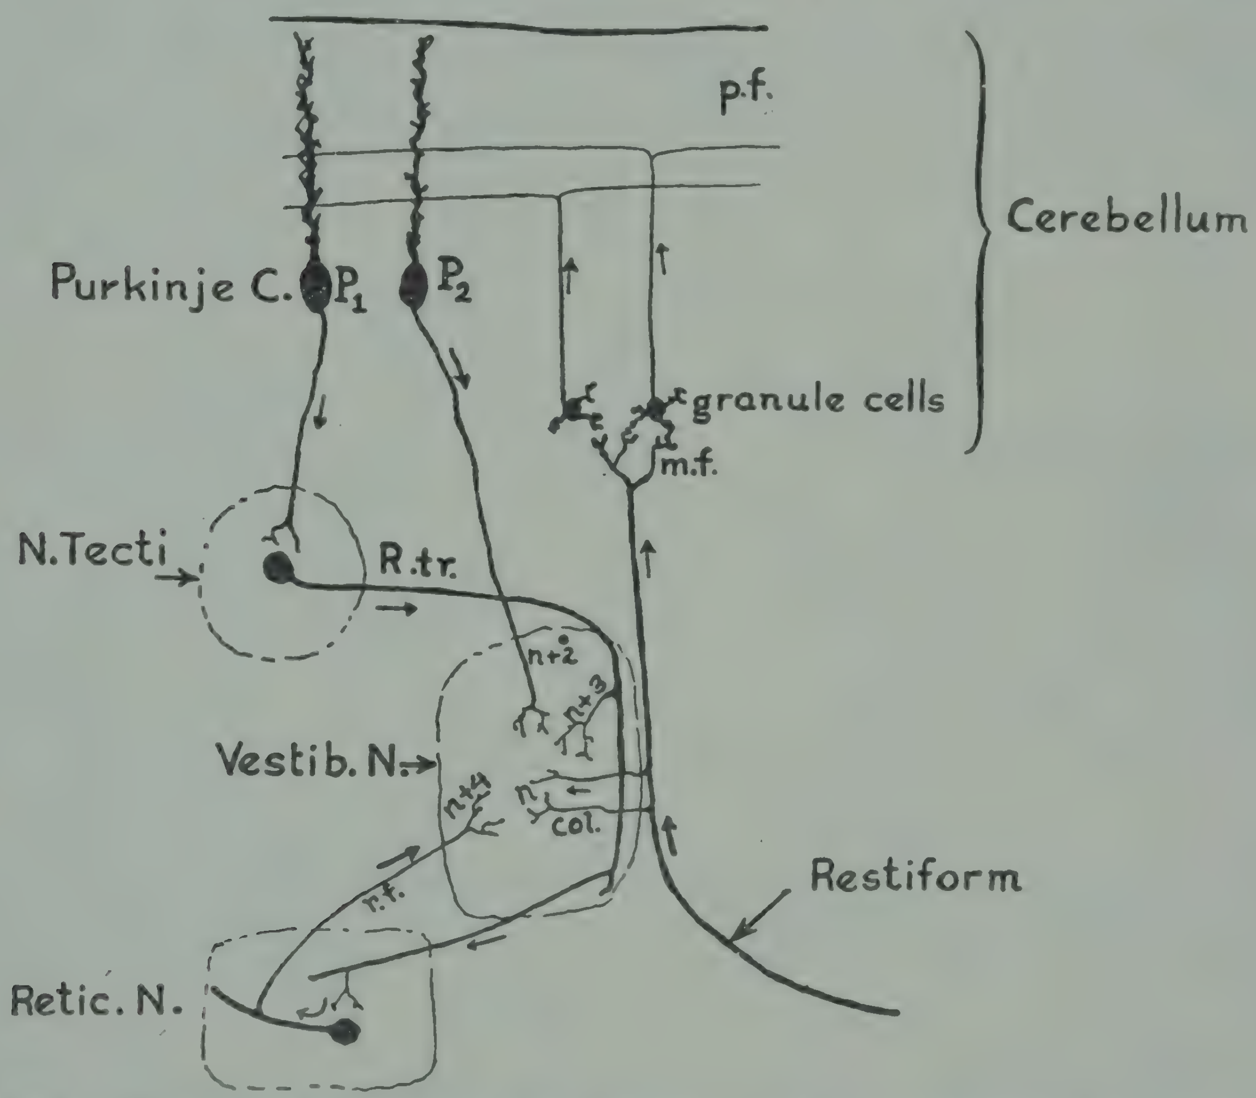

FIG. 226. Diagram of Pathways that Transmit the Proprioceptive Impulses carried by the Restiform Body to the Vestibular Nuclei. p.f., parallel fibres; m.f., moss fibre; R.tr. = Russell's tract, which gives off collaterals to the vestibular nuclei and ends in the reticular substance. From this, recurrent fibres pass back to the vestibular nuclei. (LORENTE DE NÓ. *Arch. Neurol. Psych.*, 1933, **30**, 245.)

It is important to note that the cerebellum is connected with the spinal cord of the same side and with the cerebral cortex of the opposite side.

FUNCTIONS OF THE CEREBELLUM

Knowledge of the functions of the cerebellum is derived from experiments on extirpation, on electro-neuronography, and on stimulation, and from clinical observations of the effects of disease or injury.

Extirpation. The effects of removal of the cerebellum differ according to the species of animal used and the extent of the ablation practised. It is necessary to distinguish between the effects of removal of the palæocerebellum and of the neocerebellum. The former affects equilibration and muscular tonus, the latter leads to impairment of voluntary movements.

In birds the whole cerebellum is a palæocerebellum, and when it is removed there follows a state of hypertonus of the extensor muscles.* Destruction of the anterior lobe alone (which has spinal connections) merely causes this extensor rigidity, but if the posterior lobe (with vestibular connections) is removed there is also defective equilibration, the head being bent backwards.

In mammals, removal of the whole cerebellum leaves sensation unaffected, modifies, though it does not prevent, voluntary movements, and causes disturbance of posture and equilibrium. There are great differences between species ; in lower mammals the effects are transitory, but in apes and men they may be long-lasting. Luciani † described three stages following cerebellar ablation in dogs :—(1) functional exaltation, (2) maximal cerebellar deficiency ; (3) compensation. In all stages there is inco-ordination of movement, or *ataxia*, and *tremor*.

In the first stage there is restlessness, with spasms of exaggerated tonus of the extensor muscles very similar to those of decerebrate rigidity. The positive supporting reaction of Magnus is greatly enhanced.‡ The results are probably due to release from cerebellar inhibitory influences ; an increase of rigidity can in fact be demonstrated on removal of the cerebellum from a decerebrate animal.

In the second stage, three symptoms appeared, called *asthenia* (weakness), *hypotonia*, and *astasia*—staggering gait and tremor on voluntary movement (intention tremor).

In the third stage, these deficiency symptoms are in part remedied by the improvement of voluntary control. The animal walks with the legs wide apart and so obtains a broad and secure base.

Removal of half the cerebellum, on one side only, leads to the appearance of the characteristic symptoms on the *same* side of the body, but recovery is much more complete than after total ablation.

Equilibration is not profoundly affected by removal of the cerebellum, and the labyrinthine postural reflexes are unaffected by it if the vestibular nuclei are not damaged.

Destruction of different parts of the cerebellum leads to results which are in accordance with what we know of their connections. Thus, if the flocculonodular lobe is destroyed there are disturbances of equilibrium, but not of voluntary movements § ; destruction of the anterior lobe causes great increase of extensor tonus as in the pigeon ; partial excisions of the anterior lobe show effects on face, fore-limb and hind-limb in order from behind forwards (as in Fig. 224) and most anteriorly, at the lingula, vestibular effects. Ablation of the neocerebellum results in grave disturbances of voluntary movements with hypotonia and, if the dentate nucleus is involved, with tremor and errors in range of voluntary movement.

Stimulation. No precise muscular movements are obtainable by stimulation of the cerebellar cortex.

Stimulation of the neocerebellum does, however, cause change in the motor areas of the cerebral cortex, as is shown by increase in its spontaneous electric rhythm || and by an increase in its excitability.¶

Stimulation of the anterior lobe does produce effects on the musculature, not contraction, but a relaxation of tonus, *e.g.* of that of decerebrate rigidity.**

** SHERRINGTON. *J. Physiol.*, 1898, **22**, 319.

The relaxation is usually of the antigravity muscles of both limbs of the same side, with no contraction of the antagonists, and also a smaller effect, or more rarely an augmentation of extensor tone, on the opposite side. If a crossed extensor spinal reflex is set up beforehand it is inhibited. The relaxation is followed, after stimulation, by a rebound contraction.* Sometimes extensor movements are obtained, but there is no exact localisation of these.

Stimulation of the flocculus causes movements and nystagmus of the eyes, which agrees with its known vestibular connection.

Stimulation of the deep nuclei † leads to various movements which are subjectively interpreted as being changes of posture.

The effects of stimulation are abolished by section of the superior peduncles.

Cerebellar Disease and Injury. The effects of irritative lesions of the cerebellum are usually too much complicated by accompanying effects to enable definite conclusions to be drawn.

In destructive lesions of the cerebellum there seem to be two clear-cut conditions, attended with different symptoms, namely, destruction of the palæocerebellar parts, and destruction of the neocerebellum. In neither is sensation affected.

Palæocerebellar Destruction. The palæocerebellum is insignificant in size in man, and hence is rarely affected alone. A midline tumour (medullo-blastoma) in children sometimes damages the flocculo-nodular lobe, and causes unsteadiness of gait, with walking on a wide base and a tendency to fall backwards. Tremor and hypotonia are not present, and voluntary movements of arms and legs are normal, though in walking there is inability to balance the body. A somewhat similar syndrome in adult men is seen in rare cases of primary palæocerebellar atrophy due to degeneration of the Purkinje cells, chiefly in the anterior lobe. Here again, the chief defect is in balancing the body on the legs; though voluntary movement of the legs is almost, and that of arms quite, unaffected. As in animals after removal of the anterior lobes, the proprioceptive reflexes concerned with equilibration are exaggerated, and the loss of equilibrium is no doubt due to this.

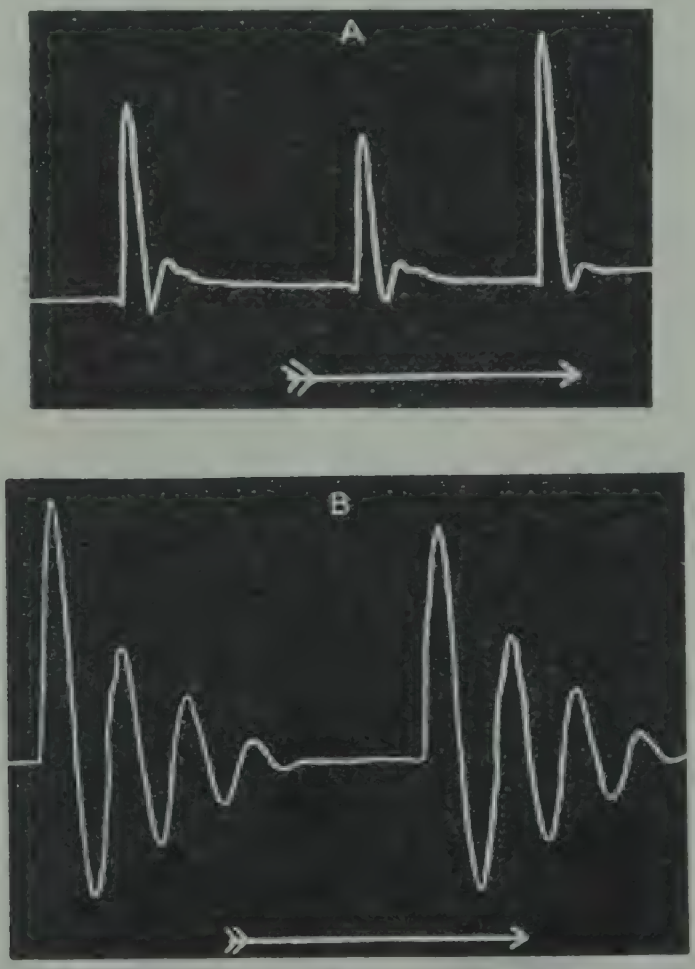

Fig. 227. Records of Knee-jerks. Normal jerk above. Jerk affected by cerebellar injury below. (Gordon Holmes, *Brain*, 1918, **40,** 461.)

Neocerebellar Destruction. A definite syndrome results from loss of the lateral lobe or lobes of the cerebellum, many cases of which, resulting from bullet wounds, were studied by Gordon Holmes. It is characterised by asthenia, definite hypotonia, disorders of voluntary movement, abnormal postures, and tremor on the same side as the lesion. These cause characteristic clinical signs, to many of which particular names have been given.

* Denny Brown *et al.* *Proc. R. S.*, 1929, **104B**, 518.

† Miller and Laughton. *Arch. Neurol. Psych.*, 1928, **19**, 47; *Proc. R. S.*, 1928, **103B**, 575.

(1) *Hypotonia.* The muscles on the affected side are flabby, and although knee-jerks are present, owing to depression of the normal plastic tone the jerk is of a lax and swinging character (Fig. 227). Hypotonia is probably the fundamental defect in neocerebellar lesions, and after removal of the whole cerebellum is also the dominant feature in some species of animals.

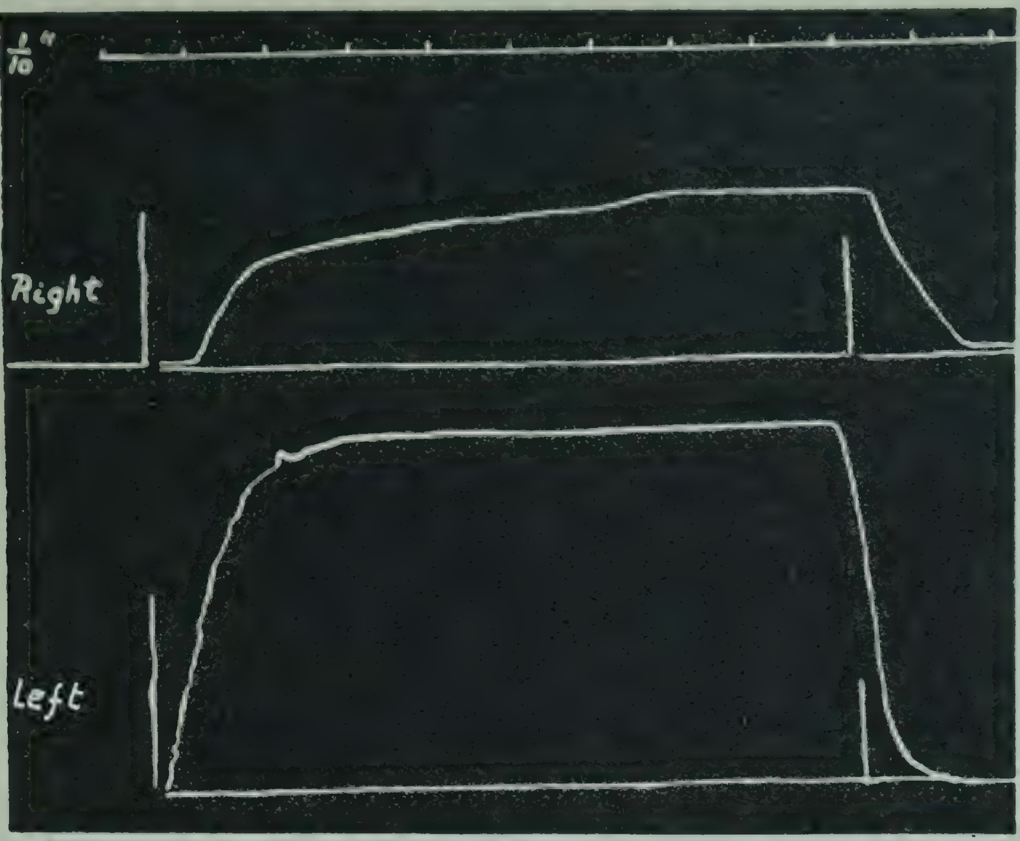

FIG. 228. Illustrating the Characters of Voluntary Contractions in Cerebellar Disease, which affected the Right Side of the Cerebellum. Slower and weaker contractions on the same side. (GORDON HOLMES. *Brain*, 1918, **40**, 461.)

(2) *Disorders of Voluntary Movement.* Voluntary contractions are weak (*asthenia*), slow in onset and ending, and easily show fatigue (Fig. 228). They also show errors in range and force (*dysmetria*). Hence rapidly alternating movements, such as pronation and supination, are difficult to perform (*adiadochokinesis*) (Fig. 229), and co-ordination of movements is poor (*ataxia*), because of improper association of the agonist and antagonist muscles concerned (*asynergia*). In order to compensate for these disabilities the patient often performs a movement in stages, as though " by numbers " (*decomposition of movement*). Speech disorders are sometimes present and are probably due to loss of delicacy and precision in muscular movements.

(3) *Abnormal Postures.* Because of interference with proprioceptive impulses, abnormal attitudes of the arms or legs may result : thus the arm held forwards deviates outwards on the affected side if the eyes are closed (*Barany's pointing test*). There is also a tendency to fall or deviate towards the injured side ; hence the gait zigzags. Nystagmus is common, (slow component towards side of lesion), but vertigo rare.

(4) *Tremor,* of a coarse character, appears as soon as a muscle or limb begins to suffer fatigue, but is only conspicuous if the deep nuclei are damaged.

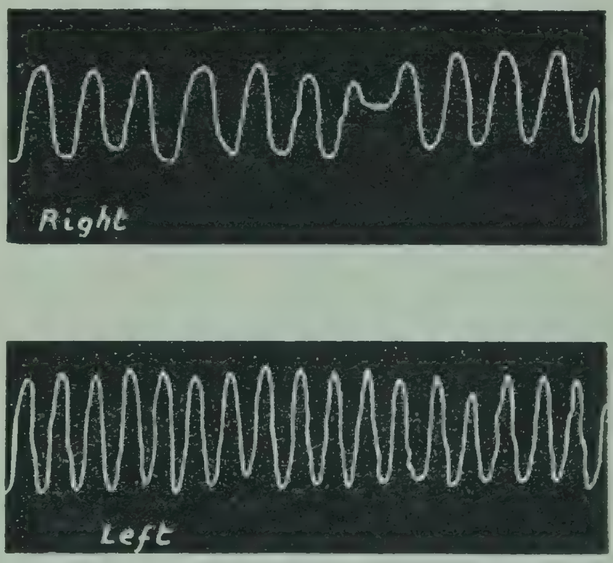

FIG. 229. Adiadochokinesis in Right-sided Cerebellar Lesion. Record of rapid supination and pronation movements of arm on injured side and on normal side (lower). (GORDON HOLMES. *Brain*, 1918, **40**, 461.)

There is rapid compensation for the effects of the lesion, and it is on the whole remarkable how small the effect of a large cerebellar loss may finally be.

CONCLUSIONS REGARDING THE FUNCTIONS OF THE CEREBELLUM

Three points seem clear about the functions of the cerebellum. First, that it is in no way connected with sensation ; second, that it has important relations to the maintenance of postural tonus ; and third, that it is concerned with the attainment of precision as regards force, timing and direction in *voluntary* muscular movements.

The phylogeny of the organ, its connections, and the effects of partial ablations all point to a difference of function as between the palæocerebellum and the neocerebellum. The former appears most clearly to be concerned in the fine adjustment and integration of the unconscious afferent impulses which play a part in the maintenance of the proper distribution of postural tonus. It is essentially proprioceptive, and involved in the co-ordination of the reflexes of muscular tonus in its relation to equilibrium maintenance. It probably, among other actions, serves to moderate the proprioceptive reflexes concerned in the maintenance of equilibrium. In man this function is a subsidiary one. The flocculo-nodular lobe is probably the control region involved in motion sickness.*

It is perhaps not possible to draw a perfectly definite line separating off the functions of the neocerebellum from those of the palæocerebellum, because normal voluntary movements are played off on a background of postural tonus, but it is evident that the neocerebellum, the development of which is phylogenetically parallel to that of the cortex, has important functions with respect to the execution of voluntary movements. We may suppose from the evidence that has been reviewed that it serves in some way to organise and, where necessary, to fortify the impulses from the cerebral cortex, and so to fit them into the existing background of postural tonus as to give precise, smooth and sufficiently powerful contractions of the various muscle groups in their correct relations to each other. Hence, in some way at present unknown, it is superadded to, and seems to exercise a kind of final editorial supervision over, the motor impulses emerging from the cerebral cortex. " By virtue of the proprioceptive impulses which it receives from all peripheral structures concerned in posture and movement, the cerebellum is in a position to send to the forebrain an integrated influx which may serve in the control and distribution of muscular tone " (Gordon Holmes, 1939). Local representation of muscular areas on its cortex is at most only vaguely indicated and indeed a study of its histological structure leads to the conclusion that its functions are generalised over its surface.

CHAPTER XXIII

THE AUTONOMIC SYSTEM: THE HYPOTHALAMUS: HUMORAL TRANSMISSION

I. THE AUTONOMIC SYSTEM

The autonomic nervous system includes those arrangements of efferent and afferent nerve fibres which are primarily concerned with the regulation of the internal processes of the body. Its efferent fibres are distinguished from the somatic efferents supplying skeletal muscle by having in the course of each ultimate fibre one synaptic connection outside the central nervous system, viz. in one of the various ganglia of the sympathetic and parasympathetic systems. Its afferent fibres are widespread and subserve many important reflex functions as well as being concerned in the appreciation of visceral pain.

The autonomic system has connections with, and tracts and centres in, the central nervous system proper, and according to the manner of the connections with the central nervous system, the efferent parts of the autonomic system are subdivided into two sub-systems of distinct, or even contrasting, function, viz. the *sympathetic* and *parasympathetic* systems.*

We may therefore consider the autonomic system under these divisions :

(1) Sympathetic—or thoracico-lumbar } Efferent
(2) Parasympathetic—or cranio-sacral } Efferent
(3) Afferent autonomic fibres.

(1) **THE SYMPATHETIC SYSTEM** (Fig. 230) consists of the *lateral chain* of sympathetic ganglia, various *collateral ganglia* and plexuses, and many scattered *terminal ganglia*. The whole system originates from neurones limited to the intermedio-lateral cell columns of the thoracic and upper lumbar levels of the spinal cord, though the sympathetic chain extends from the upper cervical level to the coccyx. The cells of the sympathetic ganglia are all multipolar.

The sympathetic chain consists of bundles of nerve fibres, medullated and non-medullated, which connect together longitudinally the "*lateral*" *ganglia* lying on each side of the vertebral column, there being as a rule one ganglion to each spinal nerve root. But in the cervical region these ganglia are condensed into two or three, the *superior, middle and inferior cervical ganglia*, united by the cervical sympathetic trunk ; and the upper three or four thoracic ganglia on each side are condensed, sometimes, as in cat and dog, together with the inferior cervical ganglia, to form the "*stellate*" *ganglion*.

Details differ from one species, or even individual, to another. In man the inferior cervical ganglion is often fused with the first thoracic ganglion, and then corresponds to the stellate ganglion in cat or dog. The lowest ganglion of the cervical vagosympathetic trunk, and which lies on the oral side of the annulus of Vieussen's, is most commonly now regarded as the middle cervical ganglion.†

At the bottom of the chain there is only one coccygeal ganglion for the coccygeal vertebræ.

The (lateral) ganglia of the sympathetic chain are connected with all the spinal nerves, just after they have given off their posterior divisions, by means of the *rami communicantes*. These rami communicantes are of two kinds :

FIG. 230. Diagrammatic Representation of the Distribution of the Sympathetic and Sacral Autonomic Systems.

The black lines represent the medullated pre-ganglionic fibres, such as those making up the white rami communicantes, while the post-ganglionic fibres are printed in red. On the extreme right of the figure is indicated the general distribution of the white rami arising from the several nerve roots, while the double brackets point to the nerve roots making up the limb plexuses. (The sacral autonomic fibres arise from S2 and 3, and are parasympathetic. The ganglion marked "inf. cerv. g." is, in most animals, now called the middle cervical ganglion, the inf. cervical g. being considered as fused into the stellate g.)

B. Bladder.

white rami consisting of small medullated fibres, and *grey rami* composed almost exclusively of non-medullated nerves. It was shown by Gaskell that the white rami are formed by fibres which have their origin in the spinal cord and perhaps also in the posterior root ganglia ; whereas the grey rami represent fibres which, arising in the sympathetic ganglia, run back to join the spinal nerves (Fig. 231). The outflow represented by the white rami is limited to a distinct region of the cord, viz. from the first thoracic to the third or fourth lumbar nerve roots ; whereas the grey rami pass back from the sympathetic chain to all the spinal nerve roots. Stimulation of a limited number of white rami produces all the effects that can be evoked by stimulation of the grey rami, showing that the impulses leaving the cord pass upwards and downwards in the sympathetic system and are broken somewhere in their course, being transferred to a fresh relay which, by means of non-medullated nerves, carries them on to their destination.

Every fibre of the sympathetic system at some point of its course forms one synapse with a nerve cell, and Langley showed that this is the only cell-break in the fibre. This applies not only to the sympathetic fibres, but also to the fibres of the parasympathetic. Each fibre path therefore can be regarded as made up of two sections—a *pre-ganglionic* fibre arising in the spinal cord and passing out to a ganglion as a fine medullated nerve fibre, and a *post-ganglionic* fibre arising in this ganglion and continued as a non-medullated fibre, to its peripheral distribution.

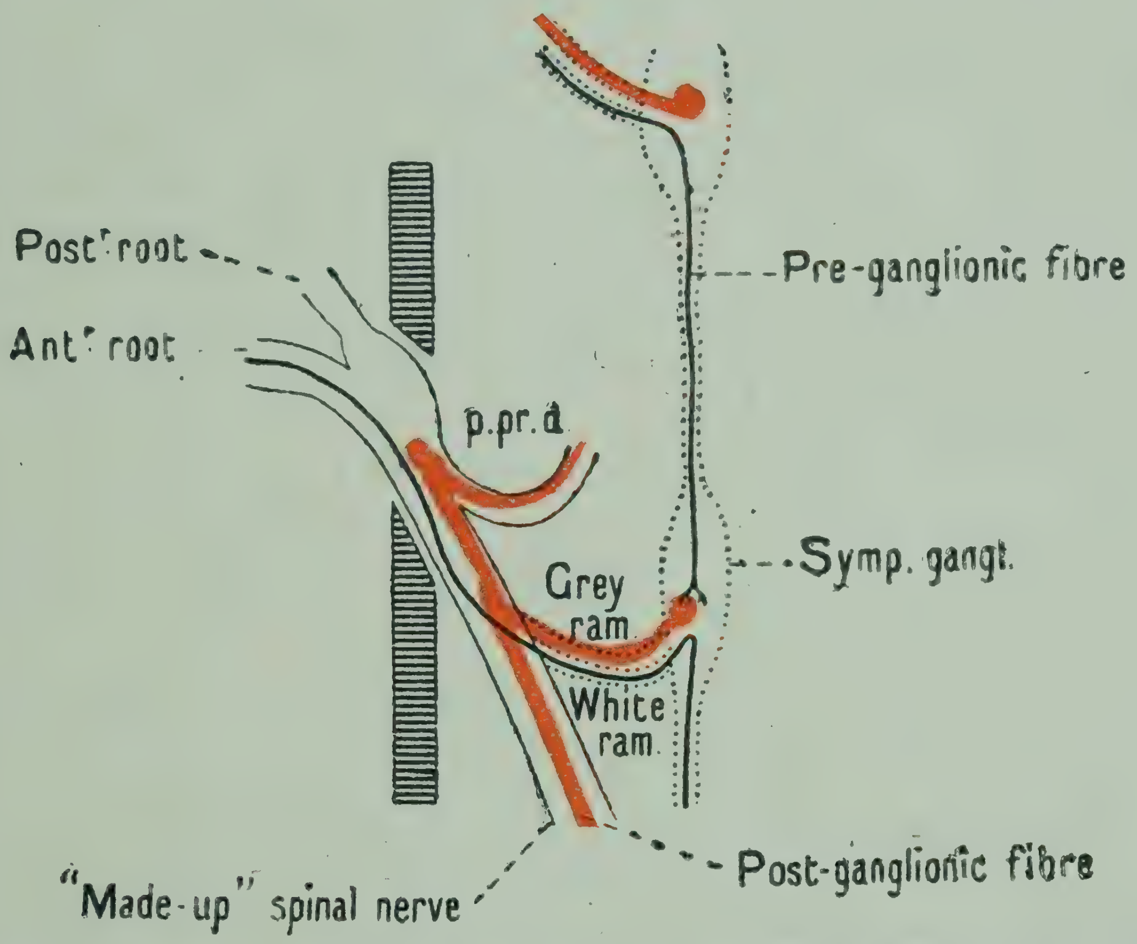

Fig. 231. Diagram to show the manner in which a Spinal Nerve is completed by the entry of a Grey Ramus, containing Fibres derived from Cells in the Sympathetic Chain. (After Langley.)

p.pr.d. **Posterior primary division. (The post-ganglionic fibres are represented in red.)**

This transference from one system to another involves the passage across a synapse and a nerve cell. The situation of this synapse may be easily revealed by utilising the action of nicotine, first studied by Langley.* If nicotine be applied to a sympathetic ganglion, it first stimulates and then paralyses any synapses which may lie in the ganglion. Intravenous injection of nicotine therefore causes a primary general excitation of all visceral ganglion cells. There is an enormous rise of blood pressure, which may be accompanied by other sympathetic effects, such as dilatation of the pupil, erection of the hairs, and so on. This rise rapidly passes off, and it is then found impossible to evoke any reflex visceral effects or any contraction, *e.g.* of the blood vessels by stimulation of the spinal cord; the passage of the impulses is blocked in every one of the visceral ganglia. By observing the effects of stimulation of a nerve before it enters a ganglion and then painting the ganglion with nicotine, and again trying the effects of excitation, it is easy to determine whether the nerve fibres which were excited in the first case form any synapses with the nerve cells of that ganglion.

---

* Langley. *J. Physiol.*, 1890, **11**, 123.

The relationships of the white and grey rami are strikingly illustrated in the case of the pilomotor fibres. These, in the cat, arise from the cord by the anterior roots from the fourth thoracic to the third lumbar inclusive. Passing by the white rami to the sympathetic system, they travel upwards and downwards and end by arborisations in the various ganglia of the main chain. From the cells of each ganglion a fresh relay of fibres starts, which runs as a bundle of non-medullated nerves (the grey ramus) to the corresponding spinal nerve, with which it is distributed to its peripheral destination. Each grey ramus causes erection of the hairs of one spinal segment, whereas stimulation of one white ramus causes erection in three or four segments, showing a distribution of the fibres of the white ramus to the cells in several successive ganglia. We thus see that, in speaking of the sympathetic functions of a spinal nerve root, we must clearly distinguish whether we mean the root as it arises from the spinal cord, in which case its visceral functions will include those of its white ramus, or whether we mean the made-up or complete spinal nerve after it has received its grey ramus (Fig. 231). In the latter case the visceral functions of the root will be more restricted than in the former case, and will have a different distribution.

The Collateral Ganglia. In the abdomen is a second system of ganglia, in special connection with the abdominal viscera, lying in front of the aorta and surrounding the origins of the large arteries to the alimentary canal. These are the semi-lunar, or cœliac, ganglia and the superior mesenteric and inferior mesenteric ganglia.

These ganglia are entangled in a fine feltwork of nerve fibres, which covers all the large arteries to form the sympathetic plexuses of the abdomen, *e.g.* the cœliac plexus, the mesenteric plexuses, hypogastric plexuses, etc. The outflow to these ganglia consists mainly of pre-ganglionic fibres, which have passed through the sympathetic chain without forming any synaptic connections there, and emerge from that chain as *the splanchnic nerves.* With them are also a few post-ganglionic fibres (Fig. 232).

The three splanchnic nerves originate from the fourth to the eleventh thoracic spinal roots, and pass to the cœliac and superior mesenteric ganglia. Small branches from the lumbar roots pass in a similar way to both the mesenteric ganglia. The majority of the splanchnic fibres form their synaptic connections in the collateral ganglia (Fig. 232). From the abdominal plexuses, which are largely non-medullated, fibres pass to all the abdominal viscera. There are also some fibres of pre-ganglionic type which pass directly to the viscera, where they form synapses with ganglion cells in their walls.

Distribution of the Sympathetic Fibres. The post-ganglionic fibres of the sympathetic system are distributed to their destinations in one of two main ways, viz. : with the spinal nerves, or by travelling along with the small arteries. The fibres of the grey rami are of the first type, the remainder are of the second.

There are grey rami to all the spinal nerve roots; this means that the grey rami may contain fibres derived from white rami at other levels, since the white rami are confined to the thoracic and upper lumbar roots. The pre-ganglionic fibre of the white ramus passes to the sympathetic chain and may travel up or down in it for one or more segments, giving off branches on the way, but ultimately it ends by synapse with many cells in one or more of the lateral ganglia. An impulse emerging from the cord by a pre-ganglionic fibre has therefore ample opportunity to affect many neurones of the chain, and to be dispersed along many differently distributed post-ganglionic fibres. Reflex responses of the sympathetic system therefore involve a wide and diffuse field of effectors.

(1) The "post-ganglionic" axons of the cells of the lateral ganglia enter the grey rami (often after some further travel up or down in the chain), and are then distributed to the region supplied by that particular spinal nerve root; these areas are the skin of the limbs and trunk, the structures supplied being the arterioles and capillaries (vaso-constrictor), the sweat glands (secretory), the hair muscles or *arrectores pilorum* (motor, causing erection of hairs): fibres also pass to the blood vessels of muscle, to which they are mainly vaso-dilator. The fibres for the *upper limb* leave the cord by the white rami of the upper thoracic roots, and have cell stations in the stellate and middle cervical ganglia. Those for the *lower limb* are derived from the lower thoracic and upper lumbar roots. Those for the trunk areas come from the middle regions of the outflow from the cord.

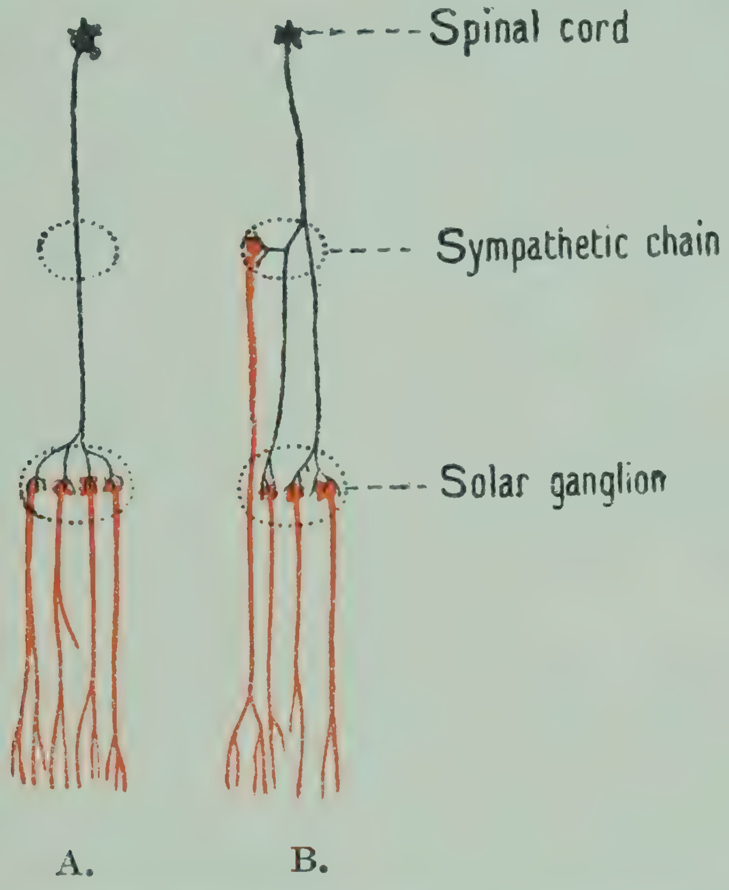

Fig. 232. Figure to show the probable Mode of Connection of the Fibres of the Splanchnic Nerve with Nerve Cells. (After Langley.)

A. Usual type, all the fibres passing through the lateral chain to end in the collateral ganglia of the solar plexus.

B. Alternative condition, in which a small minority of the fibres have their cell stations in the sympathetic chain.

The pre-ganglionic fibres are black, the post-ganglionic red.

(2) The remaining fibres of the sympathetic system are distributed by passing along the walls of the arteries, and most of the fibres to the skin of the head and neck are also of this type.

(i.) *The Head and Neck.* These fibres arise from the first and second thoracic nerves, ascend in the cervical sympathetic and have cell stations in the superior cervical ganglion, from which post-ganglionic fibres travel with the blood vessels, to supply all the structures of the head and neck. (*a*) The fibres to the *skin* supply sweat glands, arrectores pilorum muscles, and small blood vessels. (*b*) The *salivary*, lachrymal, and buccal glands receive fibres that are secretory and vaso-constrictor. (*c*) The *brain* receives vaso-constrictor fibres. (*d*) The *eye* receives motor fibres to the *dilator pupillæ* muscle, to the *nictitating membrane* (when present), to the plain muscle of the orbit (*Müller's muscle*), and to some plain muscle in the upper lid. Stimulation of the upper end of the cut cervical sympathetic therefore causes vaso-constriction in head and neck vessels, dilatation of the pupil, retraction of the nictitating membrane and upper lid, and some protrusion of the eyeball, while section, or excision of the superior cervical ganglion, gives the opposite effects. (*e*) The *thyroid* also receives fibres, the function of which is uncertain.

(ii.) *The thoracic organs* are supplied from the second to fourth thoracic nerves, with their cell stations situated in the stellate ganglion, and, in man, also in the inferior, and middle, and some even in the superior cervical ganglia. Post-ganglionic fibres are distributed with the cardiac, pulmonary and other plexuses. Those to the *heart* are accelerator and also dilate the coronary vessels ; those to the *lungs* are broncho-dilator and vaso-constrictor.

(iii.) *The abdominal organs* derive their pre-ganglionic fibres from the thoracic roots below the fourth or fifth, the fibres passing through the sympathetic chain to form the *splanchnic nerves.* These pass to the various collateral ganglia, the cœliac, and superior and inferior mesenteric ganglia and the pelvic or hypogastric ganglion, where the synapses are situated. Post-ganglionic fibres from these ganglia then travel along the blood vessels. These fibres, together with some pre-ganglionic fibres and numerous scattered small ganglia, form elaborate plexuses along all the main arteries of the abdomen, and are named after these arteries, *e.g.* renal plexus, etc. The *hypogastric nerves*, derived from the lower levels of splanchnic outflow, mainly relay in the hypogastric ganglion, the arrangement in man being different in detail from that in lower mammals.

All the abdominal and pelvic viscera are supplied with sympathetic fibres. (*a*) To the stomach and intestines, with the exception of their sphincters, the fibres are vaso-constrictor and inhibitory of movement. The sphincters are supplied with motor fibres, so that a result of sympathetic stimulation is a retention of contents in the alimentary canal. (*b*) The bladder is also supplied by inhibitory fibres, but its sphincter with motor fibres. (*c*) The liver is supplied with fibres that constrict its blood vessels and also cause a discharge of glucose from the liver into the blood. (*d*) Weak contraction of the gall-bladder may also be caused by the sympathetic.

(*e*) To the spleen the sympathetic sends motor fibres to its plain muscle, and the organ diminishes considerably in size owing to expulsion of contained blood, when the sympathetic fibres of the splenic nerve are stimulated.

(*f*) Lastly, the splanchnic also sends an important branch to the suprarenal body, which discharges adrenaline into the blood stream when the splanchnics are stimulated. These *fibres that go to the suprarenal are pre-ganglionic fibres*, and instead of forming synapses with ganglion cells, they end *directly in relation to the cells of the suprarenal medulla.* It is interesting to note, however, that these cells are actually developed from the same embryological structures as form the sympathetic ganglion cells—a fact of some significance, as we shall see.

FUNCTIONS OF THE AUTONOMIC GANGLIA

These ganglia consist of a mass of nerve cells embedded in connective tissue, each cell being surrounded by a special capsule. The nerve cells are multipolar, each cell possessing one axon and several dendrites. The dendrites end in little arborisations round adjacent cells.

Since the main nervous system is characterised by the possession of nerve cells, it was formerly thought that any collections of nerve cells must partake of the co-ordinating and reflex functions of the central nervous system, *i.e.* must act as local nervous centres. Though theoretically conceivable, all efforts have failed to prove the existence of such a function, and we must conclude that the sole use of these ganglia is to serve as distributing centres. Each pre-ganglionic fibre divides, and the branches arborise round several cells (Fig. 232). In the superior cervical sympathetic the ratio of pre- to post-ganglionic fibres is 1 : 32.* A complex of fibres and cells is found in mammals in the plexuses of Auerbach and Meissner, which do in fact act as local nerve centres for the intestine. But all such mechanism is wanting in the sympathetic ganglia.

There is, however, a certain group of phenomena which can be elicited in sympathetic ganglia, and which were termed by Langley and Anderson † *axon reflexes.* If, for instance, in the cat we divide all the nerves going from the sympathetic chain to the inferior mesenteric ganglion, leaving the bladder connected with this by the hypogastric nerves, and then after dividing the left nerve stimulate its central end, we obtain a contraction of the right half of the bladder. This effect is abolished by painting the inferior mesenteric ganglion with nicotine, showing that the activity of the cells of this ganglion is involved in the process. It has been shown, however, by Langley and Anderson that this is not a true reflex. A pre-ganglionic fibre arriving at the inferior mesenteric ganglion branches, one branch ending round the cells of the ganglion, while the other branch passes down in one hypogastric nerve to a cell situated near the base of the bladder (Fig. 233). When, therefore, we stimulate the central end of the divided nerve, we are stimulating some pre-ganglionic fibres, and the excitation spreads up to the point of junction of the two branches and then down the other branch to excite the cell in the inferior mesenteric ganglion. We thus obtain an apparent motor reflex by stimulation of a nerve which is itself motor. Similar pseudo-reflexes can be obtained for other viscera, *e.g.* the colon, *viâ* the hypogastric, as for the bladder, and also along the abdominal chain on the pilomotor nerves,‡ but furnish no grounds for ascribing to peripheral ganglia the property of reflex centres.

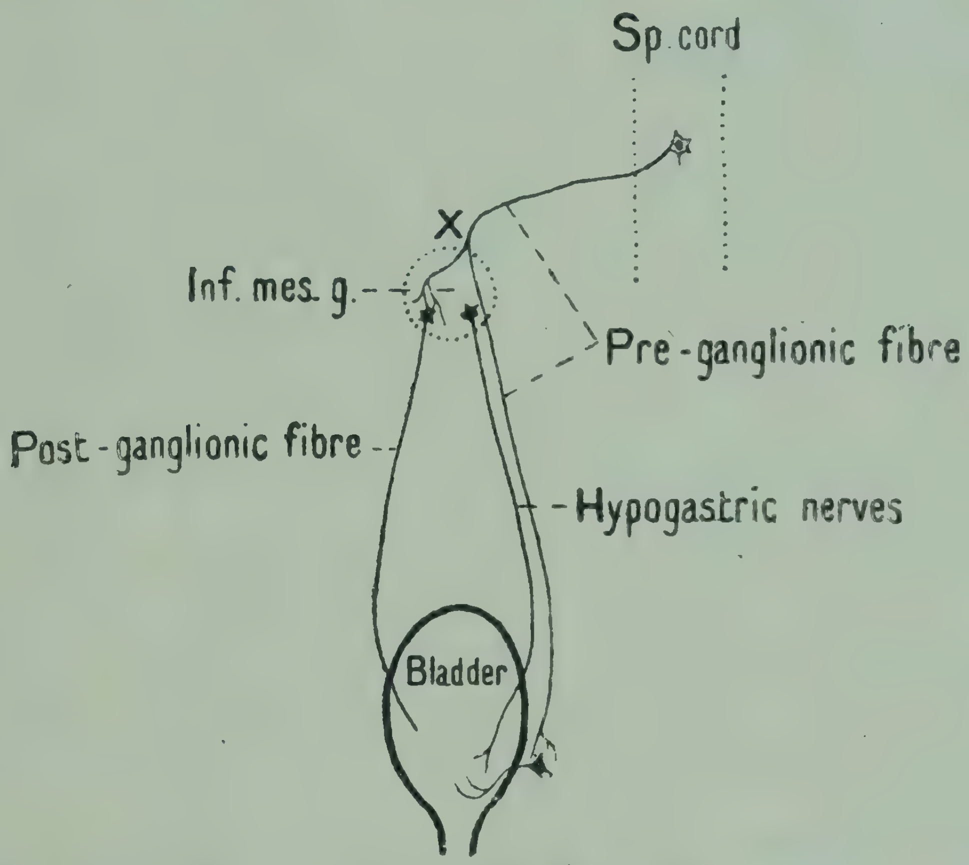

FIG. 233. Diagram to illustrate Langley and Anderson's explanation of the Hypogastric Reflex as an Axon Reflex.

The branching of the axon where the propagation or "reflexion" takes place is at X.

Another feature of sympathetic ganglia is that the effects of pre-ganglionic stimulation may be a prolonged state of excitation. This is possibly due to the presence of re-exciting circuits.§

DISPENSABILITY OF THE SYMPATHETIC SYSTEM

Complete removal or inactivation of the sympathetic system was performed on a number of animals by Cannon,‖ by removal of the thoracic and abdominal chains. Animals thus operated have lived for years in good health and of normal appearance, under the sheltered conditions of laboratory life. There is, however, a greatly reduced capacity to do work. This is because the body no longer has at its disposal the numerous reserves, such as heart acceleration, liberation of adrenaline, redistribution of blood to the working muscles, dilatation of bronchioles, etc., which are made available during exercise by the intermediation of the sympathetic nervous system. During emotional excitation or exposure to cold, also, there is none of the response associated with sympathetic activity, such as erection of hairs, or rise of blood sugar, or contraction of the spleen. It is therefore difficult to prevent a rapid fall of body temperature when the animals are exposed to moderate degrees of cold, in spite of the fact that the animals shiver much more readily than do normal animals under similar conditions. The same difficulty of regulating body temperature is seen when the surroundings are hot, so that dangerous rises of temperature are likely to occur. It is clear, therefore, that the sympathetic nervous system, though not essential to the maintenance of life, when conditions are favourable, has as an important, if not, as its chief, function, the automatic adjustment of the manifold responses of the individual to the emergencies of an adverse environment.

(2) THE PARASYMPATHETIC SYSTEM consists of the cranio-sacral outflow of the autonomic system, and is divisible into the mid-brain, bulbar and sacral portions. Its pre-ganglionic fibres pass near to their final destinations before terminating in synapses, which, as shown by the nicotine method, are situated in peripherally placed ganglia.

The mid-brain outflow is represented by fibres in the IIIrd cranial nerve, which arises from the group of oculo-motor nuclei lying ventral to the aqueduct of Sylvius. The pre-ganglionic fibres pass to the ciliary ganglion in the orbit, from which they are relayed by post-ganglionic fibres to the *constrictor pupillæ muscle* and the *ciliary muscle.* Stimulation of the IIIrd nerve leads to constriction of the pupil, and contraction of the ciliary muscle. (Other fibres of the IIIrd nerve are not autonomic, viz. the nerves, both afferent and efferent, to the extrinsic eye muscles.)

The bulbar outflow comprises some of the fibres in the VIIth, IXth and Xth cranial nerves. In the *VIIth nerve* the fibres pass to the spheno-palatine ganglion, where relays of fibres occur for supply of the *lachrymal gland* and structures in the pharynx, and other fibres pass *viâ* the *chorda tympani* to peripheral ganglia, for supply of the secretory and vasodilator fibres of the *submaxillary* and *sublingual* salivary glands. The *IXth nerve* similarly, *viâ* the otic ganglion, supplies the *parotid* gland and tongue with secretory and vasodilator fibres.

The *Xth cranial nerve* supplies most of the thoracic and abdominal viscera with parasympathetic fibres, which reach their destinations by way of various autonomic nerve plexuses, in which, as well as in the organs themselves, are placed the widely scattered ganglia on their course. The vagus fibres so distributed are inhibitory to the *heart*, vasoconstrictor to the heart vessels, constrictor to the *bronchi*, motor to the lower *œsophagus*, and augment movements of the *stomach* and *intestines*, with the exception of the sphincters, to which they are inhibitory. On the *stomach and pancreas* it has secretory functions, and also causes vasodilatation of the small blood vessels.

The sacral outflow leaves the spinal cord by the second and third sacral ventral roots, which form the *pelvic visceral nerves*, or *nervi erigentes.* These supply the pelvic viscera, the ganglia being mostly placed on their walls. The large intestine and rectum and bladder are supplied with motor fibres, and the external genitalia with vasodilator fibres. Stimulation of the pelvic visceral nerves causes erection of the penis as a result of the vasodilatation which follows.

COMPARISON BETWEEN SYMPATHETIC AND PARASYMPATHETIC

The various effects of the parasympathetic system are directed with greater precision of localisation to their effector organs than is the case with the sympathetic system. With the latter, a pre-ganglionic fibre makes connection with several ganglion cells which are all situated at a distance from the effector organs or tissues, so that one fibre may produce an effect over a wide area. The parasympathetic fibres, on the other hand, proceed as pre-ganglionic fibres until they are near to their destinations, so that there is much less diffusion of their effect.

Action of Drugs. The widespread effects of the sympathetic system are also ensured by the fact that in states of sympathetic excitation, *adrenaline* is liberated from the suprarenal body into the blood, branches from the splanchnic nerves being secretory to the medulla of the suprarenal. The injection of adrenaline into the circulation reproduces most of the effects of sympathetic stimulation all over the body, *e.g.* dilatation of pupil, widespread vasoconstriction, liberation of glucose from the liver, etc. By circulating all over the body, therefore, the adrenaline which is set free by splanchnic stimulation, causes a generalisation and prolongation of sympathetic effects in nearly all the organs that have a sympathetic supply. Thus, stimulation of the splanchnics not only causes relaxation of the tone of the stomach and intestines, but also acceleration of the heart and intense vasoconstriction of small vessels in the skin all over the body, even if the nerve supply to them has been cut.

Ergotoxine (ergotamine) paralyses the motor and secretory fibres of the sympathetic system, but has no effect on the inhibitory functions. If the drug is given, and the splanchnic then stimulated, or adrenaline injected, general vasodilatation occurs instead of constriction, so that the blood pressure falls. This is because there are sympathetic vasodilators, unaffected by the ergotoxine; normally their action is masked by that of the more powerful vasoconstrictors.

Dibenamine (n, n-dibenzyl-chloroethylamine)* has similar actions.

Cocaine greatly augments the effects of sympathetic stimulation or of adrenaline. *Ephedrine* has a similar effect, and it has been suggested by Gaddum that this is due to the fact that these substances protect the adrenaline from oxidation in the tissues.

Nicotine first excites and then paralyses all autonomic synapses, the sympathetic endings in the suprarenal medulla, and striated muscle motor end plates. *Curare* also paralyses synaptic transmission.

Muscarine (*and pilocarpine*) produce excitant effects on the structures supplied with post-ganglionic parasympathetic fibres, and also on sweat glands. All its actions are abolished by atropine.

Acetyl choline, when injected into the blood or applied to a tissue, reproduces all the effects of parasympathetic stimulation, and also causes secretion of sweat, although the sweat glands receive a sympathetic supply. It also has a nicotine-like action in stimulating certain skeletal muscles and autonomic ganglia. Its action is very transient, however, as it is rapidly destroyed in the blood and tissues by the action of an enzyme called choline esterase.

Eserine (di-isopropyl fluoro-phosphate (D.F.P.)), and certain alkyl polyphosphates† inhibit the action of this enzyme by becoming attached to its active group; hence, after eserine has been injected into an animal, acetyl choline then causes intense and prolonged effects, *e.g.* slowing or inhibition of the heart, secretion of saliva, etc. After eserine, the effects of parasympathetic stimulation are prolonged, and may also become generalised, *e.g.* stimulation of the vagus not only slows the heart, but also causes a secretion of saliva, etc.

† BURGEN, *et al., Nature*, 1947, **160,** 760.

Atropine paralyses the actions of muscarine, and the muscarine-like effects, but not the nicotine-like actions of acetyl choline; it also renders parasympathetic stimulation ineffective.

(3) AFFERENT FIBRES OF THE AUTONOMIC SYSTEM

There are abundant afferent fibres, many of them non-myelinated, in all the autonomic nerves. Thus, stimulation of the cut central end of the splanchnic nerve produces reflex effects such as a dilatation of the pupil, rise of blood pressure, etc. The autonomic afferents come from all parts of the body, and commence in receptors in the viscera and somatic structures.

Spinal autonomic afferents pass from the periphery in the splanchnic nerves, phrenics, etc., and some also with the various spinal nerves. They pass without interruption through the sympathetic ganglia, and white rami communicantes * to the dorsal roots, where their cell bodies are situated, as for

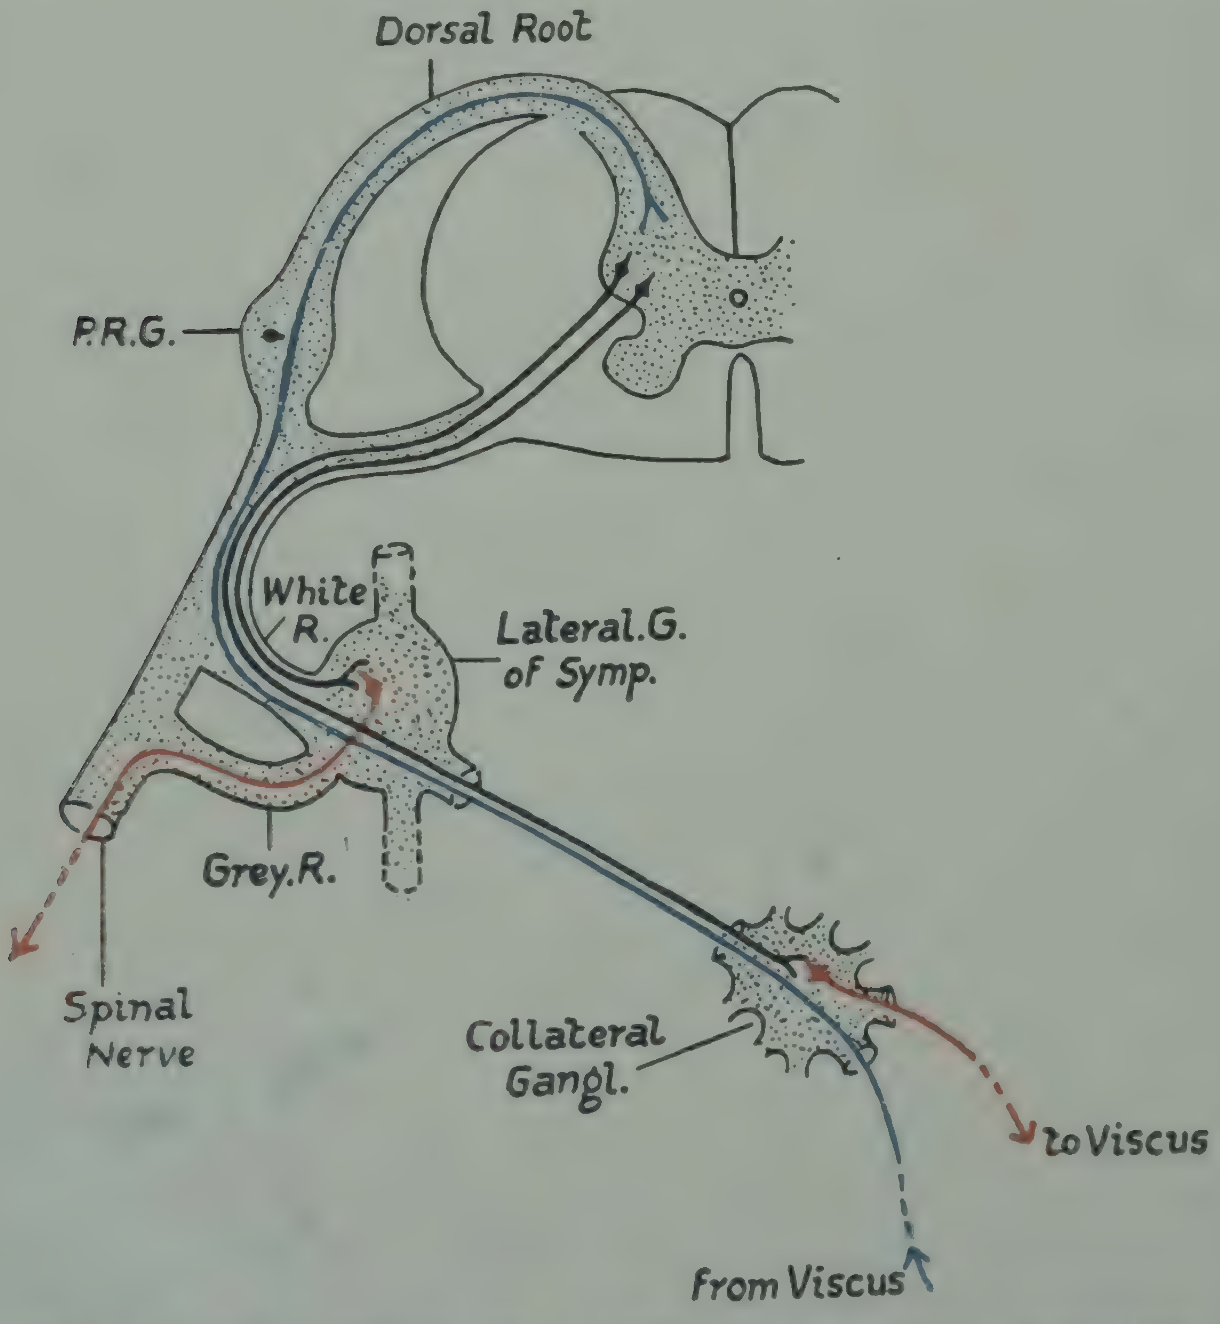

Fig. 234. Diagram showing the Afferent and Efferent Connections of the Sympathetic System. Afferent fibres blue, preganglionic efferents black, postganglionic efferents red.

---

* Ranson and Billingsley. *J. Comp. Neurol.*, 1918, **29**, 405.

the somatic afferents ; like these they enter the dorsal roots of the spinal cord (Fig. 234). The spinal roots concerned are all those that have white rami, viz. the thoracic and upper 3 lumbar and the 2nd to 4th sacral roots.

In the spinal cord the afferent autonomic fibres probably branch, much as the somatic afferent fibres do, and some terminate in relation to cells of the dorsal horn of grey matter. From here the further path may diffuse widely, by a series of relays, but sooner or later some of the collaterals form synapses with cells in the intermedio-lateral cell columns in the cord, from which the efferent sympathetic fibres emerge. How widely the efferent effects of afferent autonomic stimuli may spread is shown by the fact that on stretching of the intestine, dilatation of the pupil occurs.*

Visceral Pain. Afferent nerves from the viscera and from the parietal serous membranes are of importance in connection with visceral pain. To cutting, burning, or pinching, the viscera are quite insensitive, yet everyone knows that pain can originate in the viscera. Clinical experience and physiological experiments converge to the conclusion that pain originating in the hollow viscera is associated with, and probably due to, unduly powerful contractions of their muscular walls. Distension not accompanied by increased muscular contraction, as, *e.g.*, in paralytic ileus, gives rise to no pain.

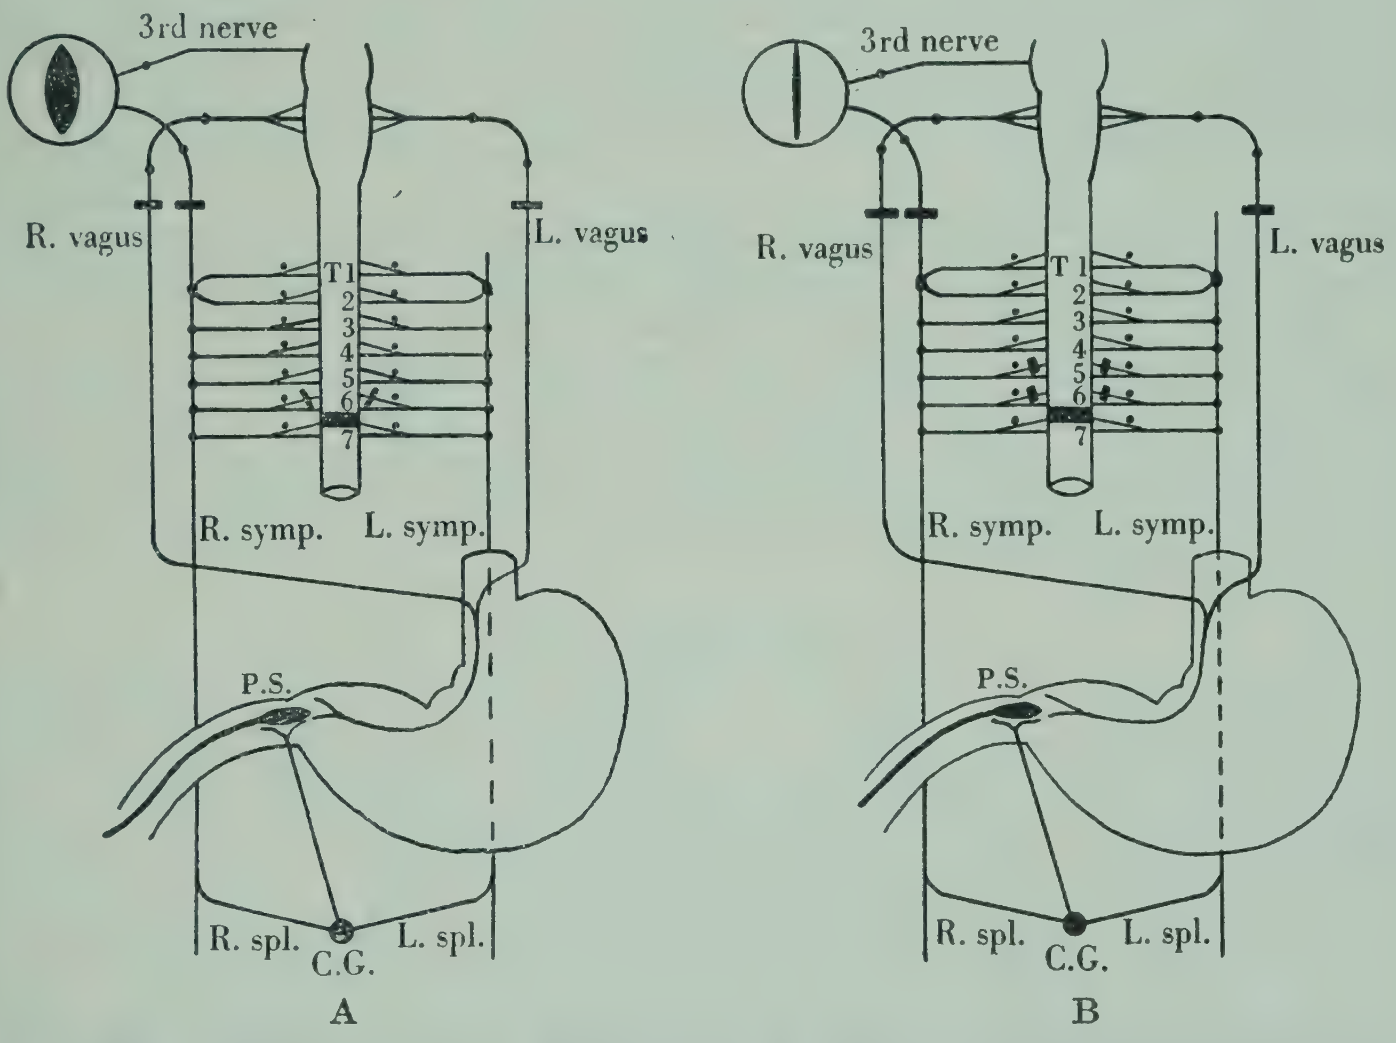

FIG. 235. Determination of Upper Limit of Entry of Afferents from Pyloric Sphincter. A. Cord cut between 6th and 7th Th. segments. R. and L. vagi and R. and L. cervical sympathetic nerves cut in the neck ; 6th Th. dorsal roots cut. Dilatation of pupil on distension of pyloric sphincter. B. On now cutting 5th Th. dorsal roots the response vanishes. C G = cœliac ganglion (McSWINEY and SUFFOLK. *J. Physiol.*, 1938, **93**, 104.)

Why the powerful contraction should cause pain is obscure : perhaps it may be related to the production of ischæmic pain (Chapter XXXVI) and so be referable to the local formation of a pain-stimulating factor.

Pain arising in the viscera is primarily felt in the region occupied by the viscus in early embryonic life, and in the case of the alimentary canal is around the mid-line.† Thus from stomach, duodenum or biliary passages it is felt in the epigastrium ; from small intestine or appendix in the umbilical region ;

---

* McDOWALL. *Q. J. Exp. Physiol.*, 1925, **16**, 177.

† BROWN. *B. M. J.*, 1942 (i), 543 ; *Lancet*, 1945, 10.

and from the colon, etc., in the hypogastrium. In addition to the above original sites of pain production, it may further arise from stimulation, especially from chemical excitation, of the somatic afferents of the parietal pleura or peritoneum, and is then often felt at a place with similar somatic innervation and accompanied by local pain, tenderness and muscular rigidity. For example, the later pain in appendicitis is felt in the right iliac fossa.

From the parietal pleura or peritoneum of the diaphragm, the pain is felt at the similarly-innervated shoulder tip (C. 3–5). The pain in angina pectoris, associated with over-distension of the heart and aorta radiates from the left chest, arm and shoulder (Th. 1–4).

When any part of the alimentary canal is distended by a balloon, a reflex rise of arterial pressure and dilatation of the pupil by inhibition of tone of the IIIrd nerve occurs.* By making sections of different parts of the central nervous system until this reaction disappears the path of entry and transit can be found. Fig. 235 shows that the afferents from the pyloric sphincter enter in and below the fifth thoracic root. The lower limit for pyloric sphincter afferents was the thirteenth thoracic root.

Cranial autonomic afferents are contained in the IIIrd, VIIth, IXth, Xth and XIth cranial nerves and perhaps in others. They have cell bodies in ganglia similar to the dorsal root ganglia, on the course of the nerves, and after entering the brain stem terminate in relation to cells of one of the afferent nuclei. Thus the afferents in the *vagus* are the axons of cells in the ganglion jugulare and ganglion nodosum. Their centrally running portions enter the medulla and branch, some of the branches ending in the dorsal vagal nucleus, in the floor of the IVth ventricle, in relation to cells the axons of which pass out in the vagus again as efferent autonomic fibres. This is a simple type of autonomic reflex arc, and many similar ones will be found in chapters dealing with the functions of the various viscera.

Another important example of an autonomic afferent is the nerve from the *carotid sinus*, a branch of the IXth cranial nerve. It conveys impulses resulting from stretching of the carotid artery and from changes in the composition of the blood therein, and important circulatory and respiratory reflexes are thereby brought about.

THE INTEGRATION OF AUTONOMIC FUNCTIONS

It is evident that, in the main, the actions of the sympathetic and parasympathetic systems are opposed to one another, and many viscera have both supplies. Generally, the sympathetic system brings about changes that enable the organism to react to emergencies in such a way as to maintain a constant environment for its cells, or to help to protect itself by fight or flight, by bringing all its reserves into action, even at some cost. The parasympathetic system is similarly credited with more conservative functions, slowing the heart, reducing light to the eye, aiding digestion and generally serving a recuperative function.

It is perhaps more useful, however, to regard these two systems as both playing their parts in maintaining uniformity of conditions for the tissues of the body, by reason of their activities being balanced one against the other in such a way as to enable the viscera to work within a very wide range according to the varying requirements. The exact adjustment of body temperature or local blood supply, for example, requires a delicately balanced co-operation of both sympathetic and parasympathetic activities, and physiological enquiry is in fact very largely occupied in unravelling such co-ordinated activities, examples of which may be found in all branches of the subject.

---

* Irving and McSwiney. *J. Physiol.*, 1935, **85**, 4P.

It would appear that there are levels of integrative function in the autonomic system, as in the somatic system, and here also these become of increasing complexity as we go higher in the central nervous system.

There are autonomic vasomotor, pilomotor and sweat centres in the thoracic spinal cord, and centres controlling pelvic organs in the lumbar and sacral cord, through all of which simple reflexes may be obtained involving only the spinal cord, *e.g.* a rise of blood pressure on stimulating the central end of the splanchnic nerve in the spinal cat.

In the various afferent and efferent nuclei of the medulla and mid-brain we have not merely centres for the carrying out of special reflexes with which those efferent nuclei are concerned, *e.g.* the salivary nuclei in the lower pons and upper medulla, a vasomotor centre and a cardiac centre in the lower medulla, but also there are co-ordinating centres which exert an effect on the centres that lie lower down. Thus the medullary vasomotor centre exercises control on the spinal vasomotor centres, a centre in the mid-brain is concerned in co-ordinating the spinal reflexes of micturition, etc. More complex reflexes, *e.g.* swallowing, or salivation, as well as extensive circulatory and respiratory reflexes can be seen in the decerebrate cat, but this animal still lacks extensively co-ordinated reflexes, *e.g.* it cannot regulate its body temperature, or its blood sugar level.

When the hypothalamus is left behind, however, as in the thalamic animal, the body temperature and other autonomically regulated characters remain normal, and it is now generally agreed that it is in the hypothalamus that the highest refinements of autonomic adjustment are effected. There is in addition some degree of voluntary cortical control of autonomic function, *e.g.* in evacuation of the bladder, modification of breathing, etc., but this is superadded and does little to modify the integrated result of the hypothalamic functions.

II. THE HYPOTHALAMUS

The hypothalamus, which lies at the base of the diencephalon, below the thalamus, forms part of the wall and floor of the IIIrd ventricle. As seen from the base of the brain, it occupies the interpeduncular space and comprises the tuber cinereum and hypophysis anteriorly, and the corpora mammillaria posteriorly ; between the latter, and forming the floor of the IIIrd ventricle is the " central grey matter." Dorsally, it is separated from the thalamus by a fissure. The hypothalamus has an abundant blood supply.

The *hypophysis* is an endocrine organ, which will be further discussed in a later chapter ; it has important functional relations to the other hypothalamic structures.

Hypothalamic nuclei. Scattered throughout the hypothalamus are numerous nuclei and certain tracts. The nuclei and their connections are complex, and have not yet been fully worked out, but Le Gros Clark * has outlined a classification, as follows :—

(1) *Anterior Group*, above the optic chiasma.
    (*a*) The paraventricular nucleus, near the IIIrd ventricle.
    (*b*) The supra-optic nucleus, just above the optic chiasma.

(2) *Middle Group*, related to the infundibulum and tuber cinereum.
    (*a*) Ventro-medial nucleus.
    (*b*) Dorso-medial nucleus.
    (*c*) Lateral nuclei.
    (*d*) N. tuberalis.

---

* Le Gros Clark. *J. Anat.*, 1936, **70**, 203.

(3) *Posterior Group*, related to the mamillary bodies.
 (*a*) Posterior nucleus, above mammillary bodies.
 (*b*) Corpus mammillare nuclei.

Some of these nuclei are shown diagrammatically in Fig. 236.

Connections. There are many short connections, not yet fully mapped out, between the various hypothalamic nuclei, and with adjacent structures. There are also longer afferent and efferent connections.

Afferent fibres reach the hypothalamus from

(1) The olfactory tract. From the hippocampus *viâ* the column of the fornix to the mammillary bodies.

(2) Thalamus to posterior nucleus.

(3) Various parts of the body, *e.g.* from vagus, various ascending tracts in mid-brain, etc.

(4) Cortex, *viâ* median forebrain bundle, and unknown paths (not definitely proved).

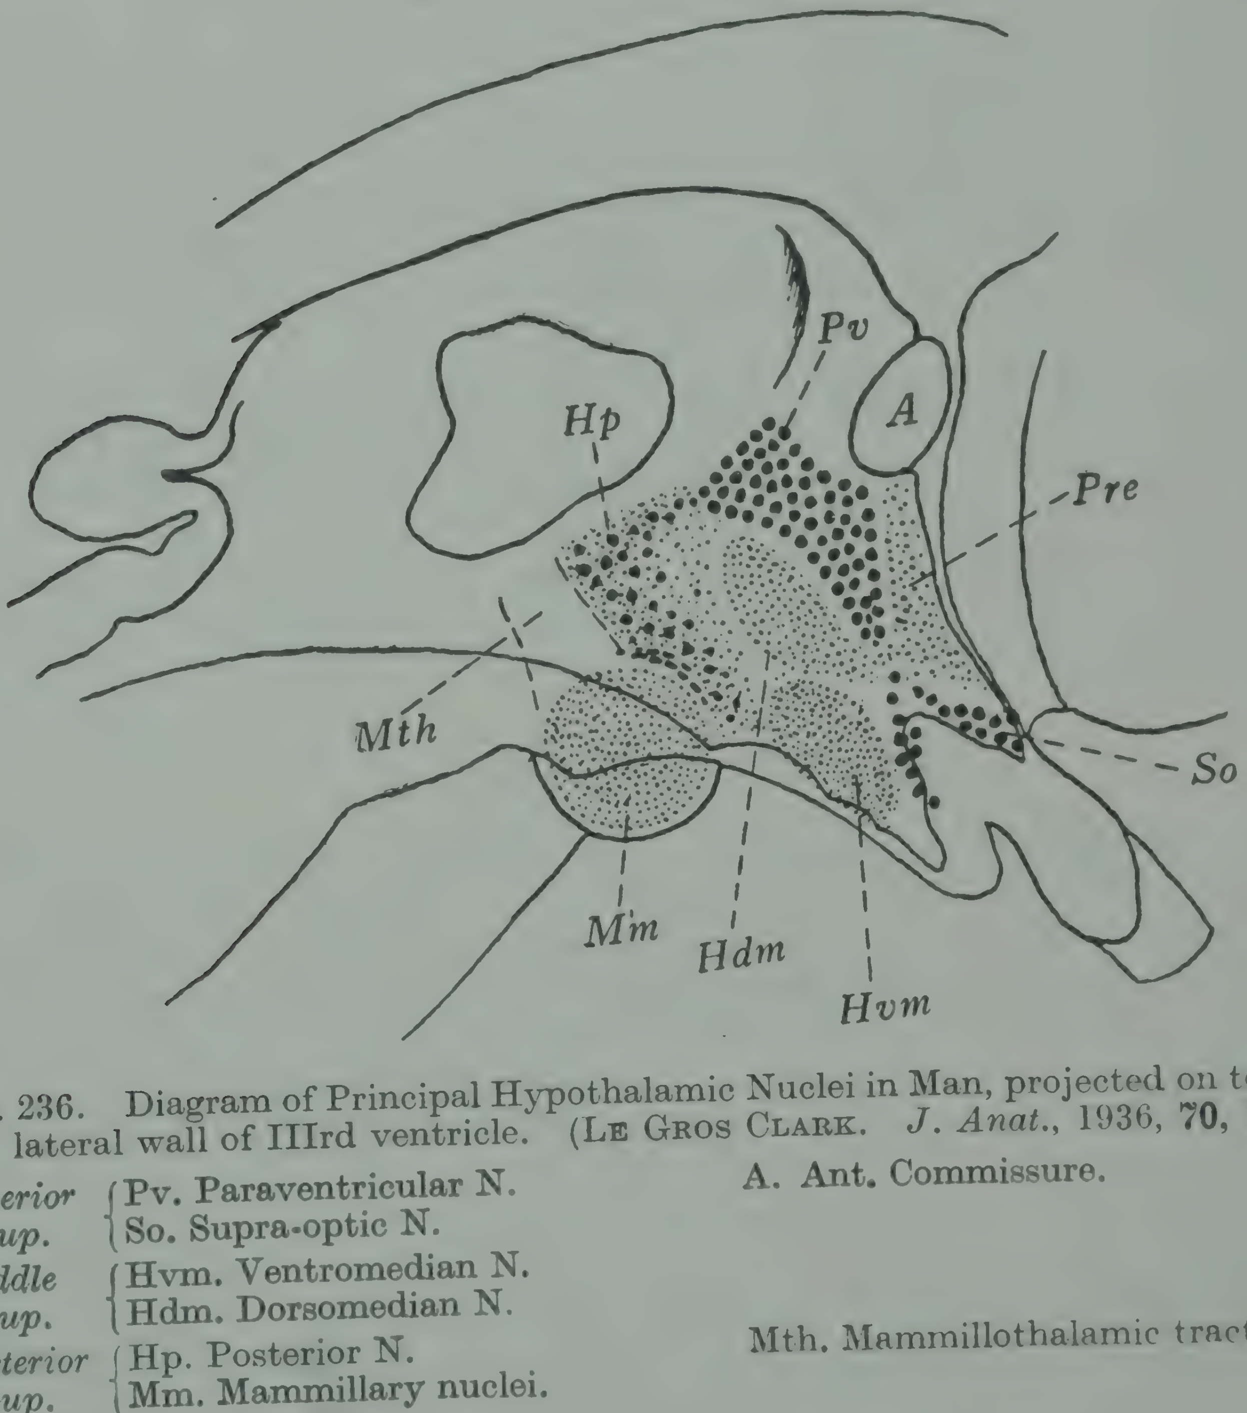

FIG. 236. Diagram of Principal Hypothalamic Nuclei in Man, projected on to the lateral wall of IIIrd ventricle. (LE GROS CLARK. *J. Anat.*, 1936, **70**, 204.)

Efferent connections from the hypothalamus pass to

(1) The anterior thalamus, from the mammillary bodies (the mammillothalamic tract is the most conspicuous tract in this region).

(2) The cortex, *viâ* the thalamus and by other routes.

(3) Autonomic nuclei of the brain stem and spinal cord (intermedio-lateral cell column). This is the most important of the descending efferent tracts : it probably starts in the lateral nuclei of the hypothalamus and leads to the reticular formation of the brain stem,* from which a series of relays passes t

---

the efferent neurones giving origin to the pre-ganglionic autonomic fibres. The connections are largely uncrossed, or if crossed, become so quite near their endings in the cord.*

(4) The hypophysis, by way of the supra-optico-hypophyseal and tubero-hypophyseal tracts which run in the stalk to reach the posterior lobe of the pituitary body (Fig. 237).

Functions of the Hypothalamus. *Stimulation.* It was found by Karplus and Kreidl in 1908 that on electrical stimulation of the hypothalamus there was widespread excitation of the sympathetic nervous system ; Beattie, Brow and Long † produced evidence that there were tracts connecting the hypothalamus with the spinal sympathetic centres ; and Beattie and Sheehan ‡ showed that both sympathetic and parasympathetic effects (*e.g.* reduction or increase of gastric motility) could be produced by suitable excitation, in the former case of the posterior nuclei, and in the latter of the tuber region. Detailed studies of the results of strictly localised excitation of known points in the hypothalamus have been carried out by Ranson and Magoun and their colleagues,§ and much precise information obtained.

In sum, the results have shown that general sympathetic responses, such as cardiac acceleration, rise of blood pressure, pupil dilatation, pilo-erection, hyperglycæmia, inhibition of bladder and intestinal tonus, resulted from stimulation of the posterior and lateral group of hypothalamic nuclei. Increase of respiration rate also occurred. Stimulation of the middle group of nuclei, in the tuber region, caused parasympathetic responses, *e.g.* bladder contraction, cardiac inhibition, and increased motility of the alimentary canal ; it also caused sweating. Anterior group stimuli also caused some parasympathetic effects of doubtful significance, and possibly caused changes in the water balance of the body. These last might be related to effects on the pituitary.

FIG. 237. Diagram of Medial Saggital Section of Hypothalamic Region of Cat showing Nervous Connections of Posterior Lobe of Pituitary Body. (RANSON, Harvey Lecture, 1936–37.)

It has been shown (p. 312) that hypothalamic stimulation can cause facilitation of the lower motor neurones involved in spinal reflexes, and it has also been shown ‖ that facilitation and intensification of the effects of cortical motor stimulation can be brought about in a similar way. The path in this case, as traced by following strychnine action potentials seems to be from the hypothalamic nuclei to dorsomedial thalamic nuclei and thence to the cortex. Spinal afferent impressions can also enter this path by first reaching ventrolateral thalamic nuclei, and then → hypothalamus → dorsomedial thalamic nuclei → cortex.

When the hypothalamus is stimulated in a conscious cat by electrodes fixed into the skull, all the symptoms of intense emotional excitement result, accompanied by powerful sympathetic effects, and it will be recalled that outbursts of "sham rage" with intense sympathetic excitation are also seen in decorticate cats, and are explained as release phenomena due to removal of cortical control.

Injection into the lateral ventricles of the brain of pituitary extracts, pilocarpine or acetyl choline, appears to stimulate certain hypothalamic nuclei, causing general sweating, vasodilatation, salivation, vomiting, etc.*

Lesions. Many remarkable effects have been found to be associated with lesions of the hypothalamus. They fall roughly into two groups, viz. those closely related to the functions of the pituitary body, and those with purely nervous effects. As regards the former group, it is still not clear where the functions of the pituitary body, which are mainly endocrine, cease and those of the hypothalamus begin, and many of the effects of lesions of the one are also found when damage is done to the other. They are closely related.

In one case the relation is particularly clear, viz. in the regulation of water balance. Removal of the posterior lobe of the pituitary causes the condition of *diabetes insipidus*, characterised by the passage of enormous volumes of urine. But lesions in the neighbourhood of the supra-optic nuclei, or in the supra-optico-hypophyseal tracts, also cause polyuria, by interference with the tract connecting this nucleus with the posterior pituitary.† It may be inferred from this that the supra-optic nuclei exert control over the formation, by the posterior pituitary, of the hormone which controls excretion of water by the kidney.

Other functions are also related to the anterior pituitary body; thus injury of the tuber causes sexual dystrophy with adiposity, injury to the anterior region affects carbohydrate metabolism, causing a lowering of blood sugar, etc. Whether such injuries produce these effects by interfering with an innervation which controls the formation of the responsible hormones in the pituitary body is at present uncertain.

The more purely nervous effects of lesions of the hypothalamus are shown by an upset of various intricately co-ordinated functions. One of these is temperature regulation, which will be further discussed in a later chapter. It need only be stated here that hypothalamic lesions, according to their extent and position may cause an animal to lose the ability to withstand heat, cold, or both.

Another complex effect of lesions is the production of a state of somnolence, or, in some species, of sleeplessness. As pointed out in Chapter XXI, the hypothalamus, and especially its posterior and lateral portions, directs the activities of those organs and tissues which are aroused in times of emergency, and it can also facilitate motor responses at various levels, and the withdrawal or inhibition of this drive, as by the inhibitory effect of a "sleep" centre, results in emotional apathy or somnolence.

Lastly, it has been found in man that psychic disturbances are common in patients with lesions of the hypothalamus. These disturbances may take the form of acute mania, or, more rarely, of somnolence and lassitude.

CORTICAL CONTROL OF AUTONOMIC FUNCTIONS

There is abundant evidence that autonomic functions are subject to some degree of control from the cerebral cortex. This is not surprising, since autonomic activity so often accompanies that which is controlled from the cerebrum. In general, the autonomic functions are controlled from areas of the cortex which are concerned with the somatic activities of adjacent structures. Hence, when the motor area for eye movements is stimulated, pupil changes, and lachrymation results, or if that concerned with tongue movements is excited, salivation is seen. Vascular responses, *e.g.* vaso-constriction or vaso-dilatation, changes in heart rate, etc.,* are obtained from certain points on areas 4 and 6, stomach and intestine movements, and sweating, from area 6, etc. These cortical areas appear in part to exert their effects *viâ* the hypothalamus, but partly by other extra-pyramidal tracts.

The Irradiation of Autonomic Reflexes. We have seen that somatic reflexes tend to be directed with some precision, and often to structures closely related to the site of a stimulus. Nevertheless, there is also a tendency for the effects to spread or irradiate to other structures, usually in a definite order.

In the autonomic system, irradiation is a much more pronounced phenomenon. Indeed, as regards the sympathetic system, the effect of an afferent impulse is to set the whole sympathetic system into activity, and its structure is well suited for such widespread responses. Hence, for example, if the central end of the splanchnic nerve is stimulated, the effects reach even to the pupil, which dilates. In the parasympathetic system there is less irradiation than in the sympathetic, but it is still well marked. Thus if the central end of the depressor nerve is stimulated, not only is the heart slowed, but also the peristaltic movements of the intestines are augmented.

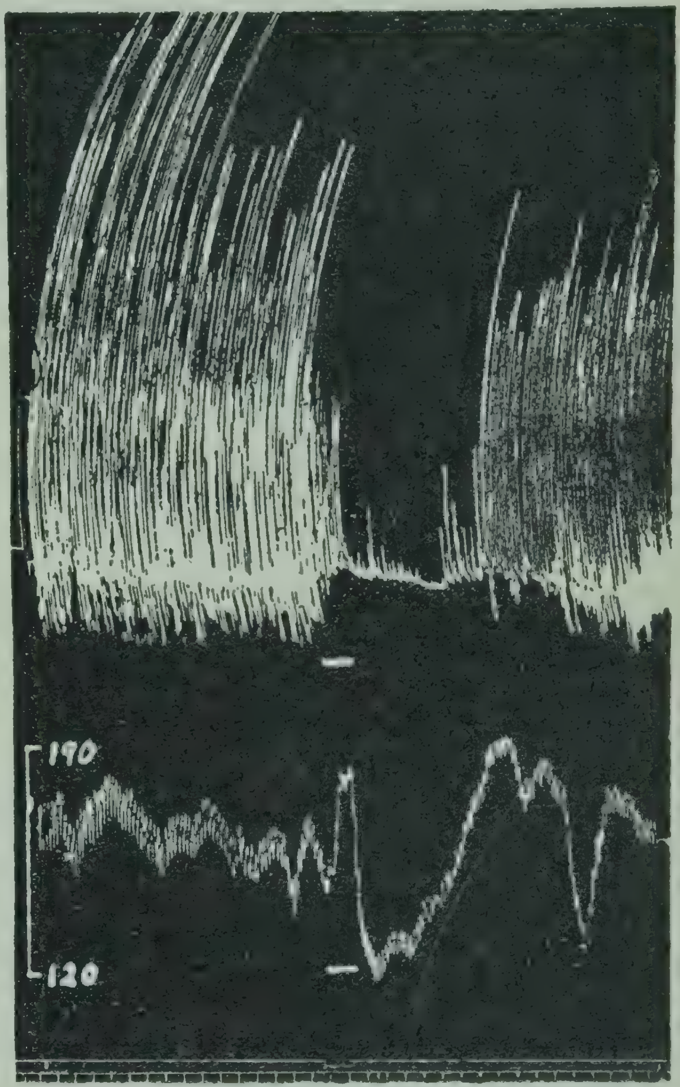

Fig. 238. Chloralosed Cat. Knee-jerks elicited every ten seconds by tapping patellar tendon (upper tracing). Blood pressure in carotid artery (lower tracing). At the signal, stimulation of central end of left vagus. (Schweitzer and Wright. *J. Physiol.*, 1937, **88**, 459.)

Usually the sympathetic and parasympathetic systems act reciprocally, an increase of the one being accompanied by a reduction in the activity of the other. So, for instance, if the nerve from the carotid sinus (Chapter XXXIV) is stimulated, the heart is slowed, partly because the vagus tone is increased and partly because the sympathetic tone is diminished.

---

* Hsu, Hwang and Chu. *Amer. J. Physiol.*, 1942, **137**, 468.

Not only do autonomic reflexes irradiate over the whole autonomic system, but the spread also involves the somatic reflexes. Thus, stimulation of the central end of the vagus nerve causes reduction or abolition of the knee-jerk, and of other somatic reflexes (Fig. 238). There is, however, the possibility that these results may be due to circulatory changes in the centres. Such effects have been shown in the linguo-maxillary reflex (opening of jaw when tongue is stimulated) when the arterial pressure is altered.[*]

THE CHEMICAL TRANSMISSION OF NERVOUS ACTION (THE HUMORAL THEORY)

The similarity between the effects of sympathetic stimulation and those of the administration of adrenaline have long been known, and have given rise to various explanatory speculations. More recently the similarity between the effects of stimulation of the various nerves belonging to the "parasympathetic" system on the one hand, and the action of acetyl choline on the other hand, have excited attention; some instances are given on p. 197 and in Chapter XXXII. As a generalisation bringing these various facts into line, there has been propounded the "humoral" theory, or theory of the chemical transmission of nervous action.

According to this theory, the peripheral effects of sympathetic nerve stimulation are due to the release, *at the nerve endings* concerned, of an adrenaline-like substance, while those of "parasympathetic" stimulation are due to the liberation of acetyl choline at the nerve endings.

The classical instances of sympathetic chemical transmitters were provided by the researches of Cannon and his associates.[†] They found that when the splanchnic or the nerves to the liver were stimulated (the suprarenals having been previously removed), the heart of the animal (previously denervated) was accelerated, as it would have been had adrenaline been injected into the circulation. A similar substance was liberated when the sympathetic nerves to the cat's tail were stimulated, and was believed to have been formed in the smooth muscle of the *arrectores pilorum* muscles and blood vessels.

Denervation of sympathetically innervated tissues (by extirpation of the appropriate ganglion) renders them exceedingly sensitive to the sympathetic transmitter substance, and to adrenaline. A useful test-object is the nictitating membrane of the cat, denervated by removal of the superior cervical ganglion. The suprarenals are also removed. If now any important sympathetic nerve be stimulated, contraction of the nictitating membrane occurs shortly after, showing that a sympatho-excitor substance has been carried by the blood stream.

Once it has entered the blood stream, the sympathetic excitant, like adrenaline, is fairly stable. In the tissues, at its site of liberation, it is liable to destruction by the action of oxidizing enzymes, and hence the action it exerts is fugitive, and more localised than it would otherwise be. The substance is liberated during activity, not only at the endings, but along the whole length of the relevant neurone.

The action of the sympathetic substance, to which the name *sympathin* was given, like that of adrenaline, is augmented by administration of cocaine: possibly there may be more than one substance, and if so, one may be adrenaline itself; another, extractable from spleen, sympathetic nerves and heart, appears to be *nor*-adrenaline, *i.e.* adrenaline deprived of its methyl group.[‡] This probably accounts for the fact that sympathin differs from adrenaline in some of its properties.

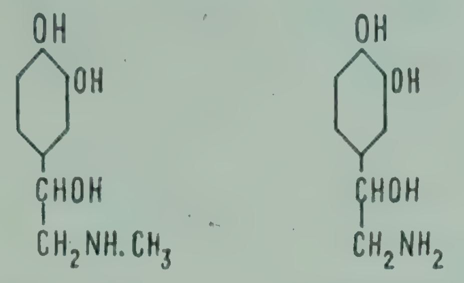
---

[*] ROBILLARD. *Rev. Canadienne de Biol.*, 1924, I, 179.

[†] *Amer. J. Physiol.*, 1931, **96**, 392; **97**, 365; 1932, **99**, 398.

[‡] v. EULER. *J. Physiol.*, 1946, **105**, 38. *Act. Physiol. Scand.*, 1946, **11**, 168; **12**, 73.

Its properties, however, agree precisely with those of *nor*-adrenaline (arterenol).*



Adrenaline *nor*-adrenaline

Nor-adrenaline has an invariably constrictor effect on blood vessels, and this action is annulled, but never reversed, by ergotamine or dibenamine.† Adrenaline has both constrictor and dilator effects, the former usually overpowering the latter: the constrictor effect of adrenaline is therefore reversed by ergotamine or dibenamine, which eliminates the vasoconstrictor component of its action.

"Sympathin" produced by stimulation of the hepatic nerves resembles adrenaline in causing acceleration of the heart, contraction of limb and spleen volumes, and contraction of the nictitating membrane, yet, unlike adrenaline, it does not powerfully dilate the pupil or relax the uterus, and its action on blood pressure is not similarly reversed by the administration of ergotoxine.

In order to attempt to bring these facts into line, Cannon and Rosenblueth ‡ postulated the formation, in the cells affected by the sympathetic, of two forms of sympathin, namely, sympathin E, which is formed when the action is an excitatory one, and sympathin I formed when the effect is inhibitory. It would probably be thought now that adrenaline and *nor*-adrenaline are the substances concerned, the latter corresponding to sympathin E. Whether adrenaline as well as nor-adrenaline is liberated from some sympathetic terminals, other than adrenal medulla cells, is undecided.

The classical instance of humoral transmission of nervous action is that of the liberation of acetyl choline in the heart when the vagus is stimulated § (*v.* Chapter XXXII). The "parasympathetic" transmitter is believed to be identical with acetyl choline. This substance has been found in nervous and other tissues, and in the suprarenal gland; it has also been shown to be present in the blood coming from organs, such as the heart,|| salivary glands, stomach, etc., when their parasympathetic supply is stimulated. After section of the relevant nerve, the endings lose their source of acetyl choline in about 48 hours, and are unable to produce more. Not only is it found in connection with the parasympathetic system, but has also been shown to be released in the cells of sympathetic ganglia ¶ (and also in the medulla of the suprarenal,** which, morphologically, corresponds to a sympathetic ganglion), when these are thrown into action by nerve stimulation, and to be resynthesised in sympathetic ganglia after a discharge.†† Acetyl choline is thus the mediator, not only of the peripheral effects commonly called parasympathetic, but *also of the effects at all pre-ganglionic connections of the autonomic system.*

From the above considerations, it was suggested by Dale that nerves which act by the production of acetyl choline at their terminations, *e.g.* the parasympathetic at their terminals, or the pre-ganglionic autonomic fibres at their synapses in the ganglia or in the suprarenal, should be classed together under the name *cholinergic,* while those that liberate an adrenaline-like substance at their terminals should be called *adrenergic* (Fig. 238). The nerves to the sweat

glands are cholinergic in some animals, such as the cat, but adrenergic in others, *e.g.* the horse, though in all cases anatomically sympathetic and post-ganglionic.

As we have seen in Chapter XII, acetyl choline may also be the humoral transmitter from the motor nerve, *viâ* its end-plates, to skeletal muscle.

The actions of acetyl choline, like the effects of nerve stimulation, quickly pass away, and this is because the substance is rapidly destroyed by enzymes, present in the tissues, and called choline esterases *: in presence of eserine, however, the choline esterase is inhibited, so that the effect of acetyl choline is then more intense and prolonged. There are "*true*" and "*pseudo*" choline esterases, the latter being non-specific esterases, of slow action. True choline esterase alone will hydrolyse acetyl-β-methyl choline, while benzoyl-choline is only split by pseudocholine esterase. There are also specific inhibitors: di-isopropylfluorophosphate (D.F.P.) inhibits "pseudo-", and *pp'*-dichlorodiethyl methylamine hydrochloride (nitrogen mustard) inhibits "true" choline esterase. The inhibition by D.F.P. is irreversible.

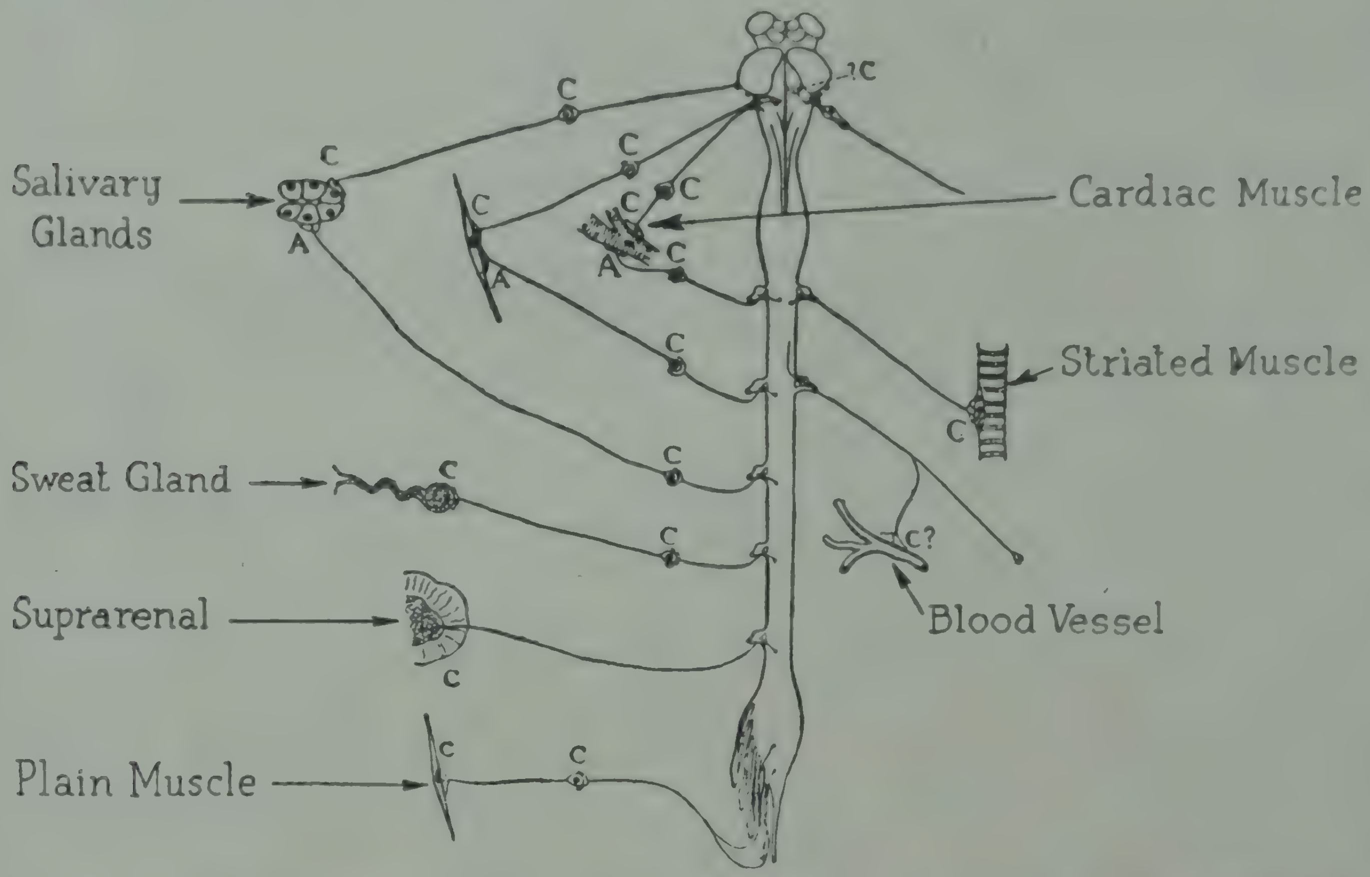

FIG. 239. Diagram of Peripheral Nervous System. At points marked C there is evidence of a cholinergic transmission, at those marked A of an adrenergic transmission. (DALE. *B. M. J.*, 1934, (i.), 835.)

A usual test-object for the detection of acetyl choline in the blood is the dorsal muscle of the leech, previously treated with eserine; this gives powerful contractions in the presence of minute traces of acetyl choline ($1 : 10^9$).

The rapid destruction of acetyl choline at or near to the site of its formation ensures that its action is not only brief, but sharply localised. When its destruction is inhibited by eserine, this brief localised action is lost, and it is then found that stimulation of a parasympathetic nerve, *e.g.* the chorda tympani, not only produces a prolonged effect on the local effector organ (secretion of saliva), but also a generalised effect (fall of arterial blood pressure), owing to the passage of acetyl choline, formed at the stimulated parasympathetic endings, into the general circulation.

Acetyl choline rapidly disappears in alkaline solution. Those of its actions which simulate the action of the parasympathetic nerves are abolished, as the effects of stimulation of those nerves are also abolished, by the action of atropine. The nicotine-like effects, however, *e.g.* the contracture of certain skeletal muscles, and the excitation of the cells of autonomic ganglia, are not paralysed by atropine.

For purposes of physiological identification it is usual to consider the presence of acetyl choline as proved if the given solution causes contraction of the eserinised leech muscle, and has this property destroyed by previous treatment with alkali or with uneserinised blood. Sometimes other tests are used instead, or in addition; these are the contraction of the eserinised rectus abdominis muscle of the frog (by 1 : 10^8), inhibition of the frog's heart (by 1 in 10^8), and fall of arterial pressure in the cat. The last two effects are abolished by atropine which renders the tissue insensitive to A.ch. By comparing these effects with those of solutions of acetyl choline of known strength, a rough quantitative estimation of the substance can be carried out.

---

* GLICK. *J. Gen. Physiol.*, 1938, **21**, 289 (estimation method).

In this way it has been found possible to detect and estimate the acetyl choline liberated in a given organ or tissue by parasympathetic stimulation. All that is needed is to perfuse the tissue in question with eserinised blood or Ringer's solution; the effluent fluid is assayed before and after stimulation of the parasympathetic supply. The use of these methods is illustrated in Fig. 240, which shows that the fluid perfusing a stimulated sympathetic ganglion contains acetyl choline, presumably formed at the synapses.

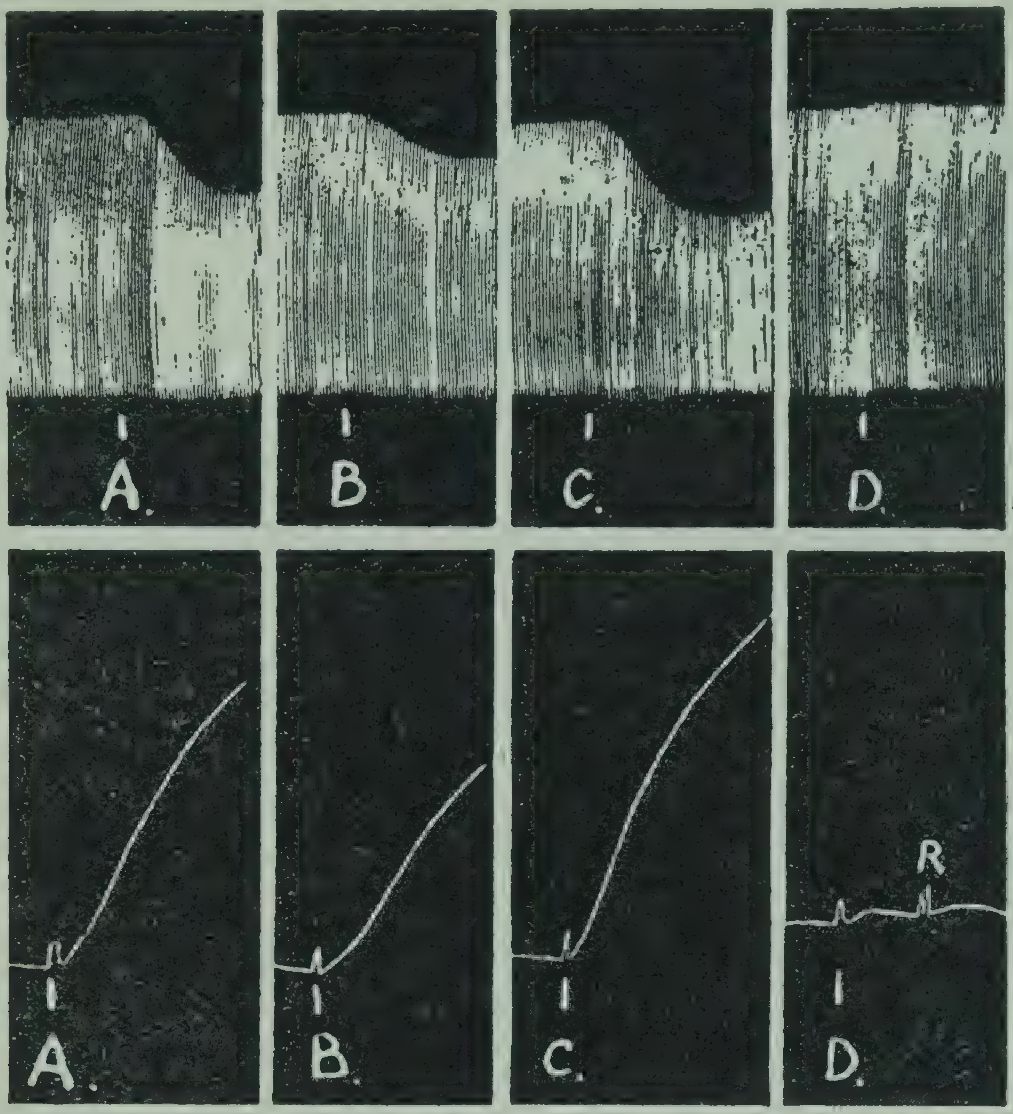

FIG. 240. Demonstration of Presence of Acetyl Choline in perfusate from the superior Cervical Ganglion of the Cat during Stimulation of the Cervical Sympathetic Nerve. Above, effect of perfusate from ganglion on perfused frog's heart; below, effect on eserinised leech. A. Fluid collected during stimulation; B. and C. Comparison by addition of acetyl choline (15γ and 30γ per l = 1 : 15 × 10^9 and 1 : 30 × 10^9 respectively). D = Control fluid without stimulation. (FELDBERG and GADDUM. *J. Physiol.*, 1934, **81**, 305.

It is tempting to suppose that the passage of nervous impulses across synapses in the central nervous system is also effected by the mediation of chemical transmitters. Acetyl choline has been demonstrated in brain perfusates, the liberation being increased by KCl.* The investigations of the Sherrington school on reflex action led to the belief that the phenomena of recruitment, after-discharge and inhibition may be explained on the supposition that some central excitatory state, or some chemical substance causing such state, persists at the synapse for an appreciable interval of time. On the other hand, if such were the case, it would be expected that the arrival of an impulse along a pre-ganglionic fibre might give rise to a prolonged activity in the post-ganglionic neurone, and that only after appreciable delay to allow for diffusion, etc. Yet it has been shown by Eccles that for each pre-ganglionic impulse there is one post-ganglionic impulse, and the delay is very brief at the synapse. Hence, if we are to accept the chemical transmission theory, it is evident that the rate of diffusion and subsequent destruction of the exciting substance must be very great. But in view of the short distances to be traversed and of the extreme rapidity with which such substances as acetyl choline are destroyed by tissues, these objections need not be held to be insuperable.

---

* CHUTE, FELDBERG and SMYTH. *Q. J. Emp. Phys.*, 1940, **30**, 65.

As we have seen, acetyl choline is liberated in a ganglion when the pre-ganglionic fibres to it are stimulated. The effects of intra-arterial injections of acetyl choline and eserine on the C.N.S. have not been shown to be uniform, though in some instances they produce a discharge, inhibited by atropine [*] and facilitated by adrenaline. Acetyl choline, whether injected intra-arterially *viâ* the vertebral artery, or applied to the floor of the IVth ventricle, causes a hyperactivity of the respiratory centre, which resembles that in a normal hyperpnœa and is subject to similar reflex control.[†]

The synthesis of acetyl choline [‡] is brought about by an enzyme "*choline acetylase*," which can be demonstrated in dried nervous tissues, placenta, etc. It requires the presence of K and Mg ions, choline, cysteine, A.T.P., citrate, and an unidentified activator. (NaF is also added to protect A.T.P. from destruction by phosphatase, and eserine to protect the acetyl choline from destruction by choline esterase.)

Acetyl choline is synthesised in the tissues in which it occurs. The choline is probably derived from lecithin; the origin of the acetyl group is unknown, but it may be derived from citrate. As it is formed, the acetyl choline is linked on to some stabiliser in the tissue, probably to a lipoid-protein complex, from which it is released more or less continuously at a slow rate, and suddenly on the arrival of the appropriate stimulus. After release it is rapidly destroyed by the action of choline esterase.

Different parts of the nervous system synthesise acetyl choline in very different amounts, as the following table shows:—

SYNTHESIS OF ACETYL CHOLINE BY NERVOUS TISSUES OF DOG [§]

	Relative amount of A.C.		Relative amount of A.C.
Ventral roots	236	N. gracilis and cuneatus	86
Motor nuclei, X, XII	178	Area 4 (motor)	71
Ventral horns	153	Vestib. nerve	29
Caudate nucl.	127	Int. caps. post. part	27
Lat. geniculate b.	105	Pyramids	12
Dorsal horns	103	Fun. grac. and cun.	10
Thalamus	100	Cerebellar cortex	9
Facial nerve	93	Optic nerve	6

(The amounts are p.c. of the amount formed by the thalamus in the same brain. The actual amount formed by the thalamus was 200–500 μg. per g. dry tissue/hr.)

From this table it will be seen that synthesis is most rapid in the lower motor neurones. The sensory nerves and posterior columns have scarcely any synthetic power, nor have the upper motor neurone (pyramids), the cerebellar cortex, or the afferent parts of the internal capsule. If we suppose that high powers of A.C. synthesis imply cholinergic functioning, and low powers a non-cholinergic mechanism, we are led to the interesting speculation (but it is merely a speculation!) that, in general plan, *successive neurones in the C.N.S. are alternately cholinergic and non-cholinergic*, as illustrated in Fig. 241.

---

[*] BÜLBRING and BURN. *J. Physiol.*, 1941, **100,** 337; CALMA and WRIGHT. *J. Physiol.*, 1944, **103,** 93.

[†] GESELL, HANSEN and WORZNIAK. *Amer. J. Physiol.*, 1943, **138,** 776.

[‡] FELDBERG and MANN. *J. Physiol.*, 1945, **104,** 8.

[§] FELDBERG and VOGT. *J. Physiol.*, 1948, **107,** 372.

The contrast is most striking in nerves or pure fibre tracts, *e.g.* ventral roots and optic nerve. In the grey matter the values are intermediate, because this contains always some cholinergic tissue, either as synaptic endings of one neurone or as the cyton at which another one begins. The nature of the non-cholinergic transmission, whether it is electrical, or adrenergic, or some as yet unknown form of mechanism, must be left open for the present; but the curious effects of adrenaline on synaptic transmission, small amounts tending to potentiate acetyl choline transmission and higher concentrations to depress it; acetyl choline tending to facilitate flexor, and to depress extensor reflexes, while adrenaline has the reverse action *; all these are probably other aspects of a complex picture: there will be little room for surprise, if this alternation speculation should be substantiated, at the conflicting results which have been obtained by the injection of sundry active substances into the general circulation.

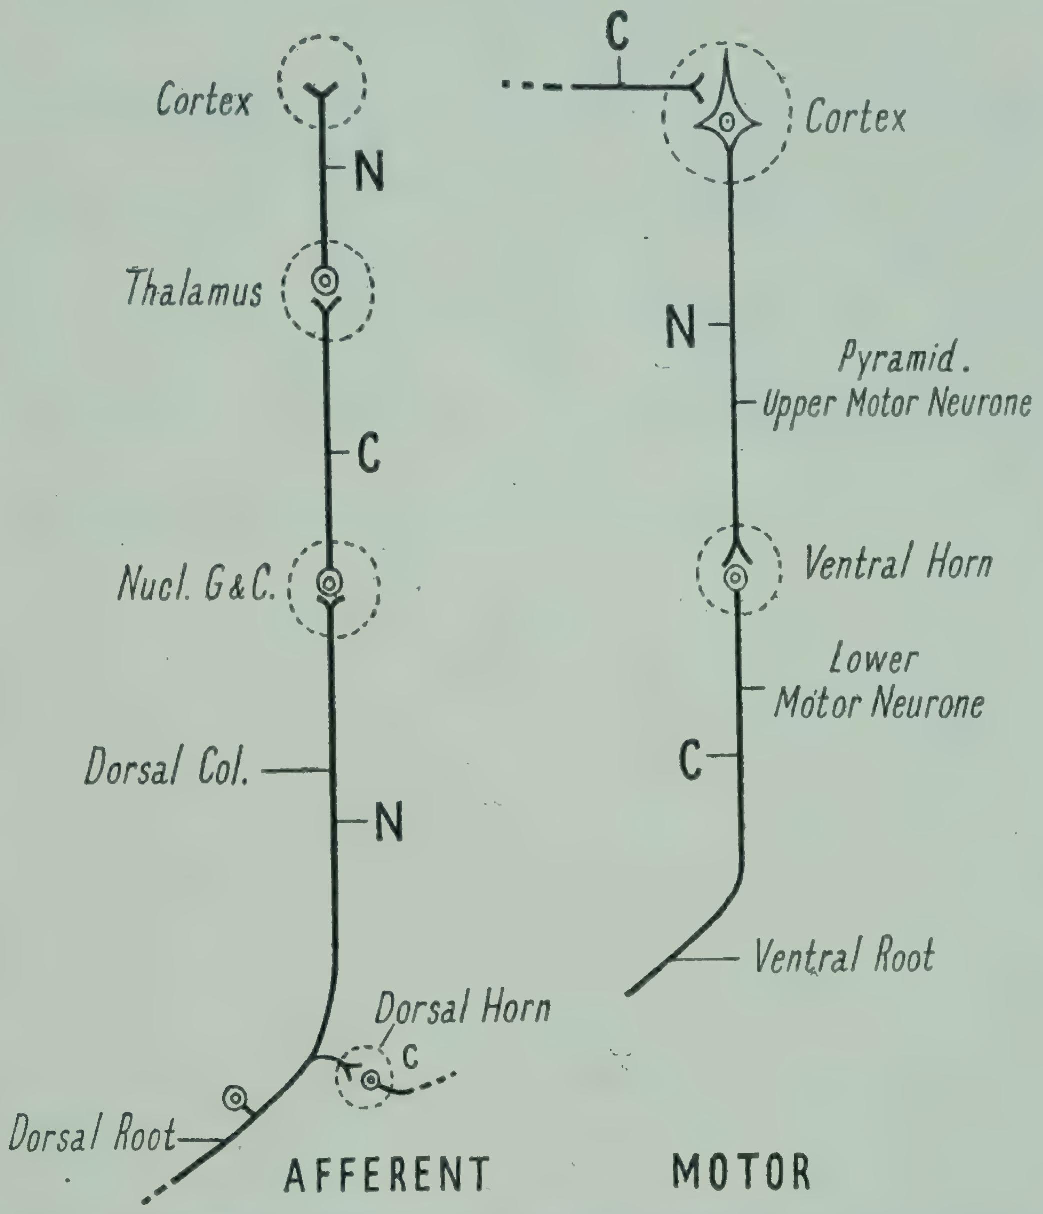

FIG. 241. To illustrate the alternation of cholinergic (C) and non-cholinergic (N) neurones in the central nervous system. Grey matter enclosed by broken lines.

The acetyl choline mechanism has also been supposed to be responsible for the transmission of the nerve impulse along nerve fibres, by causing the depolarisation which essentially constitutes the impulse. Choline esterase is concentrated at the surface of the fibres and is not present in the axoplasm. It is therefore in the best position for removing the A.Ch. very rapidly and so permitting recovery. It may be that this is so for the fibres of cholinergic neurones, but the non-cholinergic nature of the sensory nerves would then mean that the biochemical processes involved in the transmission of the nervous impulse differ fundamentally in the two types.

---

* BÜLBRING, BURN and SKOGLUND. *J. Physiol.*, 1948, **107**, 289.

There are various unexplained phenomena in connection with the theory of chemical transmissions. Thus, atropine abolishes the effects of acetyl choline, and nearly all the effects of parasympathetic excitation. But not all of them – for instance, atropine does not abolish the vasodilatation in the submaxillary gland on stimulation of the chorda tympani, though it does abolish the secretion, yet it abolishes both secretion and vasodilatation on adminitration of acetyl choline.

Ionic changes are certainly also concerned in the phenomenon. Thus the presence of K ions in the blood causes a release of acetyl choline from ganglion cells, but in absence of Ca ions K ions fail to do so ; yet in absence of Ca ions the cells spontaneously discharge.*

BOOK IV

THE SPECIAL SENSES

(BY H. HARTRIDGE, M.D., Sc.D., F.R.S.)

CHAPTER XXIV

THE NERVOUS MECHANISM OF SENSATION

GENERAL PHYSIOLOGY OF SENSATION

THE ability to originate sensations is common to almost all parts of the body. Thus the muscles, joints and viscera send nerve impulses to the brain, which records their activities. We can classify the sense organs into two main groups, those which belong to the common sensibility of the body, and those which form the special senses. The characteristics of the former are (1) that rarely do their impulses, other than those of pain, ever pass the threshold of consciousness; (2) that they play a very large part in the initiation of the numerous reflex actions; (3) that when their impulses do reach consciousness they lack definition. The characteristics of the special senses on the other hand are :—(1) that most of their nerve impulses reach consciousness; (2) that the connection between the stimulus and the resulting response on the part of the individual (as expressed by movements of limbs, etc.) is usually not of the simple nature of a spinal reflex; (3) that the information supplied to consciousness is very definite both as to quality and intensity.

The indefiniteness of the connection between stimulus and response causes us to depend almost entirely on introspection in our study of the sense organs. But introspection as a method of research has grave disadvantages, for we cannot measure our sensations in terms of physical units. We cannot say how red a rose is or how nice it smells. Neither can we compare the intensity of a beam of light, when we feel its warmth on our skin, with the strength of the stimulus which we receive when it enters our eye. Still less can we judge accurately of the sensations evoked in other individuals or animals when we apply stimuli to them. Because of this difficulty of measuring sensations, two methods of investigation have been developed which to a great extent avoid it, namely the *method of threshold values* and the *method of comparisons*.

In the method of threshold values, gradually increasing stimuli are applied to the sense organ under investigation until a sensation is just perceived. Thus, increasing weights are applied to the skin until their pressure is felt, or a light of increasing intensity is presented to the eye until its presence is seen. Such threshold values give definite information concerning the sense organ to which they refer, and allow us to compare the same effects in one and the same sense organ under different conditions and also in different individuals.

In the method of comparisons two separate stimuli are applied, and one or both are varied until the sensations caused by them are equal. Thus a ray of yellow light may be compared with a ray mixed from red and green light, and the intensities of the two adjusted until the sensations caused by both are similar. Both these methods give concordant results if care be taken to make the conditions standard, and both are for this reason largely used for studying the sense organs.

A careful study of these organs is necessary and important because it is only through their agency that we derive information about ourselves, one another, and the world in which we live. The limitations of our sense organs, therefore, restrict our knowledge of the many transformations of energy that are going on around us, except in so far as we are able to devise means of extending them artificially. Thus our knowledge of the existence of ultra-violet light began only with the discovery of photography. Wireless waves circulated through the ether around unknown to us before the invention of the coherer.

Classification of Sense Organs. Sense organs differ in their anatomical position and structure, and also according to the nature of the stimulus to which they react and the kind of sensation which they cause. Any of these differences might be used as a basis of classification, but the latter is found to be the best.

Structure.	Sensations.	
Skin	Touch Pain Heat Cold	Feeling
Eye	Light Colour Shape Distance	Sight
Ear	Pitch Intensity Position	Hearing
Tongue	Acid Sweet Bitter Salt Alkaline	Taste
Nose	Various	Smell

Stimuli adequate for one sense organ are found to be inadequate for another. Thus sound applied to the ear is adequate, but to the eye is not.

The sense organs appear to be elaborated from a very simple type, and the higher they are developmentally, the more is one kind of stimulus adequate and the less are all others.

Thus the end organs in the cornea react alike by a sensation of pain to touch, electricity, heat, inflammation, etc., while the ear reacts to sound waves only. This specific property of the end organs is also attended by an increase in the strength of response to the chosen stimulus. Thus the retina of the eye can be stimulated mechanically and electrically, but has its greatest sensitiveness to light. It is estimated that the eye is many times as sensitive to light as any instrument that has been so far constructed. This specialisation of the end organs makes the information which we obtain from them more detailed and complete, but at the same time sets a limitation to the range of stimulus to which each can respond. Thus a pain end organ can react alike to heat rays, visible rays and ultra-violet rays, while the retina of the eye responds to visible rays only.

The Law of Specific Irritability. A very little consideration suffices to show that there is no resemblance between a sensation and the stimulus, and that one and the same physical event applied to different sense organs will evoke absolutely distinct sensations. If we take a tuning-fork which is vibrating 100 times per second and apply it to the surface of the skin, we get simply a sensation of vibration, *i.e.* a series of tactile impressions repeated at rapid intervals. If the same tuning-fork be applied to the head, its vibrations are imparted to the bones of the skull and thence to the auditory nerve endings and arouse in our consciousness the sensation of a certain musical note. The same thing happens if the vibrations of the tuning-fork are conducted by the ear to the auditory nerve endings in the ordinary way through the external and middle ear. On the other hand, it can be shown that different kinds of stimuli applied to one sense organ always evoke the same kind of sensation, if any. Thus a sensation of light may be aroused not only by the incidence of radiant energy of a certain wave length on the retina, but also by electrical or mechanical stimulation of the retina. If the eye be turned inwards and the finger be pressed on the eye through the outer canthus of the lids, a sensation of light is aroused and we see a coloured circle which we refer to some spot lying to the nasal side of the eye stimulated. The character of the sensation therefore bears no resemblance to the physical events by which the sensation is evoked, but depends entirely on the nature of the sense organ which is stimulated. A sensation of light may be produced by any stimulation of the retina, or of the optic nerve, or of the terminations of the optic nerve in the brain. In the same way stimulation of an auditory nerve or its intracranial endings gives rise to sensations of sound.

Where the question has been investigated, it has not been found possible to evoke different qualities of sensation by different modes of stimulation of nerve fibres. It has therefore been concluded that the quality of any sensation depends simply and solely on the termination of these nerves in the central nervous system, and that where sensations of different quality are produced there must also be difference of nerve paths. This idea was formulated by Müller, and is often alluded to as Müller's "law of specific irritability." The law states that every sensory nerve reacts to one form of stimulus and gives rise to one form of sensation only; though, if under abnormal conditions it be excited by other forms of stimuli, the sensation evoked will still be the usual one.

Localisation. Although the different forms of sensation must be regarded as dependent on the integrity of the brain and of its connections with the peripheral sense organs, sensations are not referred to the brain, but are localised as proceeding from some part of the body or from some region outside the body. Thus the sensation of taste is always localised in the mouth; sensation of touch at the skin or surface of the body; while the sensations of hearing and of sight are "projected," *i.e.* are interpreted as coming from the environment outside ourselves. Even the organic sensations of posture or fatigue are referred to the peripheral reacting parts of the body and not to the central nervous system. A sensation, therefore, cannot be interpreted as a reproduction of external events, but as a *symbol* of these events evoked by stimulation of the sense organs of the body.

Relationship between Stimulus and Sensation. Although the sensation is not a reproduction of the stimulus, it is a symbol of the stimulus, and can be used to inform us of events occurring in the world around. Like stimuli, falling on the same end organ, always evoke like sensations, other conditions being equal. An orderly sequence of sensations may therefore be interpreted as indicating a corresponding orderly sequence of physical occurrences in the world around us. Since our sensations are merely symbols of the physical conditions which give rise to them, it is important to inquire how far they correspond *quantitatively*.

THRESHOLDS. Whatever form of stimulus be applied and whatever sense organs be affected, a certain minimum intensity of stimulus is necessary for it to be effective, *i.e.* to produce a minimum sensation. This strength, which varies with different sense organs, is spoken of as the "liminal intensity" or "threshold value" of stimulus or sensation respectively. In each sense organ we can measure the amount of energy which must be applied to it in order to evoke a minimum sensation. This figure varies considerably with the physiological condition of the subject. Thus it is found to vary in most cases with the following factors:

(1) The physical nature of the stimulus.

(2) The rate of application of the stimulus.

(3) Events occurring in the surrounding areas, *i.e.* simultaneous contrast.

(4) Events which have previously occurred in the area receiving stimulation, *i.e.* successive contrast.

(5) The time during which the stimulus acts, *i.e.* adaptation.

Weber's Law. It is an interesting question how far the strength of sensation may be regarded as an index to the strength of stimulus. Although it is easy to measure in absolute terms the intensity of a stimulus, and although we can say that such and such a light is stronger than another light, it is impossible to say that the sensation resulting from the stronger is two, three or more times that of the weaker. In measuring the effect on sensation of increasing the stimulus, we are therefore reduced to using the *smallest appreciable increase of sensation* as our unit of sensation. Weber's law states that the increase of stimulus, which is necessary to produce an appreciable increase in sensation, always bears the same ratio to the whole stimulus. Thus, if we found that we could just distinguish the difference between a weight of 20 g. and a weight of 21 g., it would not be sufficient to add 5 g. to a weight of 200 g. in order to produce a distinct difference in sensation. In the latter case we should not be able to appreciate any difference until we had added 10 g., *i.e.* one-twentieth of the whole stimulus to the weight.

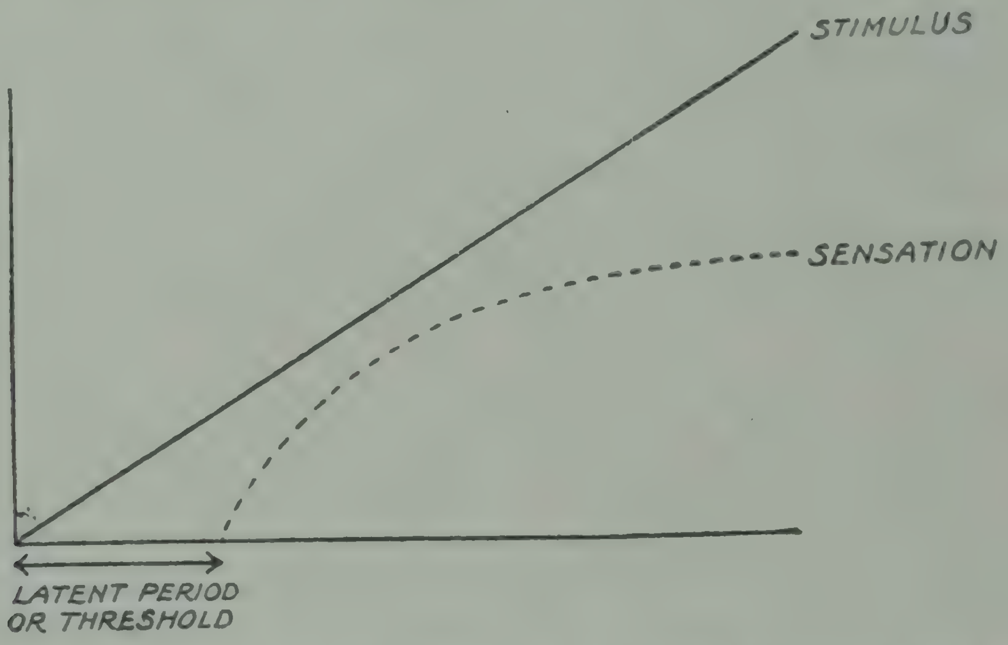

Fig. 242. Diagram to show Relationship between Stimulus and Sensation.

Several methods have been proposed for testing the limits of the applicability of this law. Of these the most important are :

(1) The method of minimal difference.

(2) The method of average error in matching.

In the first method we find by trial how much a given stimulus must be increased in order to evoke an appreciable increase of sensation, and this determination is made for a number of stimuli of different intensities. In the second method it is sought to find the strength of stimulus which is just equal to another stimulus of given intensity. It will be found that errors will be made on both sides, and the average error is taken as representing the minimum difference which is just sufficient to cause a distinct difference of sensation.

In all sense organs Weber's law is applicable only between limits which vary with each sense organ, and it does not hold either for very weak or for very strong stimuli. Within these limits the ratio, which an increase of stimulus must bear to the whole stimulus in order to produce an increase of sensation, may be given approximately as follows for the different sense organs :—

Sense Organ.	*Quality determined.*	*Ratio.*
The ear	Difference of intensity	$\frac{1}{9} - \frac{1}{20}$
The eye	Difference of intensity	$\frac{1}{167}$
The skin	Difference of weight	$\frac{1}{20} - \frac{1}{40}$

Fechner's Law gives the result of an attempt to state Weber's law in mathematical terms. It states that the sensation varies as the natural logarithm of the stimulus. This relationship is shown diagrammatically in Fig. 242.

CHAPTER XXV

VISION

1. PHYSICAL PROPERTIES OF LIGHT

The Spectrum. It is possible by suitable apparatus to cause the constituent rays in a beam of light to arrange themselves according to their wavelength. When thus arranged they are said to form a spectrum. The apparatus is therefore called a spectroscope. The visible rays thus arranged are seen as a coloured band which has the following appearance. Visibility usually begins at about 8,000–7,800 A.U., the rays of longest wavelength being red. As the wavelength becomes shorter the colour gradually changes to orange, the transition being at about 6,500 A.U. From orange the colour changes to yellow, at about 6,000 A.U.; from yellow to green at 5,500 A.U., to blue-green at 5,000 A.U., to blue at 4,500 A.U., and to violet at 4,000 A.U. The violet extends to 3,800 A.U., where visibility ceases. The spectrum exhibits therefore a gradual change of colour with wavelength. Above the red is the invisible region occupied by the infra-red or heat rays and below the violet the invisible ultra-violet or actinic rays, as explained above.

The colours of the spectrum have important properties which form the foundation of the science of colour mixture. If the spectrum produced from white light is caused to fold up again, it is found that white light is re-formed. But white light is produced if certain pairs of colours only are caused to combine in the correct proportion. Thus red (6,562 A.U.) and blue-green (4,921 A.U.) when mixed correctly form white light, so also do yellow (5,636 A.U.) and violet (4,330 A.U.). Such pairs are called *complementary colours*. But since there is in the spectrum a gradual transition from one colour to the next, so there are between red and yellow an infinite number of rays of different wavelength, each of which has its complementary colours, between blue-green and violet. If, therefore, from white light we remove one of a pair of complementary colours, the other member of the pair will be left unneutralised, and the light thus becomes tinted with its colour. Green rays do not possess a complementary in the spectrum; but it is found by experiment that, by combining red and violet to form purple, the required colour may be produced. If we include purple with the spectral colours, we can imagine these colours to form a closed ring. Each colour will then have its complementary opposite to it.

The Spectral Colours have another important property, for if red and yellow are caused to combine, they are found to produce orange, the intermediate colour. If red and green are mixed, then again the intermediate colour, yellow, may be produced. It is found that by varying the intensities of the two components, it is possible to produce orange or yellow-green, or in fact any other intermediate colour at will. Careful experiment shows that the intermediate colour thus formed is no mere approximation but an exact match. If red and green are thus able to combine to form the intermediate colour, while red and blue-green are complementaries producing white by their mixture, the question arises as to the effect produced by mixing red with a colour intermediate between green and blue-green. Experiment shows that a range of colours is produced containing an amount of white light, which varies with the intensities and wavelengths of the combining colours. Colours diluted with white light are spoken of as *unsaturated*. In order that the colours produced by a mixture of red and green rays shall be fully saturated, and thus be able to match the colours of the spectrum exactly, the green must not be shorter in wavelength than 5,400 A.U. Similar phenomena are to be found at the other end of the spectrum; green and violet, when mixed in various proportions, form colours which match the intermediate spectral colours. With red, green and violet it is therefore possible to match the whole spectrum. But since red and violet, when mixed, form the intermediate purples, it is possible with the three coloured rays to imitate the whole range of colours. Now the purple formed from red and violet is, as we have seen, the complementary colour to green; by means of these three colours it is thus possible to produce white light. It should therefore be possible to match an unsaturated colour as easily as a saturated one. Experiment shows that such is the case. The third property, beside colour and saturation, is *intensity*, which depends on the amplitude of the waves. The intensity of the mixtur formed by red, green and violet, can therefore be readily adjusted by varying the intensit of each of the three component rays. We may summarise the above facts by stating that by varying the intensities of the red, green and violet rays, it is possible to match ever shade and colour. This statement has been put to the test by Maxwell, Abney and othe observers, and has been found to hold good in all cases but one, spectral blue being slightl more saturated than the mixture of green and violet. In describing the complementar pairs of colours, we have mentioned that if the spectral colours are placed in a close ring, complementary pairs are found to be opposite to one another. If now the thre fundamental colours are placed at equal intervals round the ring, we may regard whit as occupying the centre, because it is equidistant from the three fundamentals, and at th same time lies on the diameter between the various colours and their complementaries. If the other spectral colours are arranged in position relatively to the three fundamentals, they form a figure that in shape resembles a triangle more closely than it does a ring. This is due to the facts already mentioned (1) with regard to the exact matching of the spectral colours between red and green, by mixtures of those two fundamental colours; (2) with regard to the approximate matching of the region between green and violet, by the mixtures of those colours; and (3) with regard to the exact matching of mauves and purples, by mixtures of red and violet. The colour triangle which is shown in Fig. 243 therefore has a purely experimental basis, and has no association essential with theories of vision.

Photo-chemical Change, which is the third property of light mentioned above, is well illustrated by photography. The most important principle of light action is that light, to cause chemical change, must be absorbed (Draper's law). For example, an ordinary photographic plate which is found to be opaque to blue, violet and ultra-violet rays, and to be transparent to the rest of the visible spectrum, is therefore sensitive to the former rays but inactive to the latter. Further, by colouring the plate by a dye which absorbs red, yellow and green, it is possible to make the plate react to these rays. Draper's law is therefore obeyed. Chemical reactions caused by light are of many types, but may be divided into reversible and irreversible. The former type of reaction occurs only so long as the light acts (the change from CO- to oxy-hæmoglobin may be given as an example), while the latter type remains in the final state that has been reached (the changes in a photographic plate may be given as an example). There is, further, another and more complicated type which, when once started by an incident beam of light, goes on automatically with an evolution of energy until the reaction is completed. These effects of light are probably of great importance in connection with vision, and will therefore receive further consideration later.

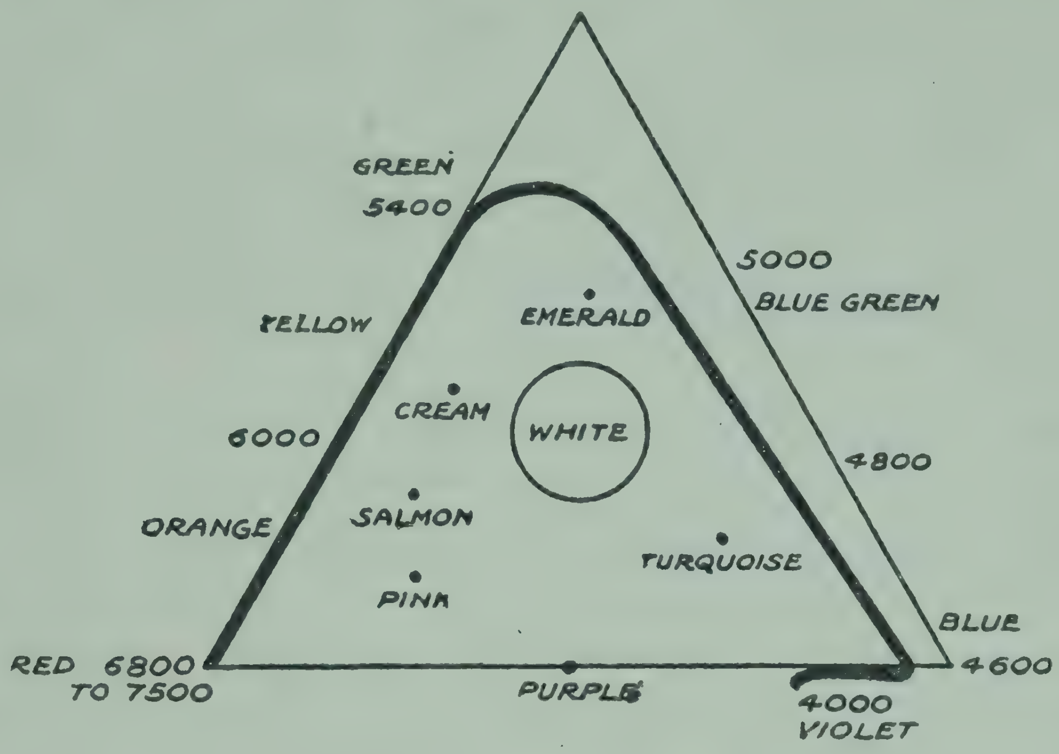

Fig. 243. Colour Triangle.

The black line shows the shape of the curve along which the different rays of the spectrum fall for white to occupy the central position.

2. EYE MOVEMENTS

ANATOMY AND FUNCTION OF THE EXTRINSIC MUSCLES OF THE EYEBALL

Six external muscles produce rotation of the eyeball:—four recti and two oblique. The recti arise from a fibrous ring attached to the margin of the optic foramen. From the positions they occupy they are called superior, inferior, external and internal. When they contract they cause upward, downward, outward and inward rotation of the eyeball respectively. In the case of the first two muscles there is a turning movement inwards at the same time. Fig. 244 shows the above diagrammatically.

The two oblique muscles, the superior and inferior, are both smaller than the recti. The former arises near the optic foramen, and passes forward to the upper and inner side of the orbit, forming on its way a round tendon. It here passes through a narrow fibrous ring, and then turns downwards and backwards under the superior rectus and becomes attached to the eyeball. The inferior oblique arises from the nasal side of the orbit, just within its lower margin. It passes outwards and backwards beneath the inferior rectus to become attached to the eyeball nearly opposite to the attachment of the superior oblique. On contraction of the superior oblique the upper side of the eye is rotated towards the nose; at the same time the pupil is directed downwards and outwards. The inferior oblique also causes rotation about the visual axis, but in the opposite direction; it at the same time produces upward and outward movement of the pupil.

On tilting the head suddenly about a transverse axis, it is found that the eyes rotate in the opposite direction, so that in fact the image formed on the retina shall still keep in the same meridian with respect to external objects. This rotation is called "compensatory" and is largely effected by the oblique muscles.

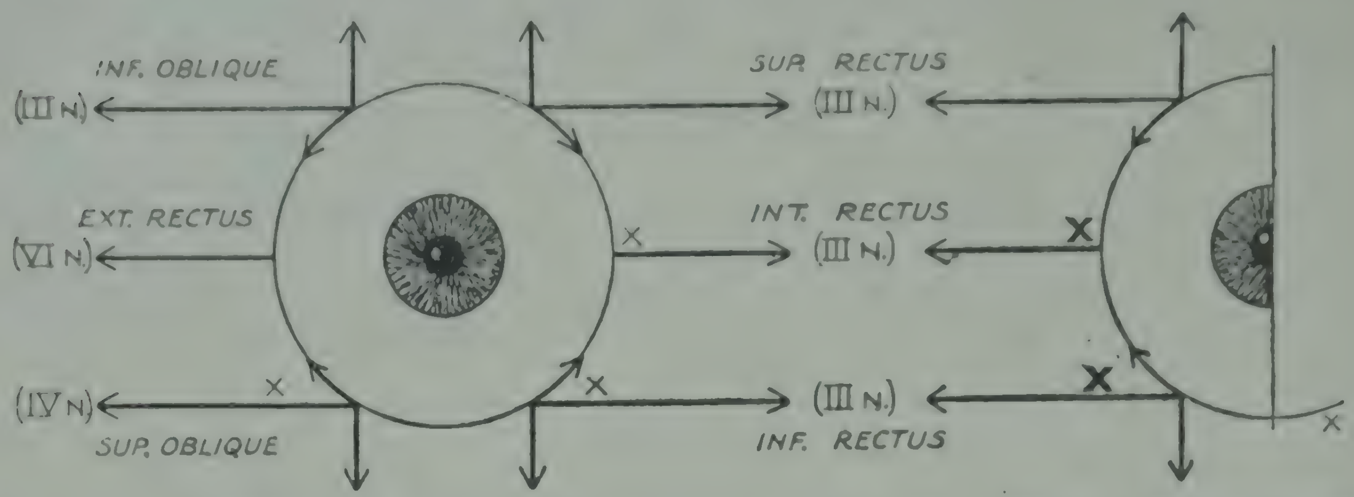

FIG. 244. Diagram showing the Directions in which the different Extrinsic Eye Muscles rotate the Eyeball. x = *crossed connection.*

Co-ordinated Movements of the Eyes. The notable feature of the eye movements is the close association which exists between the muscles of the two eyes. So perfectly has this mechanism been developed that the eyes are able to glance rapidly from place to place without there being any obvious doubling of the images. The eye movements are therefore of such a kind that the image of an object conveys a single impression to consciousness. But objects vary in their distance from the observer, and therefore, beside movements of the eyes in which the visual axes remain parallel, there are also movements in which there is a certain amount of convergence. In the latter case there is usually some associated accommodation of the lens for near objects, and at the same time some contraction of the pupil. By experiments in which prisms are placed in front of the eyes, thus calling for convergence or divergence without accommodation, and by others in which lenses are placed there instead, thus requiring accommodation without change in the angle between the axes, it can readily be shown that the association between the functions of accommodation and convergence is not very rigid. The co-ordinated deviations of the eyes appear to be much more closely connected. Thus Donders found co-ordinated deviations both in the newly born and in congenitally blind persons. This is probably due to the close anatomical relationship which exists between the nerve centres of the muscles on the two sides.

The Control of Eye Movements. The efficiency of the eyes as organs of vision depends very largely on the speed and precision with which their axes can be turned in any required direction. These movements are of three kinds: (*a*) Those in which the eye axes move together to right or left, up or down. (*b*) Those in which the eye axes move in opposite ways, the left eye axis to the right and the right eye axis to the left, thus bringing about "convergence," and *vice versâ* for "divergence." (*c*) Those in which the eyes rotate clockwise or anti-clockwise about their axes. All eye movements can be analysed into combinations of these three components. The movements may be brought into operation in two ways: voluntarily, *e.g.* the directing of the gaze from line to line of print, as in reading; and involuntarily, as when the eyes turn instinctively to scrutinise an object which has presented itself to the field of view, or when the eyes follow an object as it moves; this movement of the eyes is called the "fixation reflex."

The eye muscles are innervated by the third, fourth, and sixth cranial nerves, which are derived from nerve cells found in the grey matter of the mid-brain which lies just ventral to the central canal (or Sylvian aqueduct), at the level of the superior corpora quadrigemina. Fig. 245 shows approximately the positions of the various collections of nerve cells which innervate the different muscles. It will be seen that the third or oculo-motor nerve supplies all the extrinsic eye muscles except three, viz.: Tenon's capsule, which is supplied by the sympathetic; the superior oblique, which is supplied by the fourth nerve; and the external rectus, which is supplied by the sixth nerve. Further, while most of its nuclei supply muscles on the same side, three are found to go to muscles on the opposite side, namely, the internal and inferior recti (third nerve) and the superior oblique (fourth nerve).

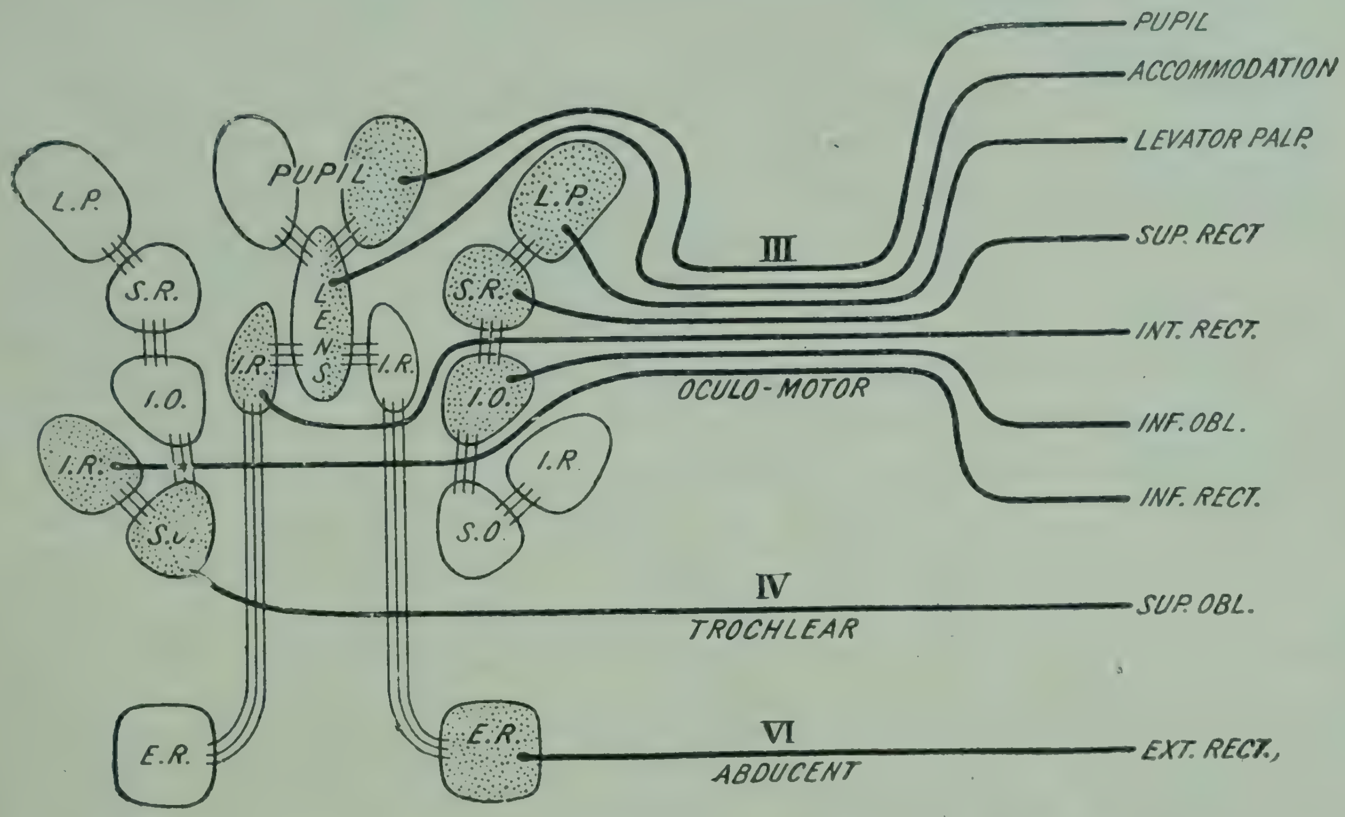

FIG. 245. **Diagram to show Relationships of different Points of Oculo-motor Nuclei, and the principal connections between them.**

Sherrington showed that, as the muscle on one side of a limb contracts, its antagonist at the same time relaxes, so as to allow the movement to take place smoothly and without waste of energy. This is called "reciprocal innervation." The eye muscles show the phenomenon very well. If the right frontal cortex be stimulated, the eyes perform co-ordinate deviation to the left. If now all the muscles of the right eye except the external rectus are divided, it is found that on repeating the stimulation this eye still moves in co-ordination as far as the middle line, through the relaxation of the external rectus muscle.

The orbicularis palpebrarum is also supplied from the third nerve nucleus, for in lesions of this nucleus paralysis of this muscle is found. The fibres innervating it probably travel all the way with the seventh nerve.

CAUSES AND DIAGNOSIS OF STRABISMUS

Squint or strabismus may be caused by a number of conditions: (1) by congenital abnormality; (2) by interference with the proper rotation of the eyeball; (3) by injury to one of the external eye muscles; (4) by injury to or stimulation of one of the nerves supplying these muscles; (5) by the presence of certain errors of refraction With regard to nerve injury the following description may be given. Injury to the third nerve causes (*a*) drooping of the upper lid owing to paralysis of the levator palpebræ; (*b*) external strabismus from paralysis of the upper, inner and lower recti and the unopposed action of the external rectus; (*c*) rotation of the eye about its visual axis from paralysis of the inferior oblique and therefore unopposed action of the superior; (*d*) dilatation of the pupil from paralysis of its sphincter and the unopposed action of the dilator fibres which are innervated by the sympathetic; (*e*) loss of the power of accommodation from paralysis of the ciliary muscle; (*f*) exophthalmos or protrusion of the eye, caused by the paralysis of so many of its muscles and the unopposed action of the smooth muscle fibres in Tenon's capsule. Owing to the fact that for a considerable portion of its course the third nerve lies beside the fourth, fifth and sixth nerves, there is usually also some associated symptom of paralysis in the structures which these nerves supply. Injury to the fourth nerve causes paralysis of the superior oblique, which shows itself by defective movements in a downward and outward direction. Injury to the sixth nerve causes internal strabismus owing to paralysis of the external rectus. This frequently occurs when tumours, hæmorrhage, inflammation or injuries involve the base of the brain. Experimental stimulation of these nerves causes contraction of the muscles supplied, and does not require specific description.

DIPLOPIA is a characteristic feature of a strabismus. Objects appear double to the patient unless or until he has acquired the ability to suppress the images presented to one (usually the weaker) eye. This suppression gives relief from the diplopia, but involve the risk of the loss of function of the unused (suppressed) eye. An eye that has suffered in this way is said to be amblyopic.

Diplopia is also observed when an individual is under the influence of certain drugs, *e.g.* alcohol. It is also seen sometimes when the spherical curvature of the cornea is disturbed by injury or disease, *e.g.* corneal ulcer. In these cases the injured eye sees a double image even when the sound eye is closed ; in fact it may see more than two, the condition being called polyopia.

Voluntary Eye Movements. The impulses for these originate in the Betz cells of that part of the voluntary motor area which has its centre about two-thirds down, and somewhat in front of the precentral (Rolandic) strip of cortex. The axons from these cells pass downwards and inwards to form part of the angle (or genu = knee) of the internal capsule. The fibres now descend vertically with the rest of the pyramidal fibres till they reach the level of the superior colliculi where, crossing to the opposite side (as all the other pyramidal Betz cell fibres cross lower down) they end in relation to the third, fourth, and sixth nerve nuclei, either directly or by means of short intervening relay fibres. By this crossing of the fibres the cortex becomes connected with the nerve nuclei of the opposite side. Now the right eye is turned towards the left by fibres which originate in the left third nerve nucleus (see Fig. 245). The left eye is turned towards the left by fibres which originate in the left sixth nerve nucleus. Both these nuclei are controlled by impulses which have originated in the right cerebral cortex. In consequence, impulses from the right cortex turn both eyes to the left. But the crossing of the other voluntary motor fibres causes the cortex on the right side to control the left side of the body, *e.g.* the left arm and hand. The turning of the eyes to the left is therefore very appropriate, since it will cause the gaze to be turned towards the side on which other activities may be in progress.

The Fixation Reflex. Fixation is the retention of the gaze of the two eyes on an external object. It is effected by such adjustments of the external eye muscles that an image of the external object remains on the foveæ of the two eyes. These adjustments are carried out with extreme precision and dispatch. The reflex develops at a very early age, since babies a few days old perform fixation perfectly. Two sets of paths are involved in the reflex : (*a*) Those from retinæ to calcarine cortex *via* the optic radiation ; (*b*) those from the calcarine cortex to the superior corpora quadrigemina (colliculi), probably on the opposite side, and from them to the third, fourth and sixth nerve nuclei.

The mode of action of this reflex is probably as follows : Suppose an object, *e.g.* an electric lamp, to be voluntarily fixated, the centres of its images will fall on the foveæ of both eyes and the stimulus produced by it will fall partly on the right and partly on the left halves of both retinæ. Both right and left calcarine cortices will therefore receive impulses. From these fresh impulses will travel to both right and left sets of third, fourth and sixth nerve nuclei, probably *via* the superior corpora quadrigemina of both sides. The eyes will not be moved since the nerve nuclei on one side would produce a movement which is opposed by that of the nerve nuclei on the other side. Suppose now that the lamp is moved a little to the right. The images produced by the eye media on the retinæ will move to the left and the left-hand halves of the retinæ of both eyes will, as a result, be more strongly stimulated than the right-hand halves. In consequence, the impulses reaching the left-hand calcarine cortex will be more powerful than those reaching the right. Stronger impulses will therefore pass down to the superior corpora quadrigemina (colliculi) and so to the third, fourth and sixth nerve nuclei of the opposite side, that is of the right side. In consequence, the eyes will be turned towards the right, and this will cause the centres of the images of the lamp to fall once more on the foveæ. In some such way as this we may picture fixation being preserved.

Ordinarily fixation is under voluntary control. When this control becomes defective, fixation is still effected, but the gaze "snaps on to" an external object and remains fixed to it. With a great effort the gaze is turned away from this object only to snap on to another. The use of the eyes, *e.g.* in reading, thus becomes impossible, since the gaze cannot be steered along the line of type.

VOLUNTARY AND INVOLUNTARY EYE MOVEMENTS

Many years ago Hering made the suggestion that visual acuity for certain kinds of test-object would be improved if the eyes were performing tiny rotations during the process of fixation. Since that time the idea appears to have been gaining ground that even normal subjects continually suffer from what may be called "a rapid nystagmus."

This matter has recently been investigated by Lord and Wright, by Barlow, and by Hartridge and Thomson. Lord and Wright record head movements as well as eye movements; so does Barlow. Hartridge and Thomson employ a method which records eye movements independently of head movements. Agreement between these observers is not complete however. The present trend of opinion is that the eyes do not perform this rapid nystagmus which Hering suggested, but that they maintain a fixed position, to a remarkable degree, when careful observations are being performed on a test-object.

MINUTE ANATOMY OF THE EYE. The Cornea has a radius of nearly 8 mm. and a diameter of 11 mm. It is composed of the following five layers: (1) Stratified epithelium. (2) The anterior elastic lamina of Bowman. (3) Substantia propria. (4) The posterior elastic lamina of Descemet. (5) A layer of endothelium.

The Iris consists of three layers: (1) the endothelium, continuous with that on the posterior surface of the cornea; (2) the stroma of the iris, which consists of connective tissue (especially elastic fibres), two thin sheets of muscle, some pigment cells, vessels and nerves; (3) the pigmented layer continuous with the retina.

It should be noted that the posterior elastic lamina of Descemet in the cornea, after its division into three parts, forms by its posterior portion the ligamentum pectinatum iridis, by which the iris gains attachment to the sclero-corneal junction.

The Functions of the Iris. The iris contains two layers of unstriated muscle fibres; the anterior, which is circularly arranged, so that by its contraction it acts as a sphincter; while the posterior is arranged radially, stretching from the attachment of the iris to the rim of the pupil, so that by its contraction it causes the pupil to open. Because of the numerous pigment cells which it contains the iris is opaque to light. Contraction of the pupil thus causes the following effects: (1) reduction in the amount of light entering the eye, so that an image of less intensity is formed on the retina; (2) the use of the more central zones of the lens system only. The advantage of this lies in the fact that, as will be described later, the more peripheral zones suffer from errors of refraction to a much greater degree than do the central ones: the contraction of the pupil therefore improves the definition of the image; (3) an increase in the depth of focus of the eye, which is of great value for near vision. The way that depth of focus is obtained will be described later (see p. 393).

Contraction of the pupil occurs under the following circumstances:

(1) If the third cranial nerve or its nucleus is stimulated electrically, or if the sympathetic nerve fibres to the eyes are cut or are paralysed.

(2) When light falls on the retina. This movement, which is known as the "light reflex," is determined by a contraction of the sphincter pupillæ, together with a relaxation of the dilator muscle. The contraction ensues within a period of 0·04 to 0·05 sec. after the moment at which the light has access to the retina, and attains its maximum within 0·1 sec. In man as well as in other animals which have binocular vision, and in which there is a partial decussation of the fibres of the optic nerves in the optic chiasma, the reflex is bilateral, *i.e.* light falling into one eye causes simultaneous contraction of both pupils. In the higher animals this reaction of the pupil to light demands the integrity of the nervous paths between the eye and the brain; but in many of the lower animals, *e.g.* in the frog and eel, the reflex nervous mechanism is aided by a local sensibility of the iris to light. In

these animals the contraction of the pupil in response to illumination takes place even in the excised eye, and seems to be determined by a direct stimulation of the pigmented contractile fibres of the sphincter pupillæ by means of the light.

II.	Optic nerve.
l.c.	Long ciliary nerves.
s.c.	Short ciliary nerves.

The effect of light on the pupil varies considerably according to the condition of adaptation of the eye. The diameter of the pupil is maximal when the eye has been in the dark for some time and may amount then to 7·3 to 8 mm. In one experiment, on exposing the eye to a feeble light, *e.g.* 1·6 candles at a moderate distance, the pupil diminished in size to 6·3 mm. ; with an illumination of 50 to 100 candles the size of the pupil was 3·7 mm., and with 500 to 1,000 candles, 3·3 mm. This effect was obtained by a *rapid* change in the illumination of the eye. When the alteration is sudden, the amount of contraction was found by Haycraft to be equal to the logarithm of the intensity of the light. When, however, the alteration is so gradual that the retina can become adapted to the change as it proceeds, then little or no change in the size of the pupil occurs ; and when the illumination, which has at first caused a maximal constriction of the pupil, is continued, the pupil gradually relaxes with the adaptation of the retina to light. This relaxation occurs within three or four minutes after exposure to light has taken place. The same influence of adaptation will be observed if two individuals are brought into a moderately lighted room, one from bright daylight and the other from a dark room. The pupils of the first will dilate widely, while those of the second will constrict. In each case the change will pass off rapidly, so that at the end of five or ten minutes there will be no difference observable between the eyes of the two persons.

(3) When vision is directed to a near object, the processes of accommodation of the lens, and of convergence of the visual axes, which result, are associated with contraction of the pupil. The sharpness of vision is thereby improved, together with an increase in the depth of focus, a result very beneficial for the close examination of detail. Since it is possible by experiment to cause accommodation without convergence and *vice versâ*, we may ascertain which function is the more closely associated with the pupil mechanism. The evidence appears to be in favour of convergence.

(4) In sleep the pupils are always contracted. This behaviour may enable us to distinguish feigned from real sleep. This contraction of the pupils, in spite of the fact that no light is entering the eyes, has been held to be caused by association with the upward and inward direction of the eye axes which was said to be found in sleep. There now appears to be irrefutable evidence that the eyes during sleep may occupy any position ; another explanation of the constricted pupils must therefore be found.

(5) Contraction of the pupils is a marked effect of certain drugs such as morphine, which acts by stimulation of the third nerve nucleus; other drugs, *e.g.* pilocarpine, muscarine and eserine, facilitate the action of acetyl choline formed at the 3rd nerve endings in the sphincter pupillæ muscle.

(6) Constricted pupils are also met with in excitable conditions of the central nervous system, and therefore during the induction of chloroform and ether anæsthesia.

(7) Small pupils, which do not react to light, are also met with in injuries to the spinal cord involving the cervical region and damaging the pathway of the sympathetic dilator fibres of the iris.

(8) Contracted pupils are found to accompany severe pain. This is probably due to the powerful flow of efferent impulses which leave the brain in this condition, affecting the 3rd nerve nucleus which controls the pupil.

(9) The pupil contracts when the aqueous is allowed to escape from the anterior chamber. The cause of this is said to be the dilatation of the vessels of the iris, owing to the fall of the surrounding pressure.

Dilatation of the Pupil occurs under the following circumstances:

(1) If the sympathetic nerve fibres to the eye are stimulated, or if the third cranial nerve fibres are cut.

(2) On removal of a light stimulus from the eyes. If the removal be complete the pupil remains dilated, but if there be any light at all the pupil gradually contracts again as the eye becomes dark adapted.

(3) On accommodation for distant vision because the associated reflex stimulation of the pupillo-motor centre with accommodation is no longer called into play.

(4) Reflex dilatation of the pupil can be excited by the stimulation of any sensory nerve. This may be due to some of the afferent impulses reaching the cilio-spinal sympathetic nerve centre in the cord.

(5) The pupils are frequently found to dilate in such emotional states as fear, anxiety, exhaustion and dyspnœa, and also at the moment of death.

(6) Dilatation is also found to accompany extreme exhaustion of the central nervous system, when the activity of all nerve centres is low, such as in deep chloroform anæsthesia, and in the coma produced by alcohol poisoning. Many drugs such as atropine and homatropine, cause dilatation by paralysing the endings of the 3rd nerve. Others, such as cocaine and adrenaline, dilate by stimulating the endings of the sympathetic nerves.

(7) Dilated pupils inactive to light are found in injuries of the 3rd nerve or its nucleus.

(8) Dilated pupils are also found when the intraocular pressure is abnormally high, as in glaucoma. This appears to be due to constriction of the vessels of the iris owing to the high external pressure to which they are subjected.

(9) Dilated pupils inactive to light are found in compression and severe concussion of the brain. This is probably due to the abolition of the normal nervous impulses to the muscles, so that the pupil dilates under the influence of its radial elastic fibres.

(10) Dilated pupils are found to accompany hyperactivity of the suprarenal glands, owing to the presence of considerable amounts of adrenaline in the blood. This occurs for example in fear and in oxygen want, dilated pupils being one of the characteristic signs of those conditions.

(11) The pupils are found to dilate reflexly on stimulating the central end of the splanchnic nerve (McSwiney). The impulses enter the spinal cord by the posterior roots as high as the 3rd thoracic segment. They reach the 3rd nucleus and cause inhibition there.

3. THE NOURISHMENT AND PROTECTION OF THE EYE

Anatomy of the Lids. Closing the orbit in front, and in close relationship to the eyes, are the lids or palpebræ. The upper, which is the larger and the more movable, is provided with a special muscle, the levator palpebræ superioris. This is supplied by a branch of the oculo-motor (3rd) nerve. The two lids meet at an angle on both sides, forming the inner and outer canthi. They are stiffened by two plates of dense fibrous tissue, parallel to their edges, which are called tarsi. Near these and embedded in the substance of the lids are two sets of glands, the Meibomian glands and those of Moll. These secrete a greasy material which spreads over the lids. Superficial to these structures, but under the skin, is a ring of muscle fibres which is common to both lids, the orbicularis palpebrarum, innervated by the 7th nerve. Its contraction closes the lids. Lining the inner surfaces of the eyelids is a thin layer of mucous membrane, the conjunctiva, which is reflected on to the front of the eye, and is continuous over the cornea as the anterior epithelial layer.

CLOSURE OF THE LIDS occurs: (1) during sleep; (2) if a very bright light enters the eyes; (3) on the sudden approach of some foreign body; (4) on contact of a foreign body with the lashes; (5) on irritation of the cornea or conjunctiva, *e.g.* by touching (the *conjunctival reflex*); (6) in sneezing; (7) in order to renew the fluid film on the cornea and conjunctiva. The reflex closure of the lids is therefore a very important function in affording protection to the eyes. The reflex apparently can be initiated by the stimulation of any of the branches of the ophthalmic (1st) division of the 5th (trigeminal) nerve. From the nucleus of this nerve in the pons Varolii, fresh fibres take the impulses, it is believed, to the 3rd nerve nuclei of both sides. The fibres leave the 3rd nerve, however, and join the 7th (facial) nerve, from which they pass to the orbicularis palpebrarum. The conjunctival reflex is one of the last to be abolished by anæsthetics and is therefore used as a convenient test.

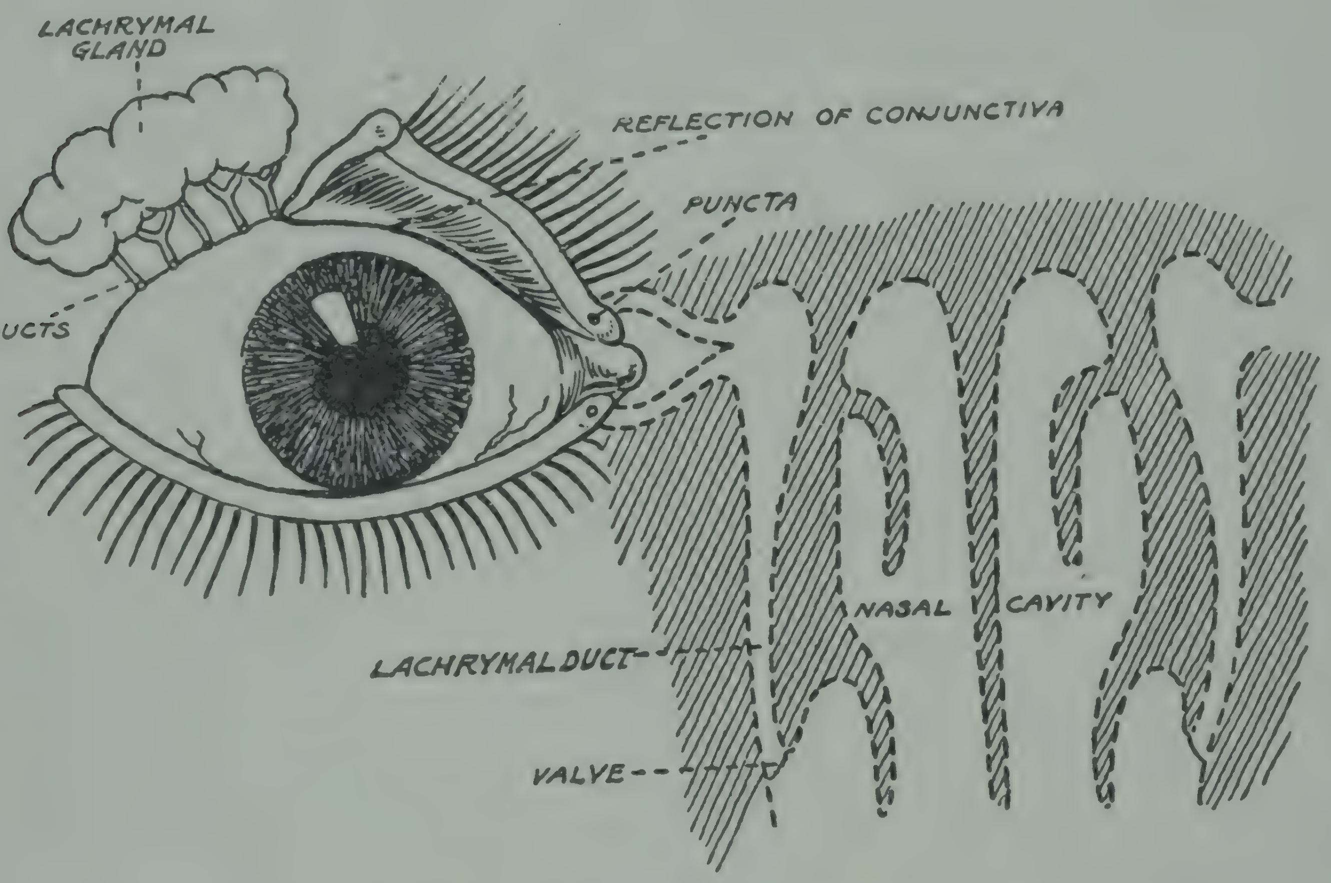

FIG. 247. Diagram to show Origin and Fate of Tear Fluid.

The conjunctivæ and the cornea are kept in a moist condition by the tears, which are secreted by the lachrymal gland, situated in the upper and outer part of the orbit. This is a small acino-tubular gland, in microscopic structure similar to the parotid. Its secretion issues through several ducts, the mucous linings of which are continuous with that of the conjunctiva. Normally the secretion is just sufficient to keep the surfaces of the lids and cornea moist, the production keeping pace with the evaporation. Under certain circumstances there is excess, and tears are produced.

TEAR FLUID consists chemically of an aqueous solution of sodium chloride and bicarbonate containing mucus, albumin and *débris*. Its functions are to keep the surfaces of the conjunctiva and cornea moist, and to remove foreign bodies and organisms. The secretion of tears is increased (1) by irritants and foreign bodies coming in contact with the cornea, conjunctiva or lids; (2) by irritation of the nasal mucous membrane ; (3) by powerful illumination of the eyes ; (4) by the incidence on the eye of infrared (heat) or ultra-violet (actinic) rays ; (5) under the influence of emotion. When excessive tear formation occurs, the fluid either escapes over the front of the lids or is drained away through the lachrymal duct into the nasal sinus. Three theories have been advanced to explain the latter : (1) syphoning, owing to the mouths of the ducts being at a higher level than their exit into the nose ; (2) capillary, owing to the tendency of the liquid to flow into the ducts through surface tension ; (3) active removal by the act of blinking. It is not at the present time definitely known how this occurs. Some say that on closing the eye the internal palpebral ligament tends to be pulled on, and that this dilates and fills the lachrymal sac ; others that the sac fills automatically through having been previously emptied by the contraction of Horner's muscle. It is possible that both processes occur.

The eyes of some mammals and fish and nearly all birds are provided with a nictitating membrane, a semi-transparent shutter which can be brought over the surface of the cornea. It is supplied with plain muscle fibres innervated by the sympathetic. Stimulation of the sympathetic causes contraction of these fibres, resulting in retraction of the nictitating membrane, and so providing a ready means of estimating the degree of sympathetic activity in laboratory work.

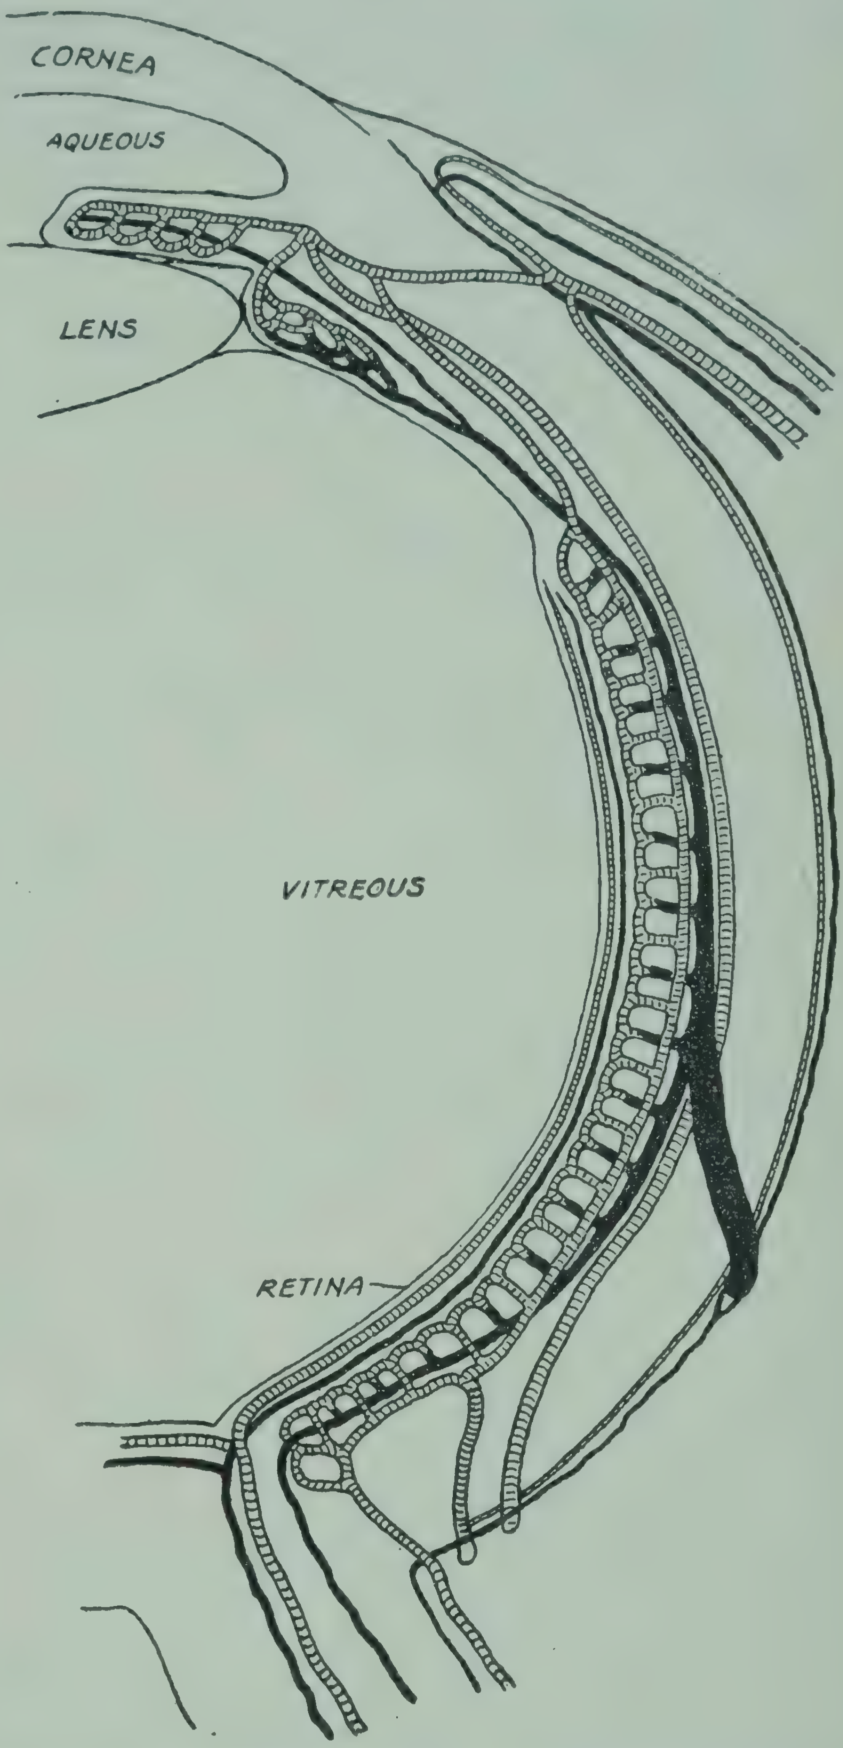

FIG. 248. Diagram to show the Blood Supply of the Eyeball. Arteries "lined," veins "black."

Nutrition of the Eye. The eyeball is richly supplied with blood vessels, which form numerous anastomoses. Among these may be mentioned the arteries of the optic nerve sheath, the long and short posterior ciliary arteries, the anterior ciliary arteries, which are branches from the muscular vessels, and the conjunctival arteries. These pierce the sclera to ramify freely in the choroid and in the ciliary bodies. The iris is supplied by two concentric vessels, the circulus major and the circulus minor. Between the two pass a number of radial fibres. The retina has a separate blood supply through the central artery of the optic nerve. Other structures, notably the transparent optical media of the eye, have no direct blood supply and therefore depend for their nutrition on diffusion from the aqueous humour. This fluid is formed principally by the ciliary bodies.

AQUEOUS HUMOUR. In chemical composition this fluid consists of water containing salts, traces of albumin and globulin, and a reducing sugar ; it is probably freely oxygenated. It has very nearly the same osmotic pressure as the blood (Duke-Elder). The fluid after secretion leaves the eye in one of three ways: (1) By travelling through the pupil into the anterior chamber of the eye and then through the spaces of Fontana at the edges of the iris (the so-called filtration angle) into the canal of Schlemm and thus into the ciliary veins. (2) Through the crypts in the anterior surface of the iris into the veins of that structure. (3) Between the suspensory ligaments of the lens to the anterior surface of the vitreous, then down the hyaloid canal to the papilla of the optic nerve, and thus out *viâ* the lymphatics of the nerve sheath or the retinal vessels. But whatever the fate of the liquid may be, it is certain that the amount secreted must be the same as that which leaves, because otherwise there would be a variation in the intraocular tension. Insufficient pressure will tend to disturb the correct relationship between the internal structures of the eye, and at the same time will prevent the proper action of the ciliary muscle in causing accommodation, because the suspensory ligaments of the lens will already be relaxed. Too great a tension on the other hand will interfere with the proper blood supply to the eye, and will prevent accommodation because the tension in the choroid will be too great for the ciliary muscles to overcome (see p. 389).

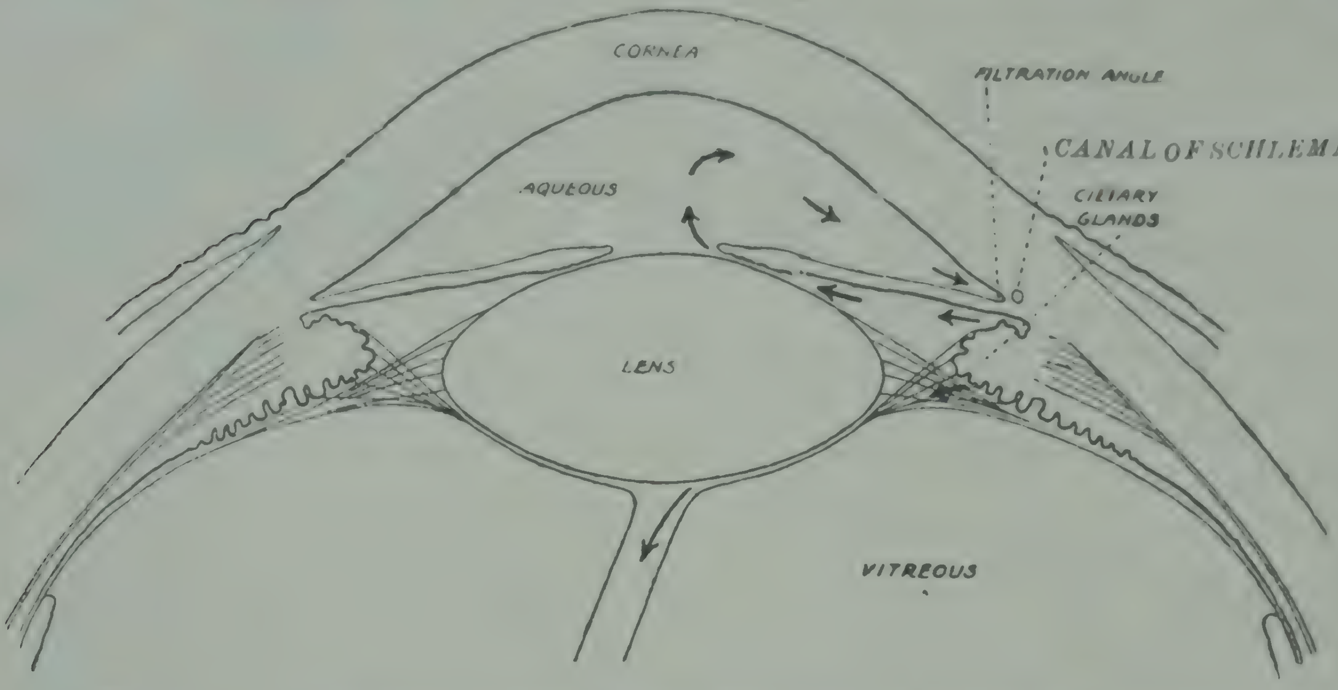

FIG. 249. Diagram showing Origin and Fate of Aqueous Humour.

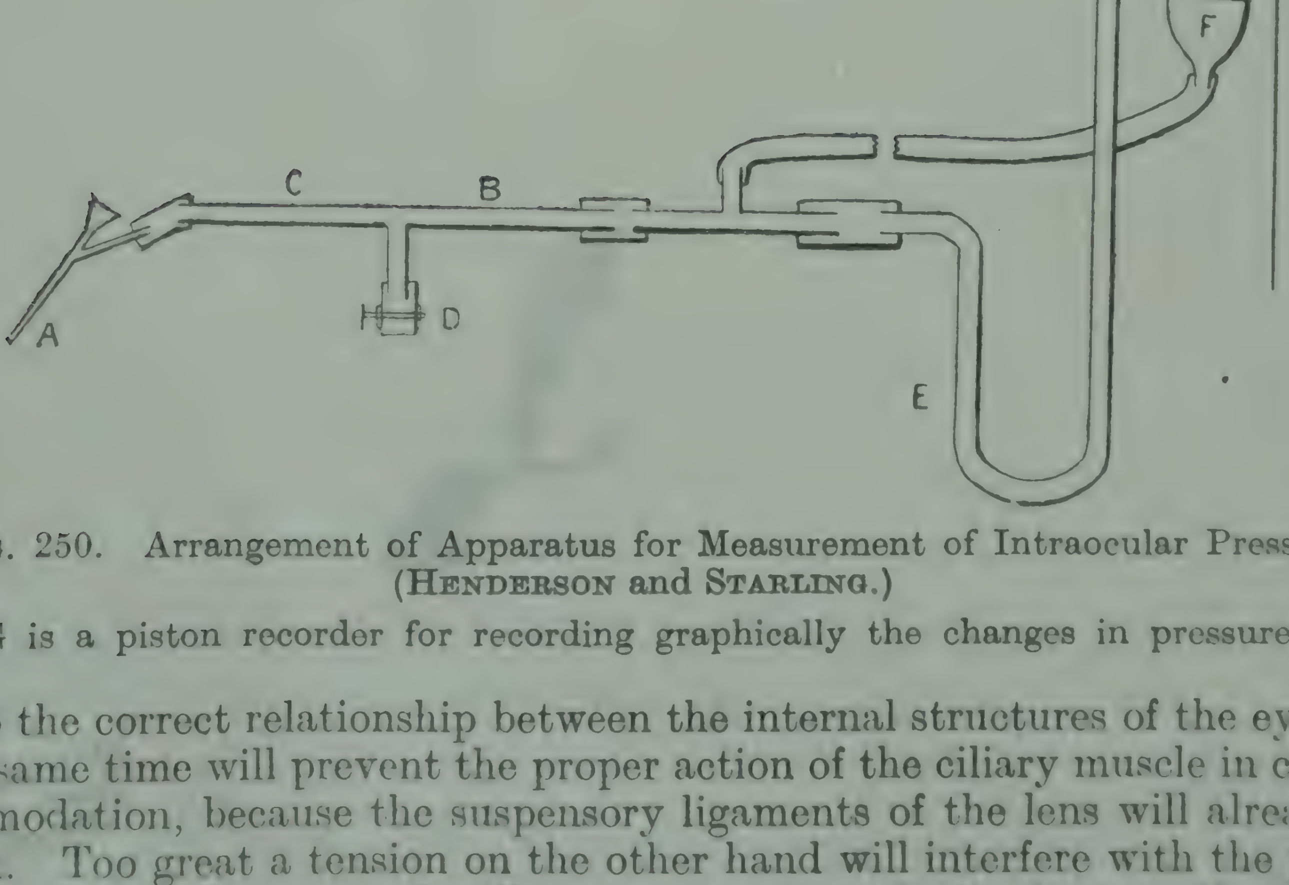

FIG. 250. Arrangement of Apparatus for Measurement of Intraocular Pressure. (HENDERSON and STARLING.)

G is a piston recorder for recording graphically the changes in pressure.

It is therefore important that there should be a proper control of the intraocular pressure. Experiments by Henderson and Starling, in which the intraocular pressure was determined by a null method (Fig. 250), showed that such a mechanism exists, because as the arterial pressure increased that in the eyeball increased much less.

Whereas the arterial pressure varied between 70 and 180 mm. (*i.e.* a difference of 110 mm.), the intraocular pressure was found to vary between 23 and 40 mm. (that is by only 17 mm.). The change in intraocular tension is therefore less than one-sixth of that taking place in the blood ; the control mechanism would therefore appear to have very considerable efficiency.

Glaucoma. The normal intraocular pressure in man is found to be between 25 and 30 mm. of mercury. The tension thus set up in the walls of the eyeball is principally borne by the sclera ; to some extent, however, assistance is rendered by the choroid owing to its elasticity, and by Tenon's capsule owing to the tonic contraction of its smooth muscle fibres (innervated by the sympathetic).

In abnormal conditions the efferent channels may become closed, either from pressure of the lens on the iris (as in hypermetropia) or from the presence of epithelial *débris* in the anterior chamber. The intraocular tension under these circumstances becomes very high, the disease being known as glaucoma. The principal symptoms of glaucoma are pain and impaired vision. The chief diagnostic signs are a stone-hard eyeball, sluggish, rather dilated pupils, and the retina when examined through the ophthalmoscope is found to show cupping of the optic disc, and vessels which are thin and show pulsation. In treating glaucoma, operative measures to lower the pressure should be taken immediately, because the high pressure interferes with the proper blood supply to the eye. Since all hypermetropes (persons with long sight) have a tendency to suffer from glaucoma, care should be taken against giving drugs such as atropine which causes dilatation of the pupil, since this increases the resistance to the escape of fluid at the filtration angle, and therefore predisposes to an attack of glaucoma.

4. THE OPTICAL SYSTEM OF THE EYE

The optical system of the eye consists of those structures which together focus an image of external objects on the retina. In the mammalian eye there are four concerned : the cornea, the aqueous humour, the crystalline lens and the vitreous humour. The histology of the cornea has already been considered. The aqueous humour is a structureless liquid. The vitreous humour which consists of a collagenous material is enclosed in the hyaloid membrane, and through the middle of it, during fœtal life, runs the hyaloid artery, which goes from the central artery of the retina to the posterior surface of the lens.

The Crystalline Lens is a biconvex transparent elastic body, enclosed in an elastic membrane called the capsule. To the periphery of the capsule are attached the suspensory ligaments of the lens, which are formed by the anterior radial fibres of the thickened portion of the hyaloid membrane (the zonula of Zinn) (Fig. 252). Between the suspensory ligaments are shallow pockets into which the ciliary processes fit closely. In this way the lens is held firmly in position, while at the same time, by the movement of the ciliary processes under the action of the ciliary muscle, the traction can be altered in the suspensory ligaments, thus effecting the change in curvature of the lens, which will be shown later to be necessary for accommodation.

Histologically the lens is composed of a number of radially arranged fibres, each of which is a modified epithelial cell. These fibres are arranged in concentric layers, the more peripheral being soft, nucleated and of low refractive index, while the central form a dense non-nucleated mass of high refractive index, the fibrous layers between having an intermediate structure and index.

Metabolism of the Crystalline Lens. If the crystalline lens be removed from the eye of an animal and placed in a microrespirometer of suitable pattern, it can be shown that oxygen is taken up by the lens and that carbon dioxide is given out. If such a lens is deprived of oxygen, or is exposed to excess of carbon dioxide for some hours, it shows signs of degeneration. The lenses of young animals have a high cystine content, which is associated with an active glutathione oxidation system. As animals get older the cystine content falls, and this may be associated with the decreased rate of metabolism which the lens shows.

Refraction by the Crystalline Lens. Refraction occurs whenever light passes from one medium into another of different optical density. It is due to the fact that the waves, of which the beam of light is composed, travel more slowly in a dense medium than they do in one of less density. Some of the effects which this produces are shown in the diagram below.

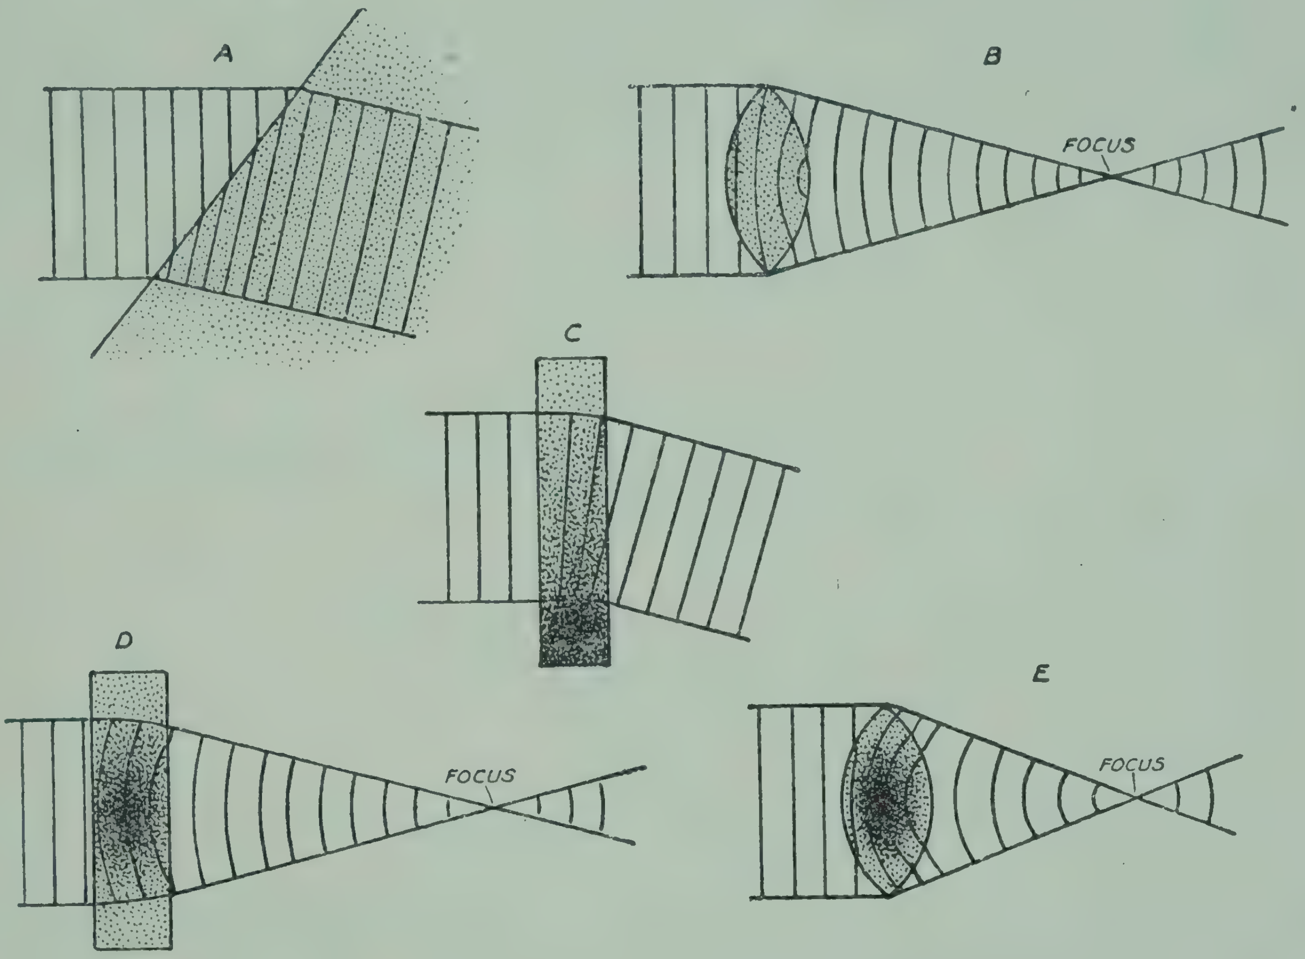

Fig. 253. Diagram showing Refraction of Light.

(A). By an inclined surface.
(B). By a lens.
(C). By a plate of greater density at its lower end than at its upper.
(D). By a plate of greater density at its centre than at its edges.
(E). By a lens of greater density at its centre than at its edges.

At A, plane waves are seen entering a dense medium at an angle. At B the medium is lens shaped. At C the medium has a plane surface but has a greater density below than above. At D the medium has a plane surface but a greater density at its centre than at its edges. At E the medium is lens shaped as at B, and also varies in density as at D. The very great refracting power of such a structure is well shown. This is the arrangement found in the lens of the eye, in which, therefore, the power of refraction is very much greater than that of an ordinary lens of the same curvature as the lens and of the same refractive index as the average density of its substance. The optical properties of the lens are therefore unique, and it is interesting to find the same (*i.e.* even immunologically identical) protein in the lens of different species of animals.

To show the effect which the increasing density of the lens produces, the refractive indices of its parts may be compared with its equivalent R.I. (that is, the refractive index of a glass lens of the same size, shape and focal length). The refractive index of the periphery of the lens is 1·37, and that of the central nucleus 1·41, the mean being about 1·39. But the equivalent density of the lens is found to be 1·42, that is, greater by 0·03 than the mean refractive index of its substance. The lens lies in contact with two transparent media, both of which have an approximate refractive index of 1·34. The power of the lens, if its composition were uniform, would therefore be proportional to the difference between its own mean R.I. (1·39) and that of its surroundings (1·34), that is to 0·05. Owing to its peculiar structure its equivalent R.I. is 1·42, and therefore its power is proportional to the difference between that and 1·34, that is to 0·08. Owing to its structure the lens has therefore increased in power in the ratio of 0·08 to 0·05. Now since the range of accommodation depends, other things being equal, on the power of the lens, we see that the peculiar structure of the lens has nearly doubled its range. The graduation in the densities of the different layers of the lens has a further advantage which will be described later, in that it reduces the spherical aberration of the eye as a whole and also reduces the amount of scattered light within the eyeball.

The Optical Constants of the Eye. In the case of the crystalline lens, two methods are available for the determination of the radii of curvature of the anterior and posterior surfaces, namely measurements on the excised lens, either in the air or preferably suspended in a fluid of known optical properties, or by estimating the apparent size of the images of an object which are formed by reflection at its surfaces. In order that the latter method shall succeed, a device must be employed for eliminating the effect of chance movements of the eye while under observation. This was first done by Thomas Young, who employed a method used in astronomy, namely that of doubling the image to be measured and then adjusting the lower edge of one image to be in coincidence with the upper edge of the other. If the eye moved during the determinations, both images moved together and therefore difficulties in adjustment were avoided. In the case of the cornea this method is alone available because only in the living state is the true curvature preserved (Fig. 254). In the case of the lens the determinations are complicated by the fact that the refraction of the cornea has to be allowed for. Further, the images that are seen are neither bright nor sharply defined; but in spite of this, considerable accuracy is attainable. The following are the approximate values given by these methods.

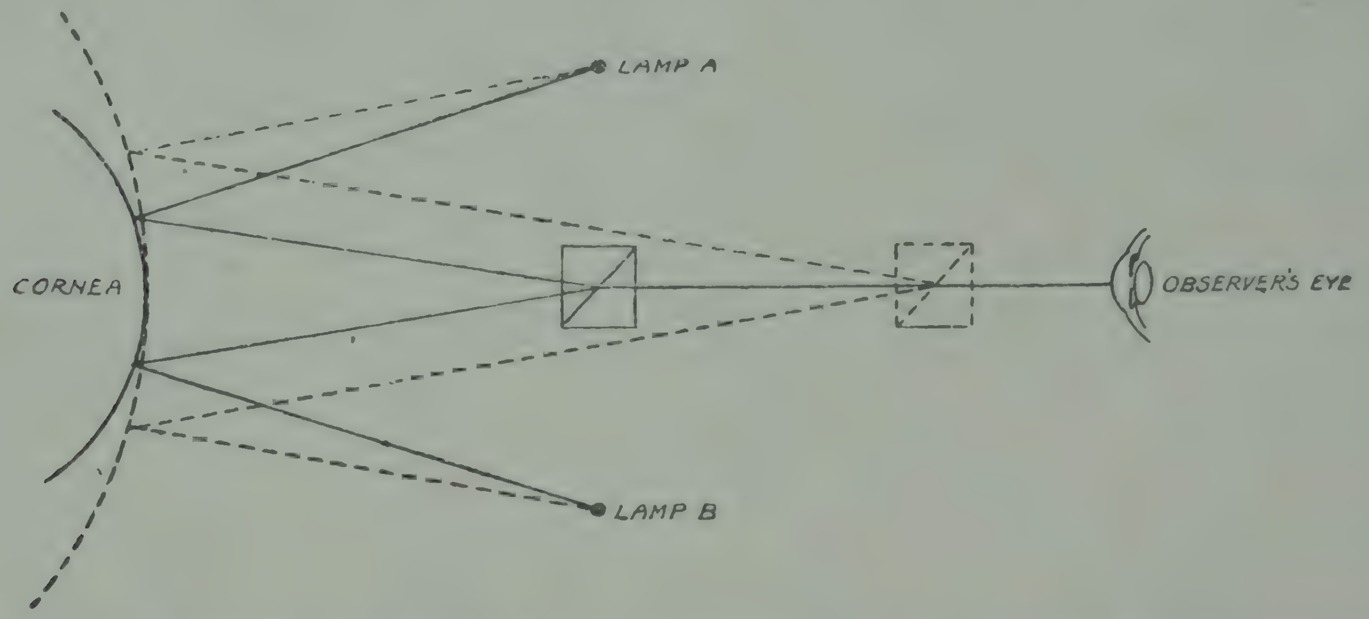

Fig. 254. Diagram to show a Method of Determining the Curvature of the Anterior Surface of the Cornea.

The images of the lamps A and B are caused to coincide by shifting the position of the double image prism. The greater the curvature of the cornea the closer must the double image prism be to the eye.

Radius of cornea	8 mm.
Radius of lens, anterior surface	10 ,,
Radius of lens, posterior surface.	6 ,,

The Refractive Indices (optical densities) of the eye media are determined on the excised eye by means of the Abbe refractometer. It is found that the cornea and aqueous are so nearly alike that for all practical purposes they may be regarded as one, particularly as the posterior corneal surface has nearly the same centre as the anterior. The refractive indices may therefore be given as follows :—

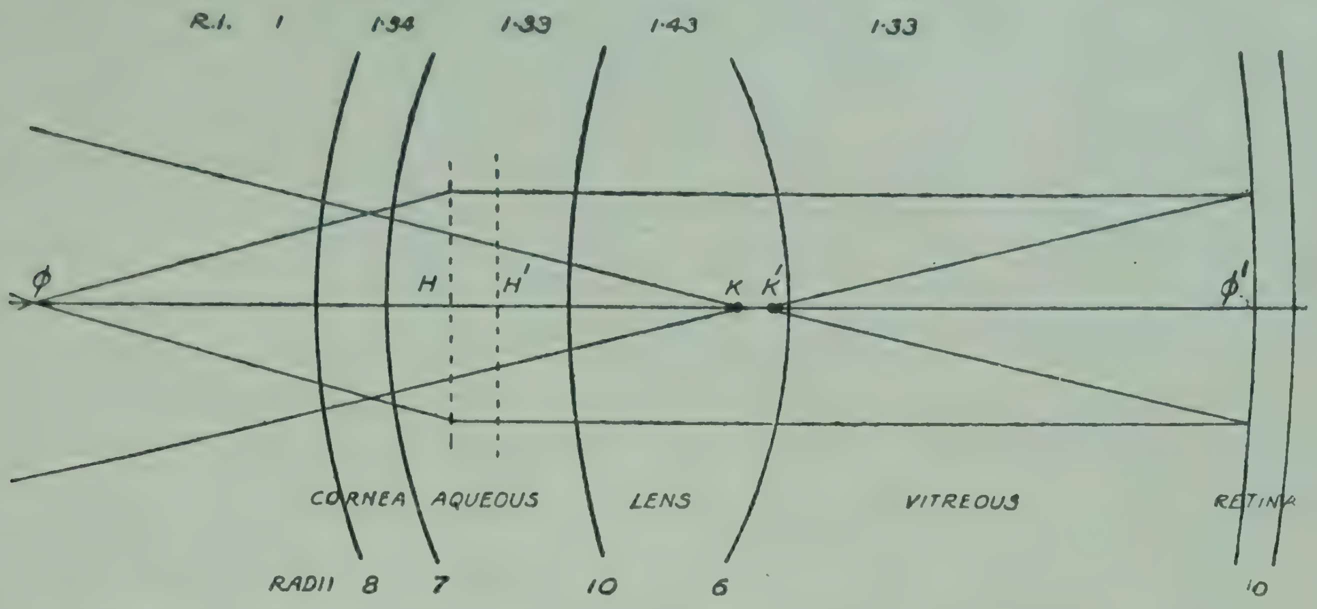

Fig. 255. The Optical System of the Eye shown diagrammatically.
H and H′ principal points. K and K′ nodal points. φ and φ′ anterior and posterior foci.

Refractive index of cornea and aqueous	1·34
Refractive index of lens (equivalent)	1·42
Refractive index of vitreous humour	1·33

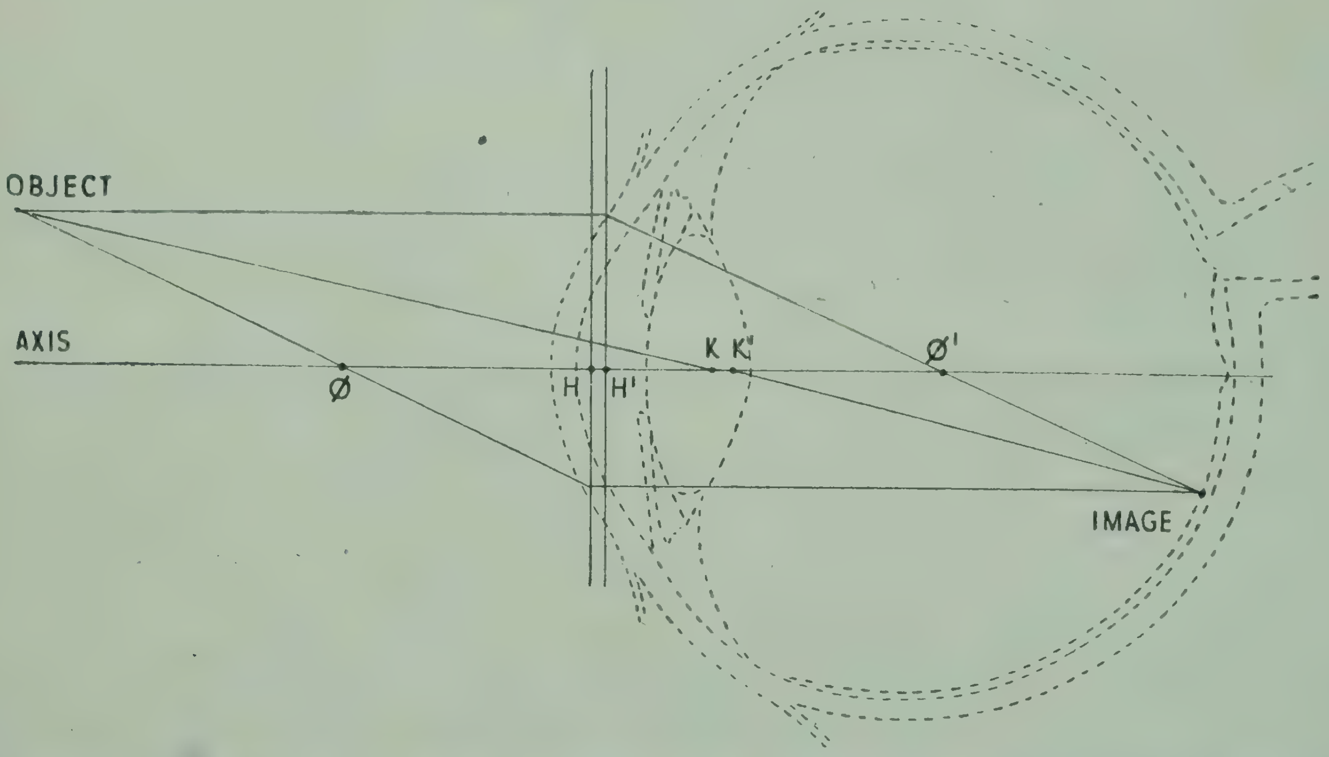

Fig. 256. Diagram showing approximately the positions of the principal planes and nodal points of the eye. The course of rays from a near object passing through the eye to form an image on the retina is shown.

The direction of the rays of light through the eye is shown diagrammatically in Fig. 256.

It is of some interest to know the relative part taken by the various refractive media of the eye in the formation of the image. By far the greater part is performed by the cornea. The following values in mm. and dioptres * may be given :—

	Mm.	Dioptres.
Focal length of the cornea	24	42
,, of the lens	44	23
,, of the whole eye	15·5	65

---

* In the dioptre nomenclature the figure represents the reciprocal of the focal length in metres. Thus 10 dioptres = $\frac{1}{10}$ metre = 100 mm.; and 24 mm. = $\frac{1000}{24}$ = 42 dioptres.

When opacities (a cataract) form in the lens this structure is removed by operation. It is then found that a lens of approximately 10 dioptres has to be worn by the patient in order that he may see distinctly. To this a cylinder has usually to be added to correct the astigmatism caused by the scar of the incision; and a 4-dioptre spherical lens has to be added when a glass for reading is being prescribed. If the glass lens could be placed inside the eyeball in the exact position occupied by the crystalline lens it would, as the above Table shows, require a power of 23 dioptres instead of 10 dioptres. When the eye is placed under water, the refraction of the cornea is necessarily abolished because water has approximately the same refractive index. Under these conditions the eye becomes too long-sighted for distinct vision. The eye of the fish has met this difficulty by the provision of a small, nearly spherical lens of very great density. In the fish, therefore, the lens takes the principal part on the refraction of the light in the formation of an image.

The Accommodation of the Eye. The above description has been made on the supposition that the rays entering the eye consist of parallel bundles, or in other words that the objects seen are at an infinite distance from the eye.

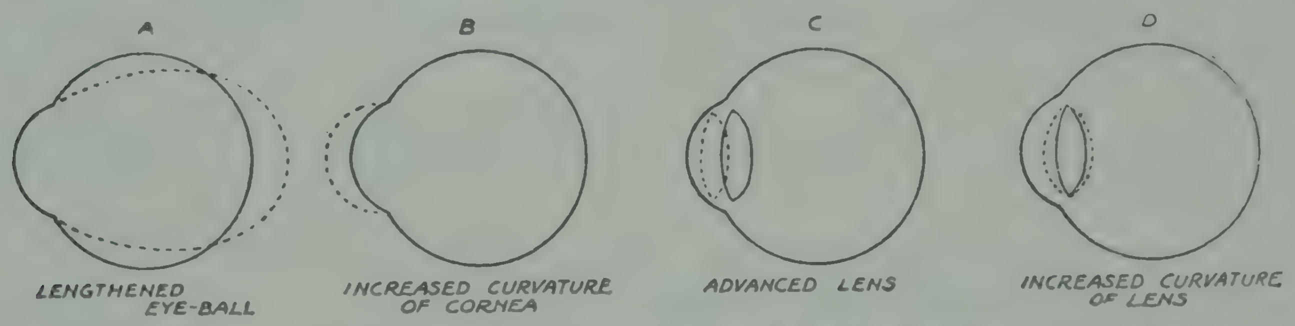

FIG. 257. Methods by which Accommodation of the Refraction of the Eye for Objects at Different Distances could be effected:

(A). By lengthening the eyeball. (C). By moving lens forward.
(B). By increasing curvature of cornea. (D). By increasing curvature of lens.

But during near vision, such is by no means the case. If there were no means of varying the focus of the eye, it would not be possible for divergent rays (those coming from near objects) to be brought to a focus on the retina. The mechanism for varying the focus of the eye is called accommodation.

THE THEORIES OF ACCOMMODATION. Of these, three are of historic interest only: (1) That during accommodation the cornea increases in curvature (similar to the bird's eye). This was disproved by Thomas Young, who placed his eye under water, replaced the corneal refraction by a convex lens, and then found the amplitude of accommodation unaffected. (2) That the eye elongates in near vision, thus causing the rays from near objects to focus on the retina (similar to the arrangement in the mollusc Pecten). This also Thomas Young disproved by placing two iron rings which could be clamped together, one in front of and one behind the eyeball. Having very prominent eyes he could do this if the eye being tested were rotated strongly inwards. The "phosphene," or subjective appearance, caused by the pressure of the posterior ring, which extended to the fovea, did not change in appearance during accommodation. He thus found no evidence for an elongation of the eye during accommodation. (3) That the lens during near vision advances towards the cornea (similar to the mechanism in the fish's eye). This view was disproved by Tscherning, who calculated that the lens would have to advance nearly 10 mm. in order to give the full amplitude found for the eye, whereas the anterior chamber of the eye is, as we have seen, approximately only 2·6 mm.

It follows that in the mammalian eye the fourth method is employed, viz. that accommodation is effected by increasing the curvature of the lens. As to the way in which this is brought about, there are three theories, those of Helmholtz, Tscherning and Thomson Henderson. The first theory (which is the one most generally accepted) supposes that the lens when removed from the eye is strongly convex and is accommodated for near vision. When in the eye, however, it is caused to become flatter through the traction of the zonula of Zinn (suspensory ligaments) on the edges of its capsule, and is therefore focussed for distance. But when the ciliary muscle contracts, it removes the tension on the zonula and therefore allows the lens to return by its elasticity to its more spherical form. Before describing the rival theories it would be well to examine the principal evidence on which Helmholtz' theory has been based. During near vision, measurement by means of the ophthalmometer shows that the anterior surface of the lens advances slightly and becomes at the centre of much greater curvature (10 mm. radius for distant vision, to 6 mm. for near). There can thus be no question that the change in the curvature of the lens is responsible for accommodation. The posterior surface is found to change but little; almost the whole range is therefore produced by the anterior surface. The changes found to occur in the lens of an adult twenty-five years old may therefore be summarised as follows :—

	Distance.	Near.
Radius of anterior surface, in. mm.	10	6
Radius of posterior surface, in mm.	6	5·5
Thickness of lens, in mm:	3·6	4
Focus of lens, in mm.	44	30
Focus of lens, in dioptres	23	33
Range of accommodation, in dioptres	10	

If the lens in near vision becomes more spherical owing to the relaxation of the zonula as Helmholtz supposed, we should expect a lens removed from the eye to be more spherical still, that is, in a state of strong accommodation. Tscherning stated that the changes in the curvature of the lens are much more complex than those given above. During accommodation not only is there, he says, an increase in the curvature near the centre of the lens, but at the same time a decrease in the curvature at the periphery. This view he supported by quoting the careful measurements which Young made by means of his optometer, and which have been confirmed by other observers. There is found to be a zone about 1·4 mm. from the centre of the lens where the curvature does not change appreciably. Inside this zone the curvature increases during accommodation, whereas outside the lens becomes flatter. Tscherning supposed that these changes of curvature are produced by an increase in the tension of the zonula during accommodation, in other words exactly the opposite action to that which Helmholtz supposed to occur. According to Thomson Henderson, the setting up of tension in the suspensory ligaments is due to the pull of the muscles of accommodation, that is, that these muscles are in tension during accommodation to distant vision. In the excised eyeball, therefore, the lens will be adjusted for near vision.

We may summarise the position with regard to these theories as follows :—

According to Helmholtz, the muscles adjust the lens for near vision. According to Tscherning and Thomson Henderson, they adjust the lens for distant vision. The state of the lens in an excised eye and when isolated from the eye is therefore as follows :—

	Helmholtz.	Tscherning.	Thompson Henderson.
Lens in excised eye accommodated for	Distant vision	Near vision	Near vision
Isolated lens accommodated for	Near vision	Distant vision	Near vision

Experiments have shown that the choroid moves forward during accommodation in both man and animals; further, Hess has shown that, when full accommodation has been performed, the lens is only loosely supported, so that gravity can act on it and cause it to sink slightly in relationship to the other eye structures These effects appear to be definitely in favour of Helmholtz' and Thomson Henderson's theories, and against that of Tscherning. Additional evidence on this point is provided by the experiments of Hartridge and Yamada (1922).

They obtained the following values in the cat's eye :—

Power of lens in excised eyeball	65 dioptres
Power of isolated lens	80 ,,

The lens in the excised eyeball is therefore in the condition for distant vision, whereas the isolated lens is in the condition for near vision, there being an increase in the power of the lens of 15 dioptres. These results are in favour of Helmholtz' theory and contrary to the theories of Tscherning and Thomson Henderson.

The Mechanism of Accommodation. The ciliary muscle consists of two separate sets of unstriated muscle fibres: the more superficial set of radial or longitudinal fibres, the deeper of bundles of circular fibres. The former take their origin from the sclero-corneal junction, and are attached to the anterior part of the choroid coat behind the ciliary processes. When these fibres contract, they draw the choroid forward and inward, the ciliary processes tending to occupy a smaller circle. The circular fibres lie in the substance of the base of the ciliary processes, so that, when they contract, they cause the apices of the processes to approach one another. In addition to these two sets of fibres, a third set has been described as meridional. These are, however, part of the radio-longitudinal set from which there does not appear to be much object in differentiating them. The ciliary muscles therefore have a common action, causing the ciliary processes to form a smaller circle.

The zonula of Zinn, or suspensory ligament, is formed of a large number of very fine fibres which run from the ciliary processes to the capsule of the lens. Further, those which arise posteriorly are attached anteriorly and *vice versâ*. When the ciliary muscle is in a state of rest, the tension in the choroid set up by the intraocular pressure causes the ciliary processes to be pulled in an outward and backward direction and therefore puts tension on the lens capsule through the zonula. The lens thus tends to be flattened and accommodated for distance. On contraction of the ciliary muscle the tension in the choroid is opposed and the ciliary processes approximated (Fig. 258). The zonula thus becomes slack, and the tension of the lens capsule decreases, allowing the lens to take up its more natural spherical shape, and thus to focus the rays from nearer objects.

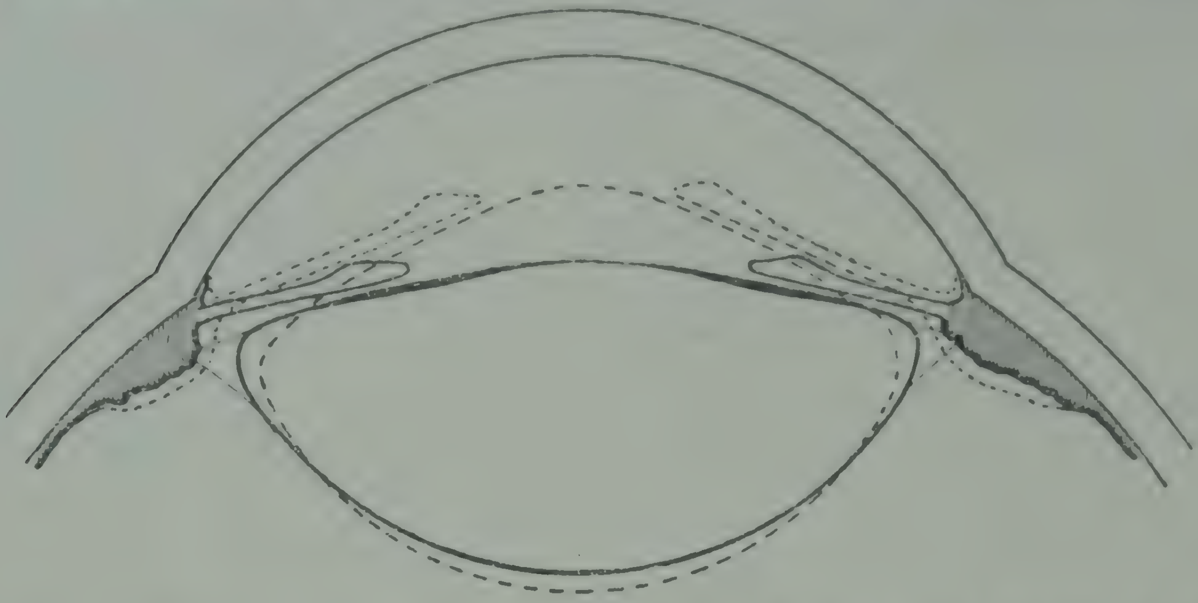

Fig. 258. Diagram to show the Changes in the Position and Shape of the Eye Structures during Accommodation. (After Fincham and Helmholtz.)

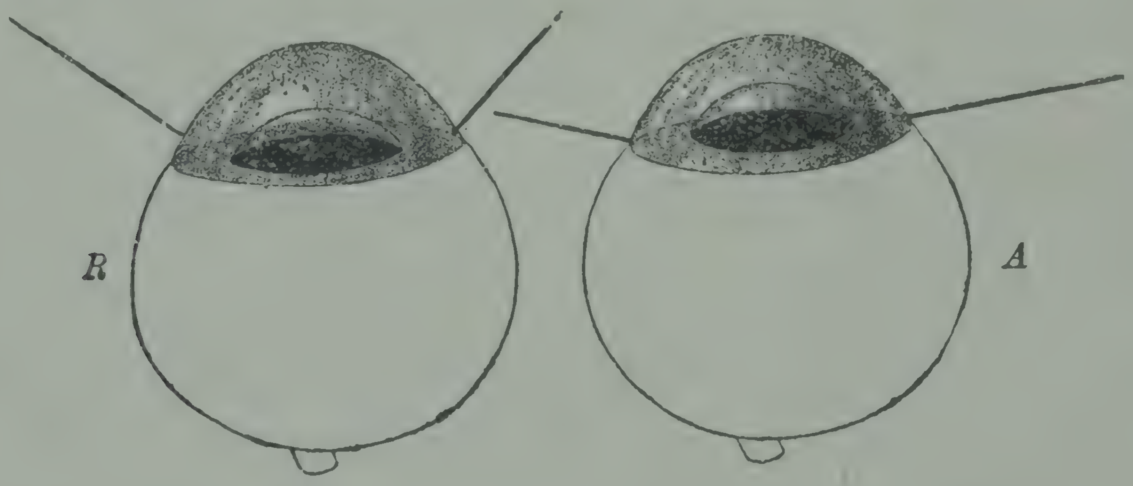

Fig. 259. Accommodation in the Cat's Eye. (Beer.)
R. Distance. *A*. For Near Vision.
Two needles have been passed through the edge of cornea into the ciliary bodies, to show forward movement of the latter during accommodation.

Fincham has pointed out the important part played by the variations in thickness of the capsule of the crystalline lens. This is very thin at the front surface near the centre, but very thick 2 or 3 mm. peripheral to the centre. The result of this is that the tension in the capsule causes the central part of the lens where the capsule is thin to become more highly curved, whereas it causes the more peripheral part of the lens where the capsule is thick to become flattened. These effects of the capsule are shown in Fig. 258 for both the unaccommodated and the accommodated lens.

Innervation of Mechanism of Accommodation. The ciliary muscle is innervated through the 3rd nerve, its nucleus being situated near the mid line under those of the pupils. Owing to the close association of the nuclei on the two sides, it is impossible to cause accommodation of the eyes separately. From this nucleus the fibres travel down with the rest of the nerve through the outer wall of the cavernous sinus, and when they reach the orbital cavity are given off to the ciliary (lenticular) ganglion, where they anastomose with nerve cells, the processes of which then proceed through the short ciliary nerves to the eyeball.

The position of the higher centre connected with the nuclei concerned in accommodation is not definitely known; it is believed to be in the occipital cortex. But since it is possible to carry out willed changes of focus as well as subconscious ones there must be connections with other parts of the brain as well.

THE AMPLITUDE OF ACCOMMODATION in the emmetropic (normal) eye is measured by ascertaining the nearest point from the eye at which perfect vision can be obtained. Since it is possible that the eyes, when examined separately, can focus nearer objects than they can when used together (owing to the limitation in the power of convergence), one of the eyes should be closed when making the determination. In the ametropic (abnormal) eye it is necessary to determine the far point as well as the near, since the former may not be at infinity as it is in the emmetropic eye. But other difficulties are encountered because, in the case of hypermetropic (long-sighted) eyes, an object placed at infinity still requires some accommodation in order to focus it. Lastly there comes the personal equation of the patient, since it is found that, even when apparently fully relaxed, the instillation of atropine usually causes some further relaxation of the accommodation; so in the same way the instillation of eserine is usually followed by a definite increase in the accommodation over that which can be voluntarily exerted. To obtain the maximum amplitude of the accommodation these drugs should therefore be used. Where a comparative and relatively approximate value is alone required they may be omitted. Of the many methods that may be employed, probably the simplest is by the use of the set of trial lenses, which vary in their curvature by small uniform amounts from strongly convex (plus) to strongly concave (minus). The test object consists of a pin placed vertically in a board at any fixed distance from the eye, a white surface being arranged behind it. A pair of spectacles to hold the trial lenses is placed before the eyes, and in them are inserted two metal plates with two vertical slits in them, so that each eye in turn may look at the test object through the slits in the plate opposite it. To determine the *near point*, minus (concave) lenses of gradually increasing power are placed before one of the eyes, the other being closed, until one is found that just causes the image of the pin to appear double. The power of the next weaker lens is therefore taken to be the correct one. To determine the *far point*, plus (convex) lenses of increasing power are tried in a similar manner, and that one taken which just does not cause appreciable doubling. The difference between the power of the two lenses found in this way gives in dioptres the value of the amplitude of the accommodation. Care should be specially taken to see that the value found for the concave lens has the minus sign placed in front of it. Thus if it was found that the far point was reached by the use of a convex lens of 2·25 dioptres, and that the near point required a concave of 7·5 D., then the amplitude is not 5·25 D. but 9·75 D. Careful measurements made in the above manner show that there is for different ages an average range of accommodation. In youth the amplitude is large, but it decreases uniformly to old age, and this decrease is called *presbyopia* (old-sight). The amplitude found as a rule at different ages is approximately constant and is given in the Table below.

Age in Years.	Accommodation in Dioptres.
10	13·8
15	12·6
20	11·5
25	10·2
30	8·9
35	7·3
40	5·8
45	3·7
50	2·0
55	1·3
60	1·1

This gradual reduction in the amplitude of the accommodation is caused by the hardening of the crystalline lens, which with the advance of years robs it of the elasticity of youth. As a rule the change goes on unheeded till the time comes when the near point of vision has receded so far from the eye that the book has to be held at a distance, in order to be focussed clearly. Then it is found that the print, particularly if it is fine, becomes unreadable, and convex glasses have to be worn. It is at that time that presbyopia may be said to begin, usually at an age of 45 to 50 in emmetropia. In hypermetropia, presbyopia shows itself earlier than normal, and in myopia (short-sight) later. The reason for these differences will be described when dealing with these conditions.

THE EFFECT OF DRUGS on the accommodation has already been alluded to. In ophthalmic practice three are used in order to paralyse the ciliary muscle, namely atropine (one-half per cent. solution), homatropine (2 per cent.) and scopolamine (one-fifth per cent.). One of these drugs is placed within the conjunctival sac, and from here it slowly travels, probably by diffusion *viâ* cornea and aqueous, to the ciliary and iris muscles, both of which are paralysed. This fact is of the greatest importance, for if this path did not exist the use of these valuable drugs would hardly be possible. Contraction of the ciliary muscles and of the sphincter pupillæ muscle is caused by the drugs pilocarpine and physostigmine (eserine). One of these is often used to counteract the effects of the atropine group.

5. THE REFRACTION OF THE EYE

In many respects the eye is an improvement on the ordinary photographic camera.

(1) The focussing of objects is performed automatically.

(2) The intensity of the illumination of the retina and its sensitiveness are adjusted automatically.

(3) The depth of focus is increased at the same time that the focussing of near objects takes place.

(4) The field of view is extremely large. In most cameras it does not exceed 90 degrees, whereas in the eye it is 208 degrees. Thus objects 14 degrees behind the observer are visible to him.

(5) In most camera lenses considerable loss of light occurs at the various surfaces of contact between glass and air. Thus in most photographic lenses there are four glass-air surfaces, and in many lenses the number is greater than that. In the eye, on the contrary, the space between the components is occupied by a medium not very different in refractive index from the refracting surfaces. There is thus only one surface where important reflection occurs, namely, at the anterior surface of the cornea. At all other surfaces the loss of light by reflection is extremely small so that the maximum light possible reaches the retina.

(6) The correction of the various aberrations from which a lens ordinarily suffers, are largely corrected in the case of the eye. In consequence its defining power is of a high order. The image of external objects which is thrown on the fovea centralis of the retina would hardly be improved if the lens system of the eye was removed and a microscopic objective of the same focal length substituted.

(7) The convergence of the eyes for the observation of near objects is automatically controlled.

(8) The retina consists of two receptor systems. One system is used for black and white in a dim light and the other is for colour used in a bright light. The fineness of grain in the latter is very good, exceeding 10,000 separate light receptors per square mm. The fineness is just adequate to make full use of the excellent definition of the lens system.

(9) The retina forms a cup-shaped surface which coincides everywhere with the position of the best definition of the lens system. Its curvature also causes the images of objects to have dimensions which are independent of their position on the retina. This factor is important for the provision of stereoscopic vision (distance perception).

Since the eye forms an image of external objects by means of its refracting media, it is found to have properties and to suffer from defects similar to those met with in the case of other optical systems. We may therefore treat the eye as if it were an optical instrument, and estimate its efficiency from that point of view. In the first place, therefore, we must consider what kind of an image it would form if it were a perfect lens system, suffering from no kind of aberration. Our experience of other lens systems, well-nigh perfect, has shown us that the image of a distant point source of light is not a mathematical point, as geometrical optics would have us believe, but is on the contrary a definite pattern of quite considerable size, the shape and dimensions of which can either be calculated from the conditions, or may be seen, measured and photographed by appropriate means. The formation of this pattern is due, not to any defect of the lens, but to the fact that light is a form of wave motion which exhibits a property called diffraction.

The diffraction pattern formed by any lens system varies directly as the focal length of the system and the wavelength of the light, and inversely as the diameter of the pupil through which the light passes. In the case of any lens system such as the eye, in which the pupil is circular, experiment and calculation are agreed that the image of a point source consists of a series of concentric rings of light, having a bright spot at their centre. The diameter of this spot in the case of the eye is found to be 0·01 mm. with a pupil of 2mm. diameter. No matter how perfect the eye be as an optical instrument, diffraction sets a limit in this way to the perfection of the image that can be formed. This should not, however, be thought of as a defect, but as a property, since it is caused by the nature of light itself. In the consideration of the principal optical errors of the normal eye, we have to decide in each case, not only to what extent the defect is present, but whether the defect produces any noticeable change in the diffraction pattern which may affect definition.

DEPTH OF FOCUS, like diffraction, is a property of a lens system and not an aberration. Its origin may be explained as follows :—Suppose objects 100 metres away to be forming sharp images on the retina, then objects at 200 metres will form images which come to a focus slightly in front of the retina, and objects at 50 metres images that are slightly behind. If however the focussed points are only a short distance in front of or behind the retina, the image of a distant point which fell on a single cone would still do so although its distance from the eye had been altered, because the cone has a certain diameter. Depth of focus in the case of the eye is the greatest distance through which a point can be moved and still produce an image which falls exactly on a cone without spreading at all on to neighbouring ones. For example, in the above case the distance moved was from 200 to 50 metres, that is, the depth of focus was 150 metres. Now it is found in the case of any lens system that depth varies with the aperture of the pupil. Thus in the case of the eye the following values are obtained :—

Pupil diameter.	Depth at infinity.	Depth at 25 cms.
1 mm.	From inf. to 8 metres	3·2 cm.
2 ,,	,, ,, 16 ,,	1·6 ,,
3 ,,	,, ,, 24 ,,	1·1 ,,
4 ,,	,, ,, 32 ,,	0·8 ,,

We see, therefore, that not only does depth decrease as the aperture of the pupil increases, but that it also decreases as the mean distance of the objects from the eye decreases. Thus with a pupil of 3 mm. the eye, if focussed sharply on objects 24 metres away, would also be in focus for objects at infinity and for objects at 32 metres. Depth of focus is therefore considerable at this distance. But if the eye is working at the distance of 25 cm., depth would be 1·1 cm. only. At a pupil diameter of 1 mm., depth would be increased threefold, and therefore the closure of the pupil, which accompanies accommodation and convergence for near objects, has the valuable property of increasing the depth of focus at the same time. The average reading distance depends on the size of the individual *i.e.*, on the length of the arm, and is about 35 cm. (14 in.) for ordinary adults.

CHROMATIC ABERRATION OF THE EYE. We have seen that white light consists of a number of rays of different wavelength, and that on refraction the short rays are more bent than the long. When, therefore, white light is

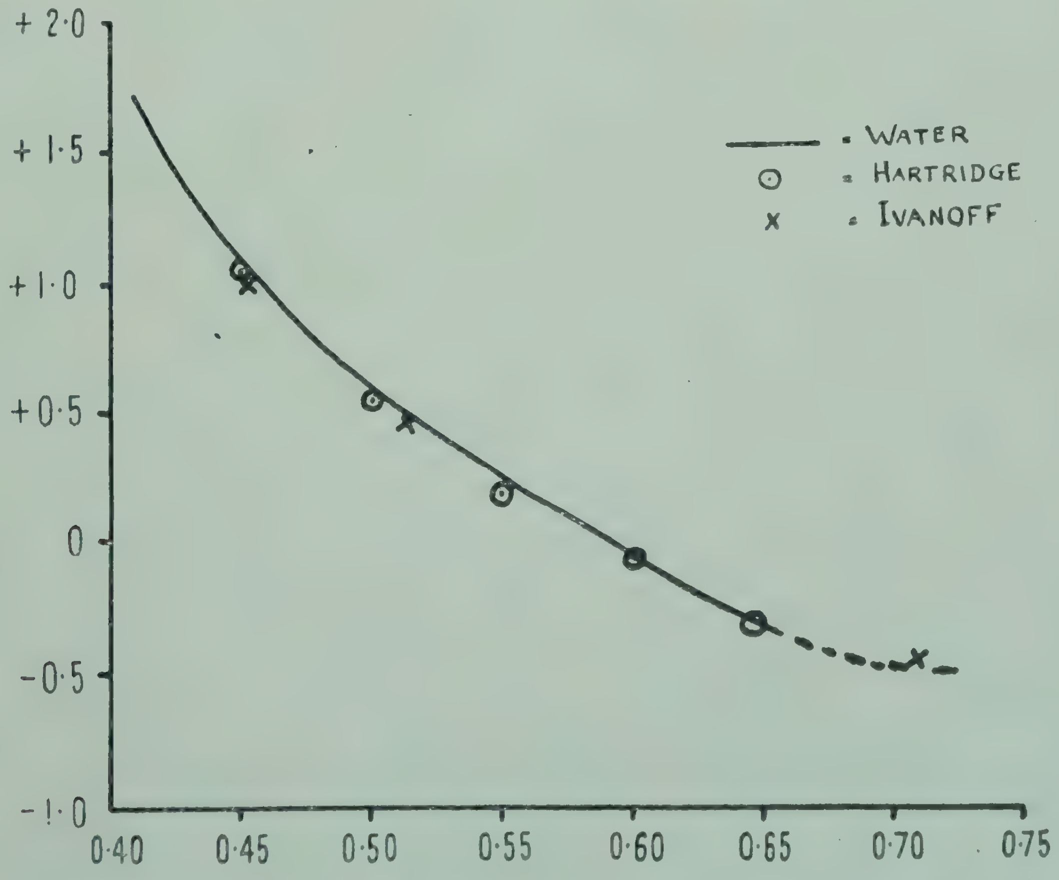

FIG. 260. Measurements of the Chromatic Aberration of the Eye. Refraction in dioptres vertical. Wavelength (μ) horizontal.

incident on a lens, the rays of short wavelength come to a focus in front of those of longer wavelength. This difference of focus for rays of different colour is called chromatic difference of focus (see Fig. 260). Experiment shows that, when such a series of foci are formed by the eye, the accommodation is so adjusted that the rays of greatest intensity (usually yellow rays) form the most sharply focussed image, and the colours of longer and shorter focus form blurred discs of light of relatively low intensity on top of this. Under these conditions it is found that quite well defined images are produced. Thus, with a pupil of 2 mm. diameter, approximately 70 per cent. of the light falls in an area of 0·005 mm. diameter.* Further it may be shown that a lens system such as the eye, which suffers from chromatic aberration, produces an image that is only just appreciably worse than one that is perfectly corrected, when the effects of diffraction are taken into account in both cases. But since the effects of chromatic aberration increase as the pupil enlarges, while those caused by diffraction decrease, it is clear that the larger the pupil the more does chromatic aberration tend to spoil definition. But as this is accompanied by a decrease in diffraction, the two changes taken together have the effect of leaving the actual definition practically unchanged. This important conclusion will be referred to again more fully in the last section. Besides effects on definition, chromatic aberration causes small bright points of light on a dark ground to form images which are largely composed of yellow rays, and on the other hand small black objects on a bright ground to be violet in colour. The reason for these colours being unnoticed in ordinary circumstances is due to the presence of the complementary colour which forms a fringe round the central point.

What happens is this: with a reduction of the visual angle, which is subtended by a yellow test object at the observer's eye, the yellow colour is replaced by white or by pale grey. Under similar circumstances blue or violet are replaced by dark grey or black. But experiment brings out the interesting point that both yellow and blue test objects tend to lose their colour more readily when they are in contact than when they are separated; thus a grating test object consisting of alternately arranged yellow and blue bars is easily mistaken by the observer for one consisting of black and white bars. Similar losses of colour are found to occur in the case of the pairs of fringes which are produced by the chromatic aberration of the eye. This subject will be found referred to in greater detail on p. 444 in the section describing "The correction of the chromatic aberration of the eye."

SPHERICAL ABERRATION OF THE EYE. The employment of spherical surfaces as boundaries for optical media leads to a difference in the position of the foci of rays that have passed through the centre of the lens and those that have passed through the more peripheral parts. The latter usually form a focus nearer to the lens. Since the eye is bounded by nearly spherical curves, it might be assumed that this aberration must be present in this organ. It should be remembered, however, that the crystalline lens has a structure quite different from that found in the lens systems of optical instruments. For the presence of a graduation of optical density, culminating in a nucleus of relatively great curvature, causes rays passing through the centre of the eye to be refracted to a greater extent than more peripheral rays, or, in other words, exactly the opposite effect to that produced by spherical aberration. Measurements on the eyes of different individuals, therefore, show the presence both of small amounts of under-correction (when the correcting effect of the lens nucleus has not been enough) and also actually of over-correction (when the lens nucleus has had too big an effect). In quite a number of cases the amount of spherical aberration is negligible even with pupils of 4 mm. diameter. With larger pupils there is probably a certain amount of under-correction, but this again is less than would be found in the case of spherical surfaces, because the more peripheral parts of the cornea are flattened and therefore refract less (as

---

* HARTRIDGE. *J. Physiol.*, 1918, **52**, p. 175; and 1922, **57**, p. 52

Gullstrand has shown). We may say, therefore, that in everyday life the effects of spherical aberration are altogether negligible, compared with those of diffraction and chromatic aberration.

PERIPHERAL ABERRATIONS OF THE EYE. So far the definition of an image lying on the principal axis of the lens has alone been considered. When this is not the case, other conditions are encountered which are more unfavourable in their effects. In the first place, the rays that form images on the peripheral parts of the retina make considerable angles with the surfaces of the eye media. This will cause chromatic difference of magnification, since blue rays will be more bent and will therefore form smaller images than red rays. It will also introduce " comma," that is, the effect due to non-compliance with the sine condition. It is seen at once, therefore, that the image formation by the periphery of the eye is altogether more imperfect than it is at the centre. The presence of the nucleus of the lens still further impairs the marginal definition. In fact we may say that in the eye, as in the microscope objective, the marginal images have been sacrificed in order thereby to improve the central ones. That this has been a very valuable result will be shown later. It will be shown in the next section that the most sensitive region of the retina is not exactly in correspondence with the optical axis of the lens system of the eye, being displaced approximately 0·5 mm. to the temporal side.

STRUCTURE OF FOVEAL IMAGE may be determined approximately by considering in turn the effects of the different aberrations on the light rays which enter the eye. For this purpose the only errors of importance are chromatic differences of focus and magnification. In addition, however, we must take into account the very important effects of diffraction. The final results of such a calculation show that the images of rays of different wavelength overlap one another. At the centre of the image is seen the sharp yellow focus of the highest intensity. Eccentric to it, and overlapping one another, are seen the diffuse red and green foci, which are of much less intensity. Where these overlap they produce a compound yellow according to the rules of colour mixture. Further outwards is the still more diffuse image of the blue rays, which is of almost negligible intensity. It is seen therefore that the centre of the image is entirely occupied by the sharp and intense focus of the yellow rays. Not only are these rays the brightest in the spectrum, but they are also those nearest to white light in their physiological properties. It is because of this structure of the image that the acuity of vision is so great at the fovea.

PERIPHERAL IMAGES have, as stated above, been to a considerable extent sacrificed, so far as their definition is concerned, in order to obtain the best possible conditions at the fovea. We find, therefore, at the periphery images that in no way compare with those formed near the optical axis of the eye. Even here, however, there is evidence that the eye has been designed to give the best results obtainable.

Scattered Light. In describing the histology of the retina it will be shown how generously the layer of cells lying immediately outside the sensitive layer of rods and cones is supplied with pigment; the object of this is clearly to absorb scattered light. In spite of this, however, we find considerable amounts of light being reflected back again by the retina; in fact it is this light that enables us to see the retinal nerves and vessels through the ophthalmoscope (see p. 411).

Abnormal Refraction of the Eye. It would almost be anticipated that such a complicated organ as the eye would be found to show individual abnormalities. A further consideration would probably suggest to us that, considering the smallness of the change that is necessary in any one of the optical media in order completely to destroy definition, it is nothing short of astonishing that abnormality of refraction is relatively so uncommon. In the newly-born the eye is almost always long-sighted (hypermetropic); this is due to the eyeball being too small for the optical system which it contains; the image formed by the latter is therefore focussed behind the retina. As age advances the eyeball grows until the point is reached at which the eye is emmetropic (normal). If, however, the child is allowed to use its eyes too much for near work, the eyeball goes on increasing in size until it has overshot the mark, and has thus caused the eye to become short-sighted (myopic). There would appear to be some kind of automatic control, which causes the eye to grow till it is in adjustment with the conditions most frequently encountered. This hypothesis is confirmed by the fact that if a child which is beginning to develop short-sight is prevented from using near vision for a year or two, the development of short-sight stops. The importance of the early detection of the onset of short-sight therefore cannot be too strongly urged.

The Methods of Diagnosis. The detection of errors of refraction in the eye may be effected in various ways, each of which is said to possess advantage. Some of these have come into such general use that they may be briefly considered as an introduction to the description of the more important types of error which they are used to investigate.

The Determination of the Visual Acuity. It has been found by experiment that persons with normal sight can distinguish between objects when the angle separating them is not much less than one minute. Test type has therefore been prepared in which the letters are composed of lines which subtend this angle at the eye, when the type is placed at a standard distance of six metres. Persons who are able to read the type at this distance are said to have normal vision. Above these standard letters are placed a series of larger letters, which at two, three or four times the standard distance would subtend the standard angle. A person with reduced acuity might be able to read at six metres the type that should be read at sixty. He therefore has visual acuity one-tenth the normal. Such a person might have long-sight, short-sight or astigmatism: to determine which is present, there is placed before his eyes a lens-frame, into which can be inserted any two of a large selection of glasses of different power, which are known as trial lenses. These are tried in turn in an orderly manner, until some are found which allow the man to read the standard type at the standard distance. His visual acuity is now at the normal and the strength and shape of the glasses in front of his eyes is carefully noted, so that others of the same power may be fitted to spectacles for him to wear. If the glasses are found to be convex (plus), then he was suffering from long-sight (hypermetropia), and if concave (minus) from short-sight (myopia). Very great care must be taken in this latter case, however, not to prescribe a stronger lens than is necessary. But if, on the other hand, cylindrical lenses had to be used, then he had astigmatism, either alone or in conjunction with long- or short-sight.

The Method of Retinoscopy. Such a method as that just described could only succeed if the person tested were an intelligent adult, because we depend entirely on his giving the correct answer, when we ask if the substitution of a different lens for the one we have already placed before him makes vision better or worse. With a child such a method could never succeed. Another method is therefore practised, which has the great advantage of being independent of the patient; in fact for the purpose of the test he might be blind. This method consists in throwing, into each of his eyes in turn, a beam of light reflected from a plane mirror, in the centre of which is a hole through which the observer looks. When the beam of light is directed into the patients' eye, the observer sees through the pupil a pink reflected beam of light. As the mirror is gently tilted, so as to throw the beam slightly upwards and slightly downwards, so the pink beam appears to move up and down behind the patient's pupil. If it moves down as the mirror is tilted down, the movement is said to be WITH the mirror, and the patient is hypermetropic, requiring plus spectacles. If on the other hand the beam moves "AGAINST the mirror," minus spectacles are required, since the patient is short-sighted. By placing glasses of different power in front of his eye, until one is found which causes the pink beam to move neither with nor against the mirror, the actual power for the spectacles required by the patient is ascertained. It should be carefully noted however that, since the observer is standing at about a metre distance from the eyes of his patient, plus one D must be subtracted from the power of any glasses that are found to be necessary. Thus if the patient was found to be myopic and minus 7 D spherical lenses were required to neutralise the movement of the beam, then the power that should be ordered is minus 8 D spherical. This test is found to work admirably in practice. It is usual to paralyse the pupil reflex and the accommodation of the patient previous to the test by the use of atropine, but some say that this is unnecessary.

Other Methods. Of other methods of testing vision little need be said: some require the use of special instruments such as the optometer and the refractometer. Another again depends on the determination of both the far and near points. This is of distinct value because it at once gives the amplitude of the accommodation, which is an important determination. Others are based on the use of the ophthalmoscope. But none of these methods is so simple or accurate as the method of retinoscopy described above.

Stenopæic Aperture. Often in practice the question arises as to whether low visual acuity is due to defect in the optical media of the eye, or to disease of the retina. This question can be readily answered by placing in front of each eye in turn a metal disc in which has been drilled a hole 0·3 mm. in diameter. If this improves acuity the defect is not in the retina; if it does not, it is. This test should be done in a good light because of the small amount of light passed by the hole. A hole used in this way is called a stenopæic aperture.

Hypermetropia or Long-sight. There are two principal varieties of long-sight: firstly, that in which the eyeball is too small and too short for the normal optical system; secondly, that in which the eyeball is normal but the refracting power of the lens below the normal. The first variety is found in childhood, because the optical system reaches its adult size much earlier than does the eyeball. In the majority of children the eyeball

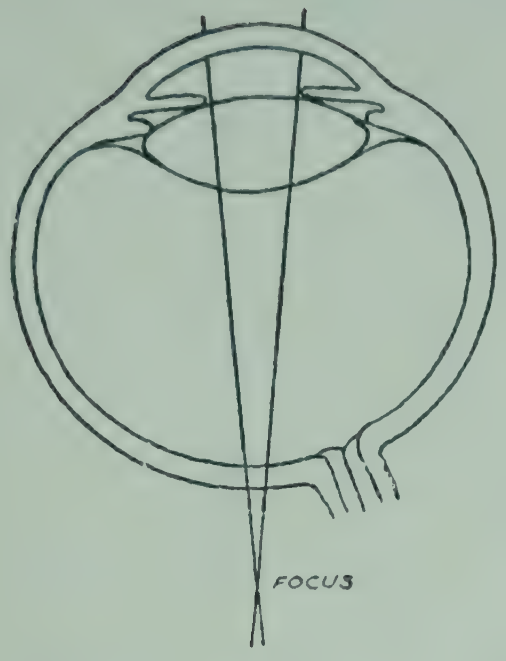

FIG. 261. Hypermetropic Eye.

The eyeball is too short, and therefore rays from a distant object come to a focus beyond the retina.

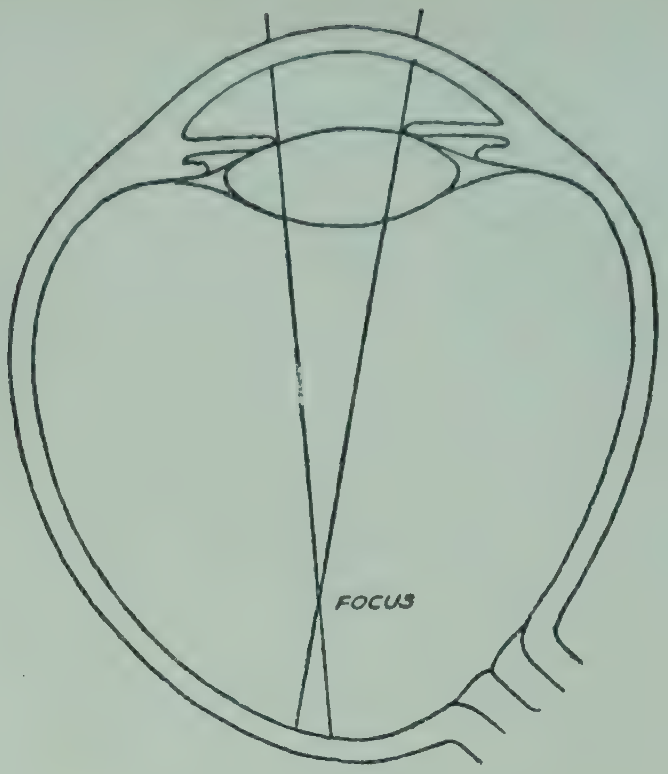

FIG. 262. Myopic Eye.

The eyeball is too long, and therefore rays from a distant object come to a focus in front of the retina.

continues to grow until it is the correct size, and therefore long-sight disappears. In a certain number of cases this does not happen, and therefore long-sight remains through life. The second variety is found in old age, and appears to be due to the absorption of water by the lens. The result in both cases is that the rays of light from distant objects are brought to a focus behind the retina, and therefore in order to focus them the accommodation has to be used (see Fig. 261). It follows from this that there is less accommodation remaining for the focussing of near objects, and therefore an inability to see distinctly at relatively short distances from the eye. Thus the use of the term long-sight.

Hypermetropia in adults is, therefore, more an abnormality than a disease; it causes a disposition, however, to three more serious conditions, namely glaucoma, internal strabismus and eye-strain. Glaucoma has already been described (see p. 383); it is due to an abnormal rise in the intraocular pressure, which occurs owing to the free escape of the aqueous humour at the filtration angle being checked. Now in hypermetropia we have seen that the eyeball is too small for its optical apparatus, and therefore the lens occupies too much of the space in the small anterior and posterior chambers. This causes the ciliary bodies and roots of the iris to be squeezed and greatly reduces the space at the filtration angle. An attack of glaucoma is therefore more liable to occur in the hypermetrope than in a person with normal refraction.

Internal strabismus is caused in hypermetropia by the accommodative effort that is made in order to focus an image on the retina because, as we have seen above (p. 374), convergence and accommodation are associated actions. When, therefore, the long-sight has been corrected by means of spectacles, and the accommodation is no longer called into play for seeing at a distance, the associated convergence no longer occurs and the strabismus disappears.

Eye-strain is caused in hypermetropia by the continual call for accommodation. Further, this must occur without convergence, for otherwise diplopia (seeing double) and strabismus develop as just described. A special strain is therefore placed not only on the ciliary muscles, but also on the external eye muscles. This state of affairs very rapidly causes fatigue, and headaches are therefore common.

The treatment of long-sight consists in prescribing suitable convex spectacles. It should be noted that the amount of long-sight actually present is shown only when

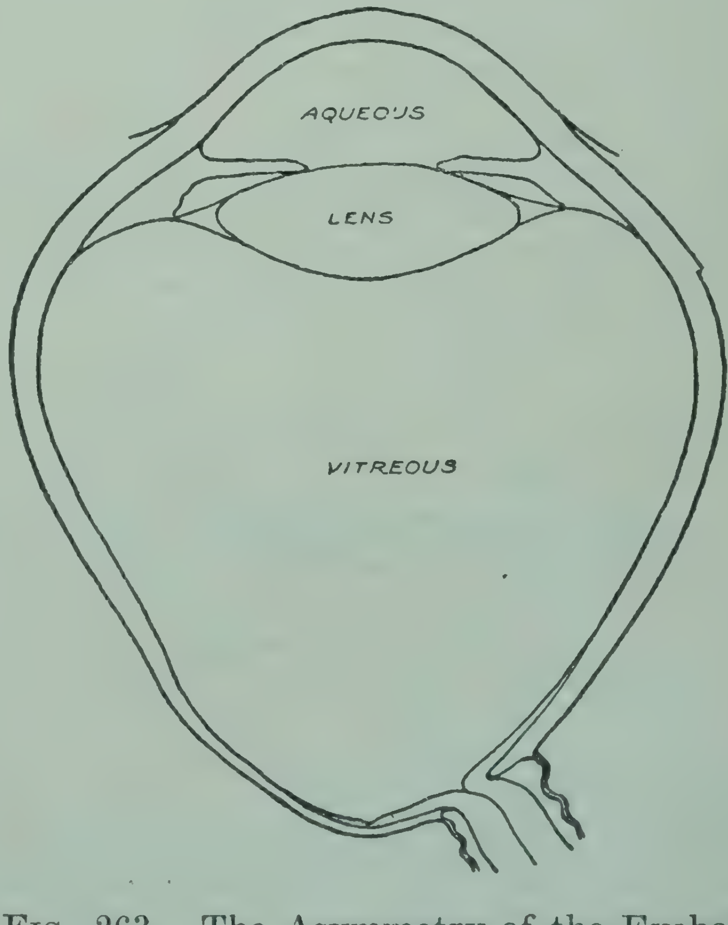

FIG. 263. The Asymmetry of the Eyeball and Kinking of the Optic Nerve caused by High Myopia.

the accommodation has been paralysed by atropine, because the patient has grown so accustomed to use his accommodation in ordinary vision that he is unable voluntarily to relax it. There is a certain amount of spasm of the accommodation. Because of this, the glasses prescribed should be less strong at first than the full correction shown to be necessary. These may be substituted by more powerful ones later.

Myopia or Short-sight. In this condition parallel rays, that is those coming from distant objects, come to a focus so far in front of the retina that the image appears blurred (see Fig. 262). Myopia may be caused in two ways, which are similar but opposite in action to those that cause hypermetropia; the first type is caused by the eyeball being too long, and the second by the refraction of the lens being too high. The former, which is the more common, usually develops in youth, particularly at the school age when the growth of the body makes special demands on the system, and at the same time feeding is usually bad. The constant use of the eyes for near work causes them considerable strain, which they are unable to withstand owing to their being unable to compete for nourishment with the rest of the body. The choroid and sclera therefore become thin, are no longer able to stand the tension set up by the intraocular pressure, and therefore expand, causing the eyeball to become larger than normal, and taking the retina beyond the focus of the optical system (Fig. 262). The treatment of myopia is therefore not only the wearing of spectacles, but the absolute prohibition of near work or close study, the administration of extra-nourishing food and an open-air life for a year or more. If these steps are taken at once, the myopia may get no worse, and may in fact get better. But if neglected the condition will almost certainly get worse. As myopia is a disease particularly liable to occur at the school age, schoolmasters and others associating with children should be on the look out for conditions likely to cause it, such as bad light, bad food and poor ventilation, and for its presence in any of the children. Glasses should always be prescribed, and care taken that the child wears them constantly, because it is found that beside assisting good definition and relieving eye-strain, they actually tend to check the further development of the trouble.

Certain complications sometimes attend myopia; these are divergent strabismus, eye-strain, and spasm of the accommodation.

The divergent strabismus has a similar origin to the convergent strabismus met with in hypermetropia, namely association of deviation of the eye axes with the adjustment of the accommodation. Now since, in the normal individual, the relaxation of the accommodation of the eye is associated with parallel axes of the eyes (in order to look at distant objects), in myopia the disuse of the accommodation for near vision causes the eye axes to remain straight and therefore produces the effects of an external strabismus. The use of glasses introduces again the necessity of accommodation, exactly as if the eye were normal, and therefore abolishes the strabismus. In the majority of cases an actual strabismus does not develop, but there is nevertheless a strong tendency to diplopia, especially when the eyes are tired. The eye-strain which frequently accompanies myopia probably has its origin in the effort to converge the eye axes without at the same time calling the accommodation into play.

Spasm of accommodation frequently accompanies myopia, and has the effect of making the myopia seem greater than it actually is. The true state of affairs is at once found when atropine is used, because the accommodation is thus abolished. Sometimes in children spasm of accommodation occurs without any actual abnormality of refraction. Such cases should be treated with the same care as those that are already developing myopia.

Astigmatism. The condition of the eye called astigmatism is one in which parallel rays are not brought to a focus in a single plane, but in a number of different planes. There are two different varieties of astigmatism. In the first, or irregular, variety the separate parts of one meridian of the eye form different foci. This is found to occur during the development of cataract in the crystalline lens, and also after ulceration of the cornea. The effects of this form of astigmatism on vision vary with the severity of the condition; in moderate cases a frequent phenomenon is the formation of a double image in the affected eye. Glasses as a rule do not give benefit. In severe types the use of a stenopæic aperture may improve definition.

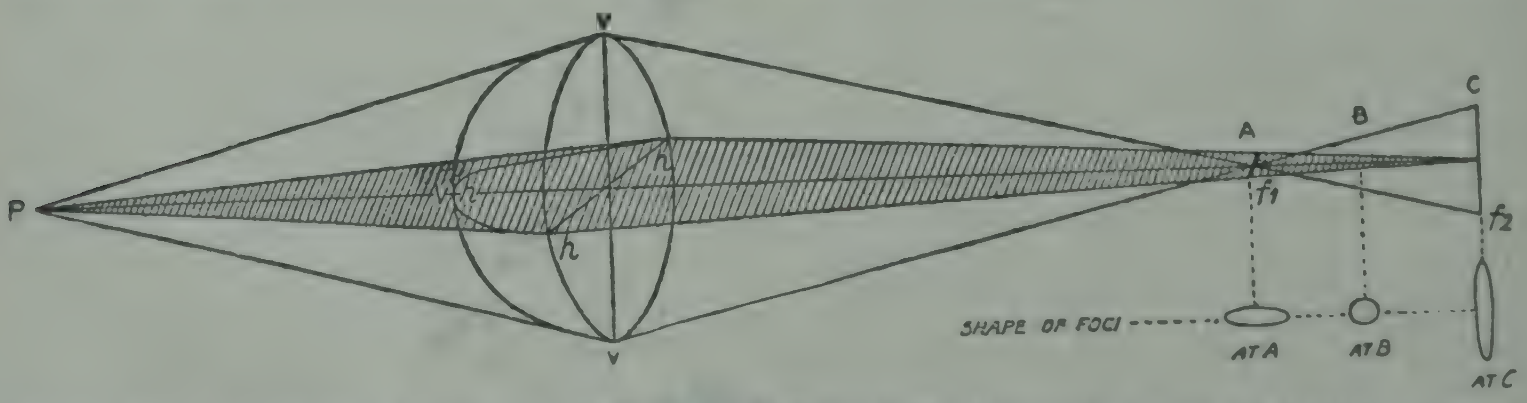

Fig. 264. Showing the Shape of Foci at different Positions in cases of Astigmatism.

In the second variety, or regular astigmatism, the parts of any one meridian give the same focus, but the different meridians have different foci (Fig. 264). There are, however, two meridians at right angles to one another, one of which has the longest and the other the shortest focus, the meridians in between showing an orderly sequence between these two extreme values. Thus the use of the term "regular astigmatism." Two types of patient are found to suffer from this condition, those who have inherited and those who have acquired it as a sequence to injury, operation or disease. The effects on vision are varied, but the characteristic features are distortion of objects looked at, and indistinctness of lines in one direction, while those at right angles are quite sharp. Headaches, eye-strain and dimness of vision are very common. Many types are met with because the maximum and minimum meridians may occupy any angle, so long as they are at right angles to one another, and there may be any accompanying degree of myopia or hypermetropia.

The diagnosis and measurement of astigmatism present no difficulties. Its existence may be readily proved by causing the patient to look at a figure consisting of a series of lines radiating from a common centre. It is then found that while some of the lines are sharp those at right angles are indistinct. This test also shows the axes of the principal meridians. By retinoscopy (see p. 396) the axes and the amounts of the abnormality in those axes may be readily determined. The treatment consists in giving spectacles which have been ground on one side to a cylindrical surface. The axis of this cylinder is adjusted to correspond with one of the principal meridians of the eye of the patient. The curve given to the cylinder is that which will cause the focus of the meridian with which it corresponds to be equal to the focus of the other meridian. The other side of the spectacle lens is ground to that spherical surface which will make the eye emmetropic after it has been corrected by the cylinder.

ANISOMETROPIA. The last abnormality of refraction which we have to consider is called anisometropia. It simply means difference between the refraction of the two eyes. The effect on vision is very slight, since it is found that as a rule one eye does all the work, and the image of the other, which is necessarily indistinct, is prevented from reaching consciousness. The result in course of time is that the unused eye loses to a considerable extent its power of seeing and as a result strabismus develops. Treatment consists in giving glasses which correct each eye separately, and then instituting exercises for the poorer eye, in order to improve its vision. The results of this treatment are good.

X-RAY MEASUREMENTS ON THE LIVING HUMAN EYE. The X-ray methods have been used recently in order to make two kinds of measurements on the living human eye: (*a*) The dimensions of the globe of the eye and (*b*) the focal length of the lens system of the eye. The methods depend on two facts, that the incidence of X-rays on the retina produce a sharply localised visual effect, and that these rays are not deflected during their transmission by the tissues. Prior to the employment of these methods it was only possible to measure the diameters of the globe of the eye after death and the focal length of the lens system of the eye was evaluated by complicated optical methods, tiring to the subject and exacting to the observer. Now, both classes of measurement can be made on living human subjects quickly and easily.

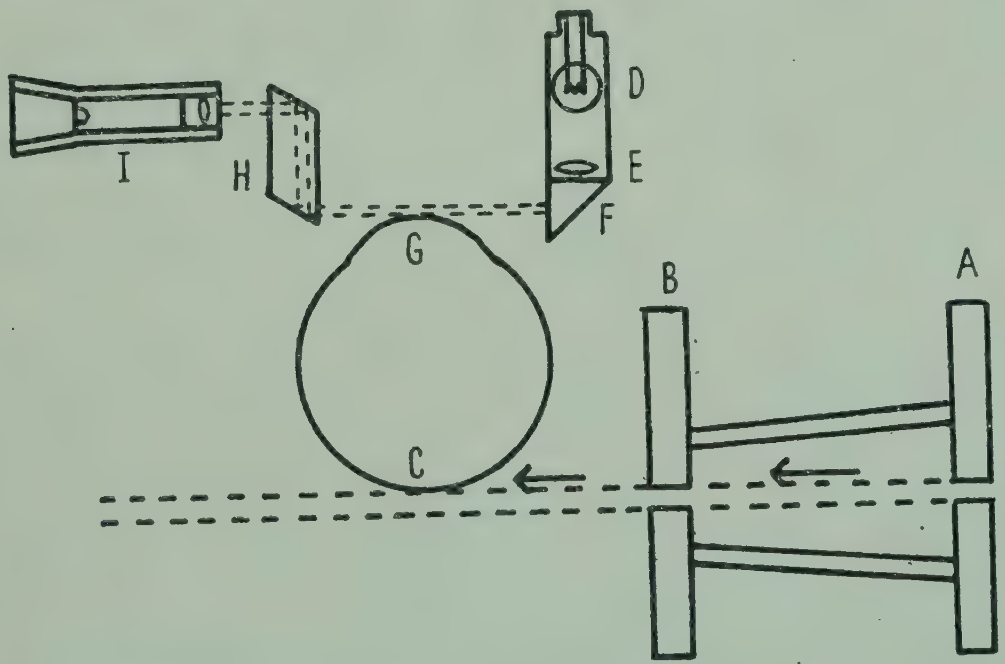

FIG. 265. The X-ray measurement of the axial length of the living human eye.

The X-ray apparatus AB is adjusted until its beam just traverses the retina at C. Light from the lamp D rendered parallel by the lens E is reflected by the prism F past the cornea and is observed by the operator through the prism H and the low power microscope I. When both X-ray apparatus and microscope apparatus have been correctly adjusted the axial length of the subject's eyeball is indicated by the distance between these two beams. (After RUSHTON, R. H., 1938, *Trans. Ophthal. Soc. U.K.*, **58,** 136.)

In order to measure the front to back dimensions of the eye Rushton used the methods illustrated diagrammatically in Fig. 265. A narrow ribbon of X-rays is caused to graze the posterior surface of the retina by adjusting the position of the apparatus relative to the patient until he sees in the dark a tiny bright disc of light. By means of a low power micrometer microscope the position of the summit of the cornea is now determined relative to the X-ray apparatus, and thus the antero-posterior length of the eye is measured.

The side to side and top to bottom dimensions are ascertained by first causing the X-ray beam to graze the retinal surface on one side and then on the other. Some measurements made by Sorsby and O'Connor using this method are shown in Table I. Myopic eyes are usually found to have greater lengths and hypermetropic eyes shorter lengths than those of emmetropes. But this is not always the case and the latter are found to vary considerably among themselves.

TABLE I

THE DIMENSIONS OF THE LIVING HUMAN EYE (SORSBY AND O'CONNOR)

Case.	X-ray measurements (mm.).			Refraction (Dioptres).	
	Transverse.	Vertical.	Axial.	Vertical.	Horizontal.
1	21·5	20·5	22·0	0	0
2	23·5	23·0	23·0	+ 1	+ 2
3	24·0	24·5	25·0	− 3·5	+ 2
4	23·5	24·0	23·0	+ 1·0	+ 1·5
5	24·5	25·0	28·0	− 16·0	− 14·5
6	24·5	23·5	24·5	0	+ 0·5

Goldmann and Hagen have used the X-ray method for the second purpose mentioned above, namely for ascertaining its focal length, or, to be precise, its posterior nodal distance. For this purpose two parallel ribbon-shaped beams of X-rays are directed towards the posterior part of the retina so that they lie one on either side of the fovea (see Fig. 266). The consequence is that the subject sees two bright lines projected into space in front of him. Two movable bright pointers are now adjusted in turn until their tips correspond to these bright lines. Now the distance apart of (*a*) the X-ray beams, and (*b*) the pointers, and (*c*) the distances of the pointers from the subject being known, the posterior nodal distance "N" may be calculated from similar triangles by means of the formula :

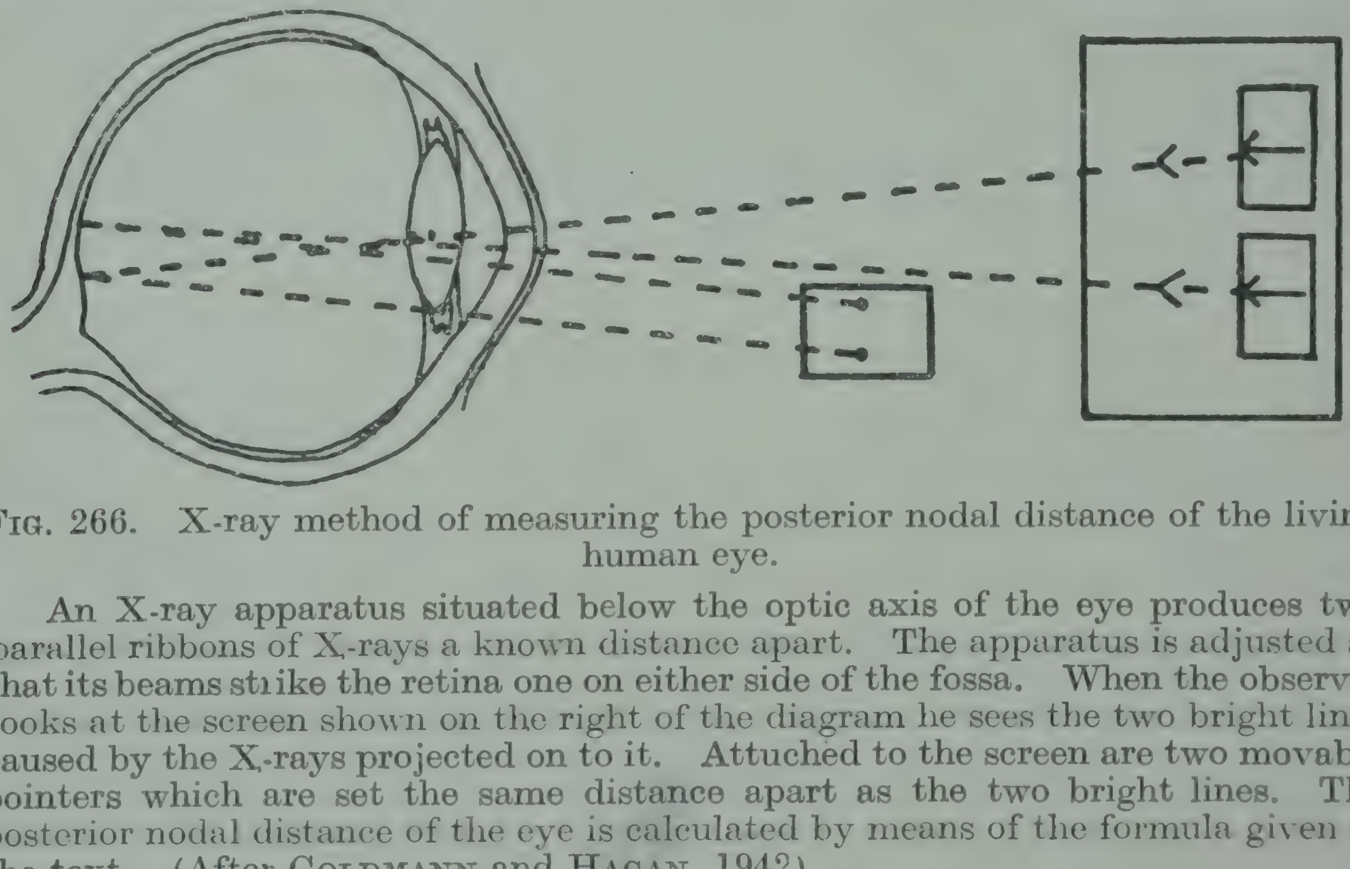

FIG. 266. X-ray method of measuring the posterior nodal distance of the living human eye.

An X-ray apparatus situated below the optic axis of the eye produces two parallel ribbons of X-rays a known distance apart. The apparatus is adjusted so that its beams strike the retina one on either side of the fossa. When the observer looks at the screen shown on the right of the diagram he sees the two bright lines caused by the X-rays projected on to it. Attached to the screen are two movable pointers which are set the same distance apart as the two bright lines. The posterior nodal distance of the eye is calculated by means of the formula given in the text. (After GOLDMANN and HAGAN, 1942).

$$N = \frac{c}{b} \times a$$

Some values obtained by Goldmann and Hagen are shown in Table III.

THE HYPOTHESES OF ABNORMAL REFRACTION. There have been three main hypotheses concerning the causes of the errors of refraction : (1) That they are largely due to errors in the length of the eyeball, a myope having too long an eyeball, and a hypermetrope having too short an eyeball ; (2) that they are caused by the chance association of two completely independent variables : the length of the eyeball and the posterior nodal distance of the lens system of the eye ; if this were true, then refractive errors would be found to fall into nine classes, as shown in Table II. (3) That emmetropia is more common than either of the above hypotheses would suggest, owing to eyeball length and posterior nodal distance undergoing similar variations. Thus an emmetrope with an eyeball of normal length has a lens system with an average posterior nodal distance, and one with a long eyeball has a long posterior nodal distance, and *vice versa*. If this hypothesis be true there must be some association between the factors which cause a long eyeball and those which cause a long posterior nodal distance, and *vice versa*.

TABLE II

Eyeball length.		Long.	Medium.	Short.

	Medium	Myope.	Emmetrope.	Hypermetrope.
	Large	Emmetrope.	Hypermetrope.	High hypermetrope.

Which of these hypotheses is the correct one ? In Table III are given some of the results obtained by Goldmann and Hagen by means of their X-ray method. The last column shows that the posterior nodal distance may vary from 14·9 to 17·83 mm. ; and therefore the first hypothesis must be incorrect. Dealing similarly with the second hypothesis, if there is completely independent variation of eyeball length and posterior nodal distance, one would expect the average values for the latter would be the same for hypermetropes, for emmetropes and for myopes. Now the average for 10 emmetropes was found to be 16·81 mm., that for 6 myopes was 17·04 mm., and that for the single hypermetrope was 14·90 mm. Now it would be greatly to the advantage of this analysis for there to be averages for many more subjects. But so far as the figures available go, the averages of the three classes vary too much for the second hypothesis to be correct. That the third hypothesis is probably correct is shown by an examination of the posterior nodal distances for the emmetropes, which varied from 15·38 mm. to 16·69 mm. ; in order that these subjects should be emmetropic it would be necessary for compensatory changes in eyeball length to occur. This idea is supported by an examination of the posterior nodal distances of the hypermetropes and the myopes, for they would have been more seriously hypermetropic and myopic, respectively, if it had not been for the existence of compensatory variations in their posterior nodal distances.

6. THE RETINA

The retina is a delicate membrane lying inside the choroid coat of the eye. Its internal surface lies in contact with the hyaloid membrane of the vitreous body. It is thus supported on both sides. The retina itself consists of two layers, the outer or pigmented, and the inner or nervous. Whereas embryologically the retina covers the whole internal surface of the eye including the ciliary processes and the iris, this is not the case with the nervous layer, because this stops near the equator of the eye at the ora serrata, and is here replaced by a layer of columnar epithelium. Opposite the pupil a yellow spot is seen on the retina, the *macula lutea*, and in the centre of this there is an oval depression, the ***fovea centralis***. The optic nerve enters the eyeball through an aperture in the sclera and choroid, and then passes through the posterior surface of the retina to spread out over the internal surface. In the fovea, however, this is not the case, for the depression at this point is caused by the absence of nerve fibres. The point at which the optic nerve enters the eye is easily recognised from inside the eyeball because the numerous white nerve fibres, as they bend over the edge of the aperture in the retina, form a characteristic white mound called the colliculus, at the centre of which is a depressed portion called the optic cup. It is in the centre of this cup that the central artery of the retina and the corresponding vein first make their appearance. These have the important function of nourishing the retina; the additional blood supply through the intimate contact between the retina and the vascular choroid, although important, is quite insufficient to supply the needs of vision, as is shown by the immediate and permanent blindness which follows blocking of the central artery of the retina.

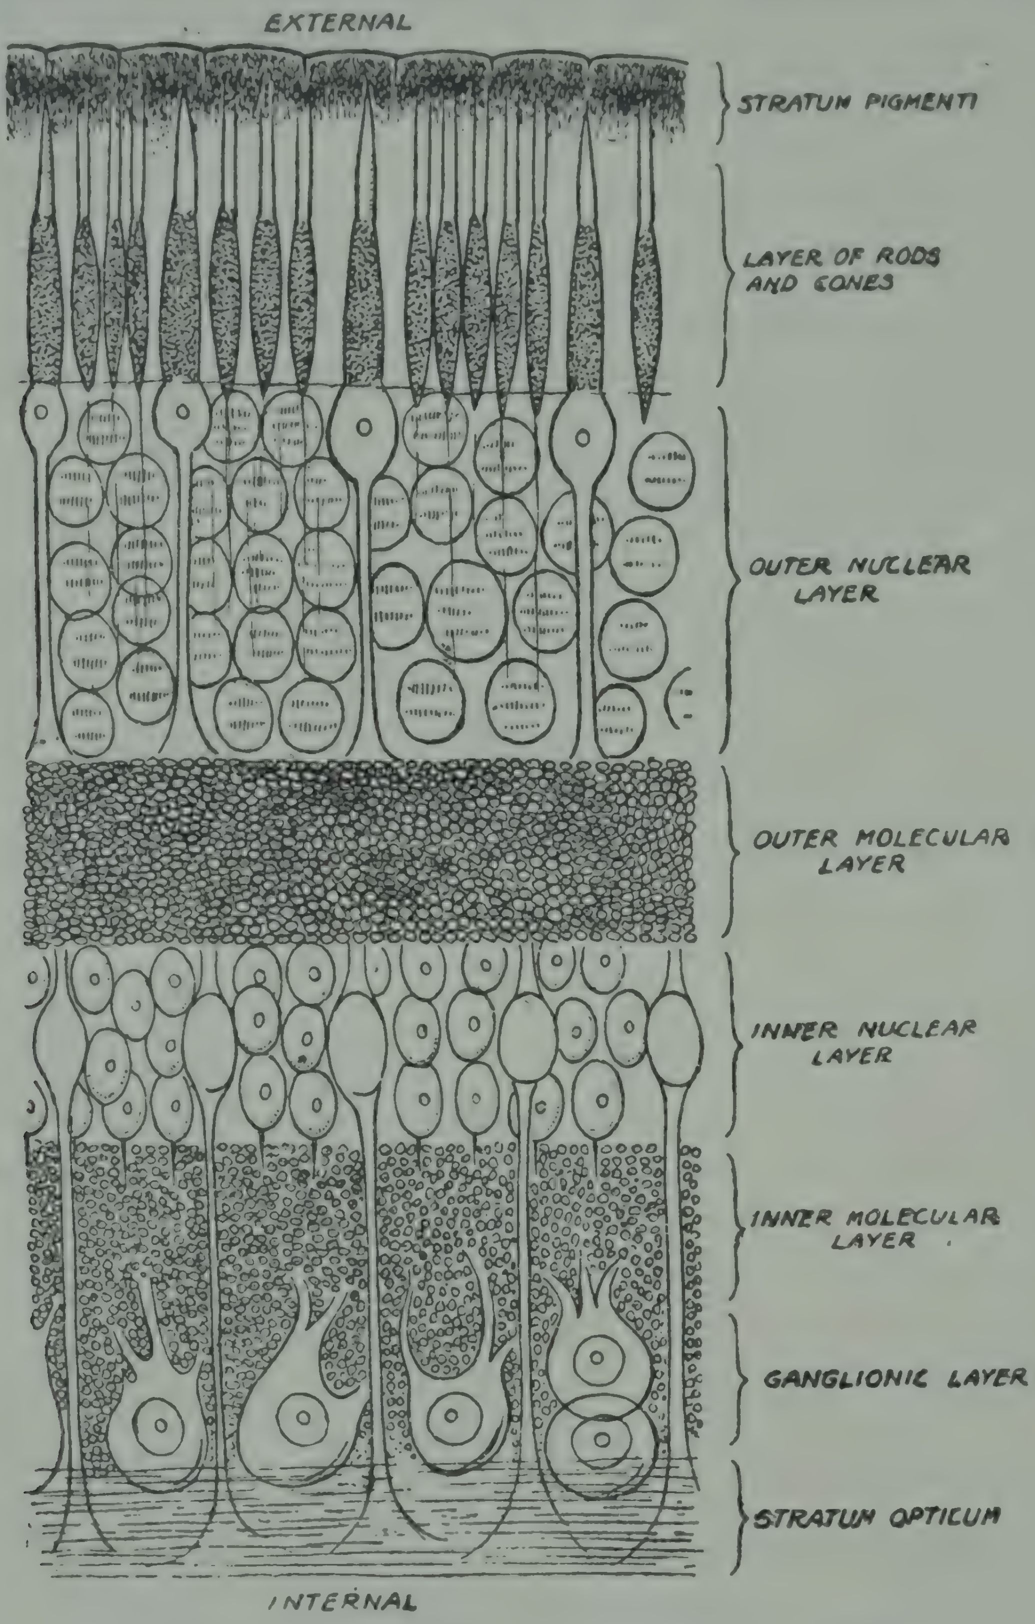

Fig. 267. Diagram of Transverse Section of Retina.

When sections of the retina are examined under the microscope it is found that they consist of the following layers from without inwards (Figs. 267 and 268):—

1. Layer of pigmented epithelium	Developed from posterior layer.
2. Layer of rods and cones (bacillary layer)	Developed from anterior layer of optic vesicle.
3. Outer nuclear or granular layer	
4. Outer molecular or plexiform layer	
5. Inner nuclear or granular layer	
6. Inner molecular or plexiform layer	
7. Layer of ganglion nerve cells	
8. Layer of nerve fibres and vessels	

In order to understand the structure of these layers, it is necessary to keep in mind the fact that the optic nerve and cup are outgrowths of part of the brain. We must therefore be prepared to find in the retina all those structures which are found in every sensory path to intervene between the sense cell and the brain nucleus. In every case the stimulus is conveyed through three sets of neurones or relays before it reaches the brain.

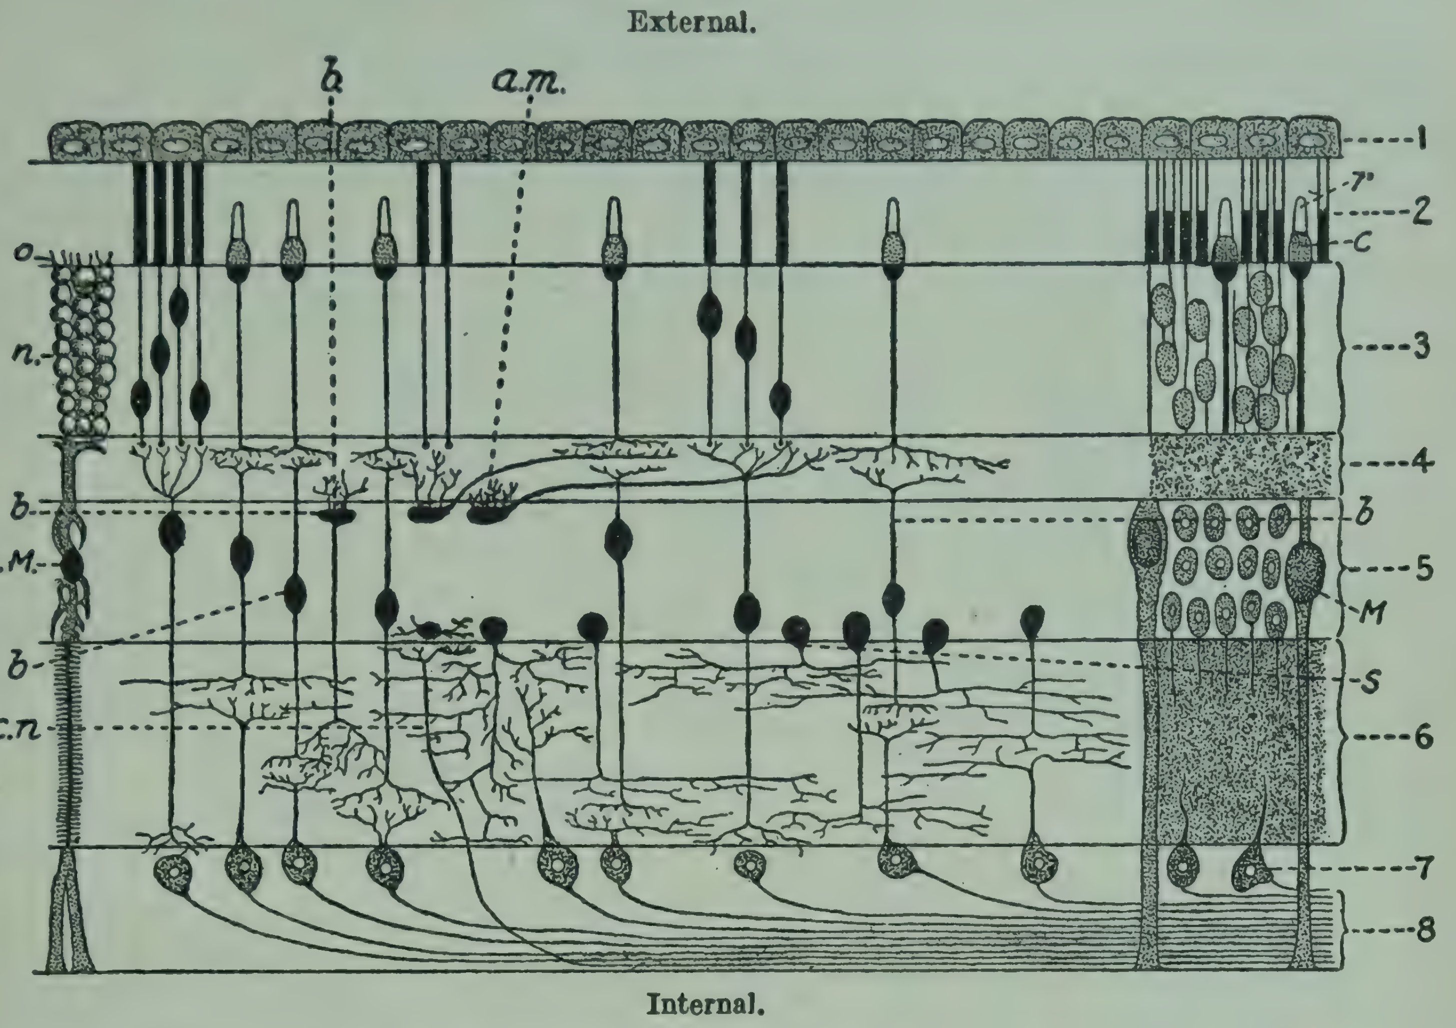

Fig. 268. Diagram to show the different Cellular Structures found in the Retina.

The Stratum Pigmenti is the only one that is developed from the external layer of the embryonic optic cup. The epithelium consists of a single layer of hexagonal nucleated cells containing numerous pigment granules. The cells send fine processes between the limbs of the rods. The bases of these cells are firmly attached to the choroid, and thus give support to the rest of the retina.

The object of these cell processes and the pigment granules which they contain would appear to be either the prevention of an image formed on one part of the retina from spreading to the sensitive elements of surrounding portions, or else the protection of these elements from excessive light action. But it has been definitely proved that the cells themselves have another and important function to perform, namely the secretion of the pigment called visual purple (rhodopsin). The important functions of this pigment will be described later.

The Bacillary Layer of rods and cones is separated from the succeeding layer by the external limiting membrane. Each rod and cone consists of an outer and inner limb, the forms of which are well shown in Fig. 269. It will be seen that the outer limbs are striated, the cones coarsely, the rods finely; they tend after hardening to break up into discs. The inner limbs of both rods and cones have a strong affinity for dyes.

The Outer Nuclear Layer consists of the cells of the first order neurones or the granules of the rods and cones. The cells are nucleated, somewhat smaller than the bipolar cells, and their nuclei are striated. They give off two processes, one of which forms dendrites in the fourth layer, the other connects with either a rod or cone as the case may be (see later).

The Outer Molecular Layer is much like the inner; it consists of the dendrites of the second order neurones and the first.

The Inner Nuclear Layer largely consists of bipolar second order neurone cells. There are, however, also present the nuclei of the horizontal cells, and also the nuclei of similar cells (amacrine cells, *a.m.*, Fig. 268), whose dendrites travel in the outer molecular layer. The bipolar cells, which are fusiform in shape and nucleated, are of three kinds: (*a*) those which connect with rods, (*b*) those which connect with cones, and (*c*) giant bipolars which connect with either.

The Inner Molecular Layer consists of a feltwork made up by the interlacing dendrites of the ganglion cells with those of the inner nuclear cells or second order neurones. There are also the dendrites of horizontal cells or spongioblasts (*s*, Fig. 268). These possibly serve to associate the impulses from different parts of the retina, such as is supposed to occur in the brain. It should be noted that they appear to be absent from the fovea and macula.

The Ganglion Cell Layer consists of a single layer of large oval cells. These are nucleated and give off the axons which we have already described, and a bunch of dendrites which ramify with others in the inner molecular layer. Only at the macula is more than one layer of ganglion cells present; this is due to their almost complete absence at the fovea. The macula therefore not only has its own relays but those of the fovea as well.

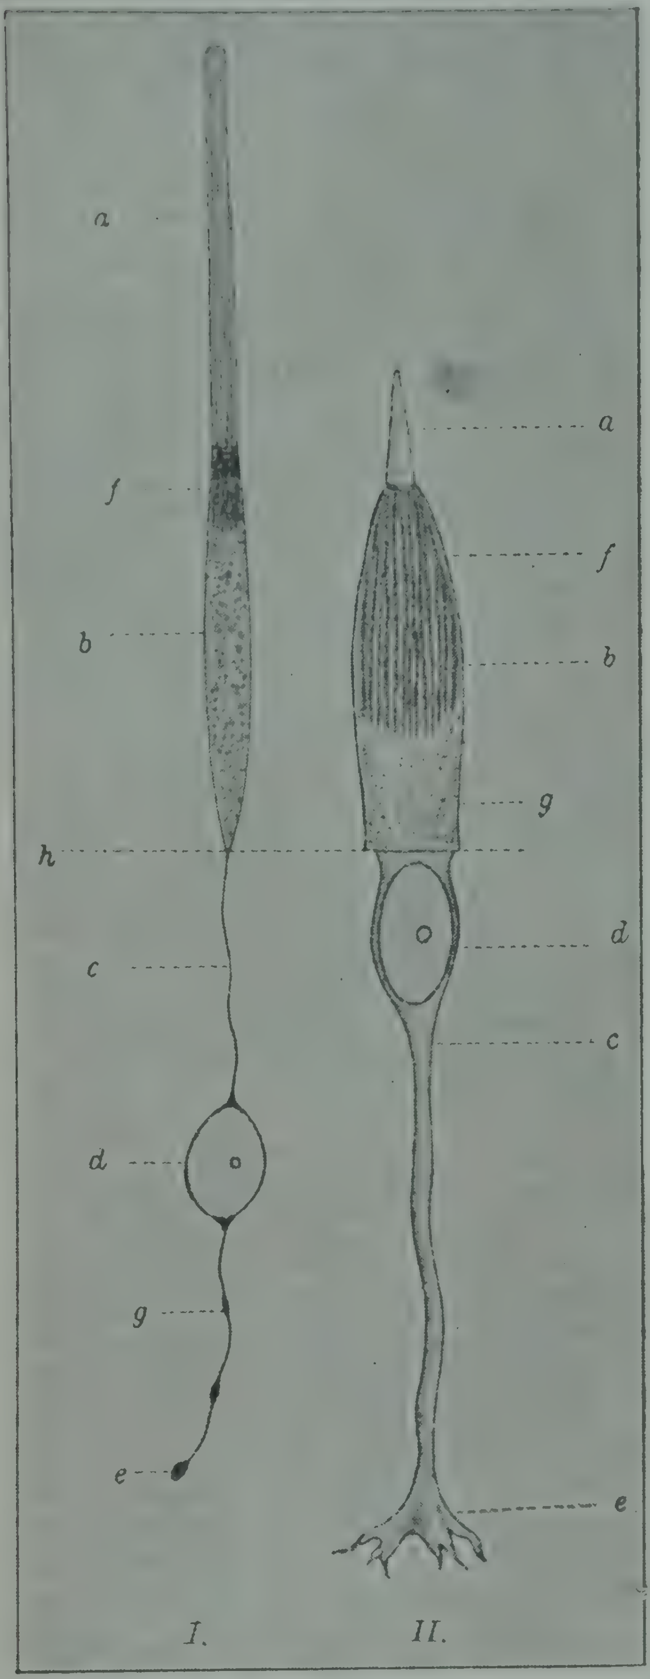

Fig. 269. (R. Greeff.)

I. A Rod.
II. A Cone of Mammalian Retina.
h. External Limiting Membrane.

The Nerve Fibre Layer (stratum opticum) consists of the non-medullated axons of the large ganglion cells found in the second layer. These axons are the third order neurones which become myelinated after they have passed out of the eyeball, and travel by paths to the calcarine cortex described on p. 287. Beside the fibres conveying visual impressions there are others which belong to the pupillomotor reflex. Others again bring impulses from the brain to the retina; their functions will be considered below.

It should be noted that beside the structures described above, which have the functional activities of the retina to perform, there are a number of connective tissue elements which form the retina into one coherent structure. Since the retina is developed from an out-growth of the brain, these structures are similar in type to those met there; we therefore find neuroglia and also long cells which extend through the first seven layers and hold them together, namely the fibres of Müller (*M.* and *n.M.*, Fig. 268).

The Different Parts of the Retina show marked variation in detail. At the fovea (Fig. 270) cones alone are found; only one of these connects to each axon. The structural peculiarities of the fovea may be summarised as follows:—(1) Absence of rods. (2) The cones are longer, more highly developed, and some say more rod-like than those found elsewhere. They are very closely packed, so that their inner limbs are seen in transverse section to have a hexagonal shape, the flat surfaces being in contact with those of their neighbours. (3) The rows of nerve cells and dendrites, which in the rest of the retina are approximately in line with the rod or cone to which they belong, are in the fovea pressed to one side in a direction away from the centre. In this way a cone may have the nerve cells to which it is connected placed at a considerable distance away in the surrounding macula. It is this displacement of the nerve fibres and their cells that causes the fovea to appear hollow. The purpose of this physiological arrangement would without question appear to be the avoidance, at this important region of the retina, of the scattering of the image which passage through the nerve cell layers would introduce. (4) The fovea, unlike the rest of the retina, is devoid of blood vessels. The purpose of this arrangement would appear to be similar to that just described. (5) Visual purple is said to be absent from the fovea. This would appear to be connected with the absence of rods.

Round the fovea is a ring in which rods and cones are present in almost equal number. In still more peripheral regions cones are relatively few, and several rods connect with each axon: this reduces the relative number of nerve fibres.

CHANGES IN THE RETINA ON EXPOSURE TO LIGHT

A light stimulus falling on the retina causes a number of changes to occur which may be classed as structural, physical, chemical and physiological.

Structural Changes occur on exposure of the eye to light: firstly, movement of the pigment from the outer epithelial layer into the spaces between the rods and cones; secondly, shortening of the cones themselves (Fig. 271). These changes occur only when the connections of the eye with the brain are intact. The rate of movement appears to vary with intensity, and violet

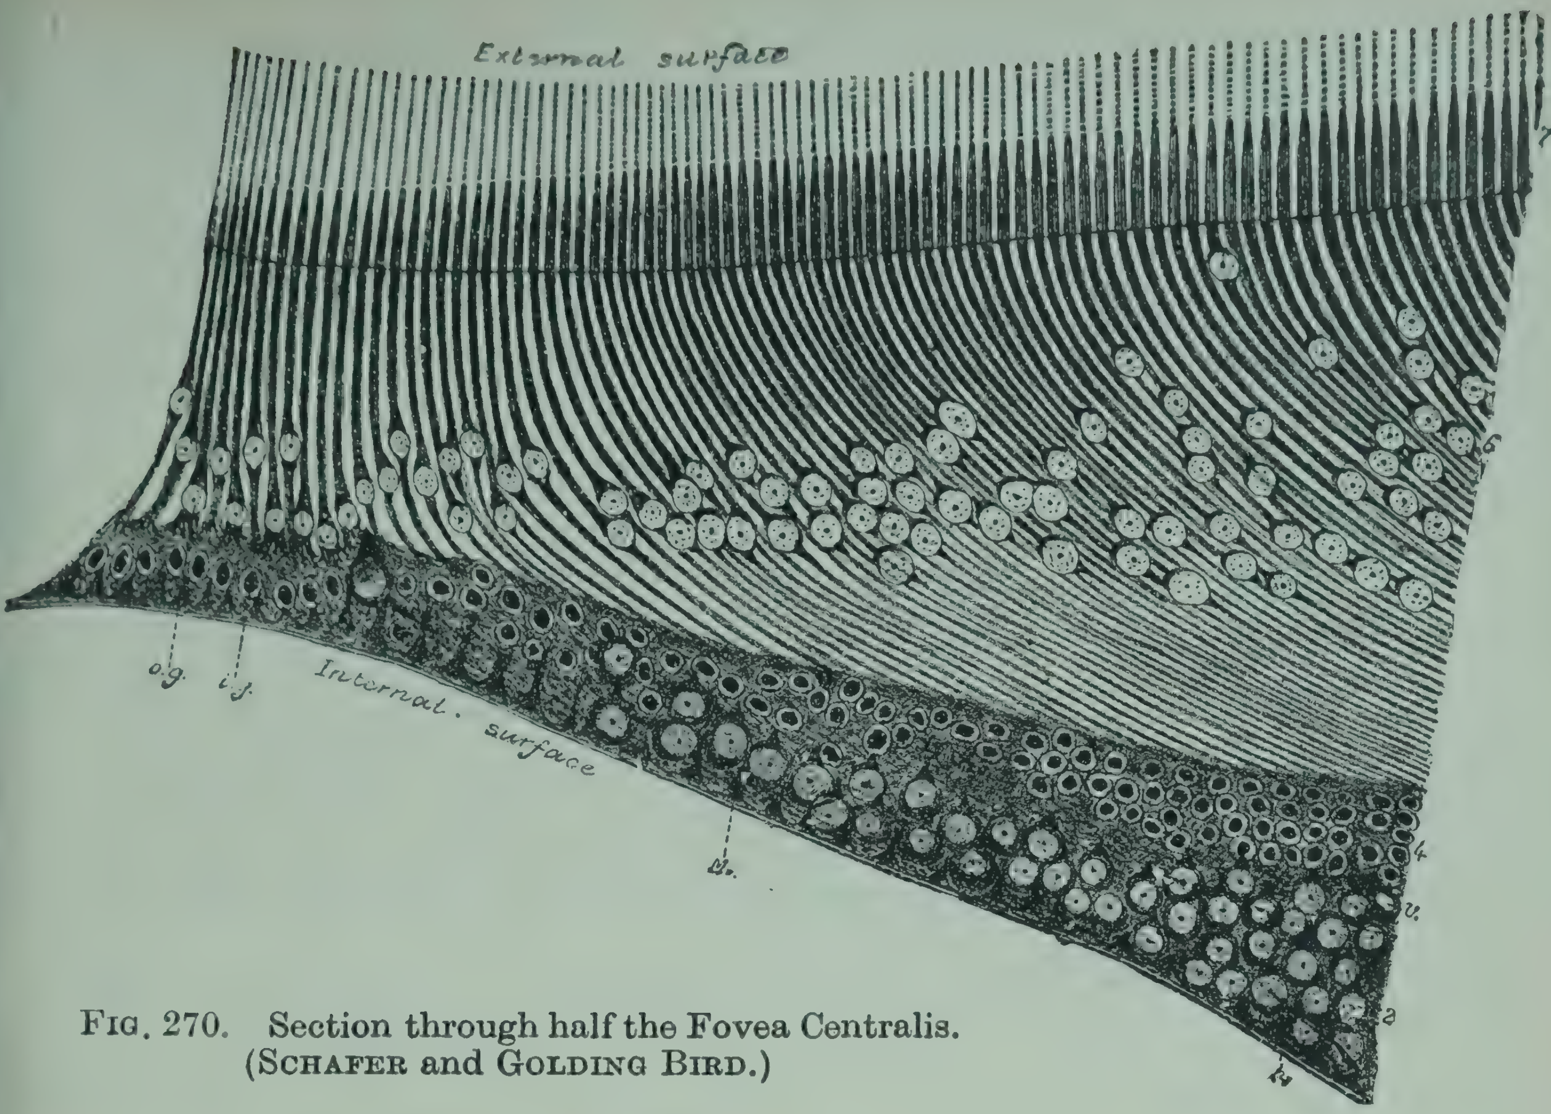

FIG. 270. Section through half the Fovea Centralis. (SCHAFER and GOLDING BIRD.)

light is said to be more effective than red. It is interesting to find that electrical stimulation of the optic nerve or the falling of light on the other retina to that of the eye observed also causes these cone movements. It is supposed that the impulses which effect these movements travel through the nerve fibres already described as descending from the brain to the retinæ; it is for this reason that Engelmann called these fibres "retinomotor."

Other structural changes that are found, by histological investigation, to follow exposure of the retina to light, are swelling of the outer limbs of the rods, and the disappearance of chromatin granules from the ganglion cells. Both these changes are said to occur more rapidly under the action of rays of short wavelength.

PHYSICAL CHANGES are also found when the retina is stimulated by light, namely an electrical response somewhat similar to the current of action in

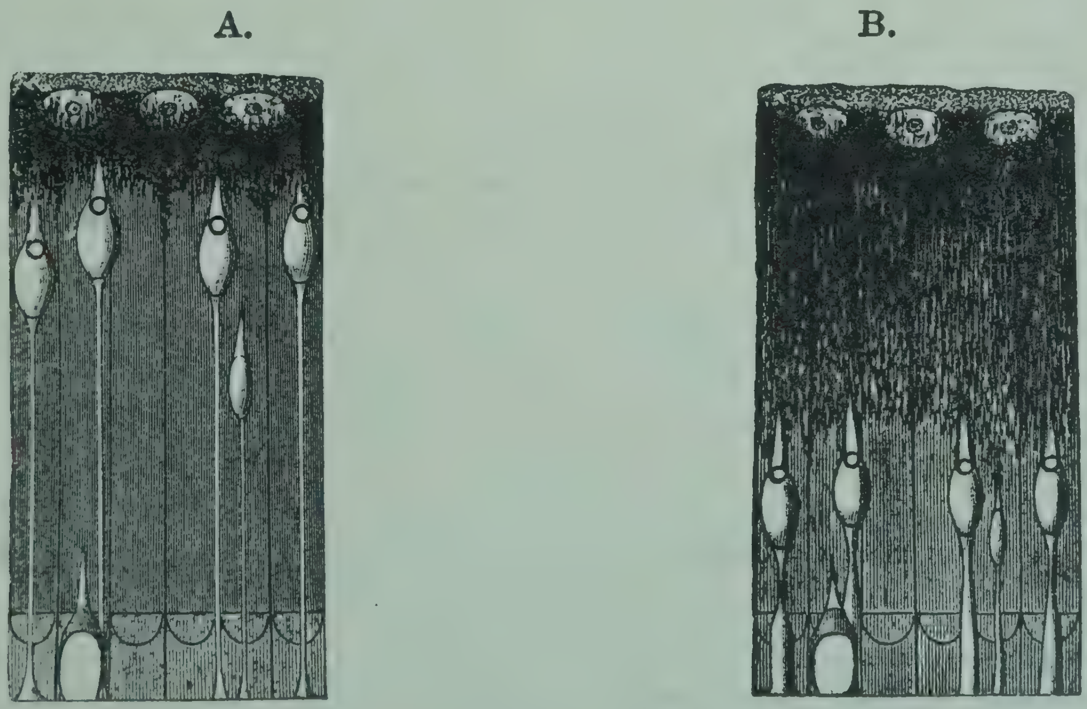

FIG. 271. Sections of the Frog's Retina.

A. Kept in the dark. B. After exposure to the light, showing retraction of the cones, and protrusion of the pigmented epithelium between the outer limbs of the rods. (ENGELMANN.)

nerve. A typical curve is shown in Fig. 272. A study of the electric response to lights of different colours and intensities has given the following results. With light of any one colour, a geometric rise of intensity causes an arithmetic increase in the current. With coloured rays of apparent equal intensity, yellow rays are said to give a larger current in the light adapted eye, and green in the dark adapted eye. It is interesting to observe that the current commences after a latent period, which is of the same order as that found for the perception of light by the eye. This and other facts mentioned above, would seem to point to the currents observed being the accompaniment of the passage of the nervous impulses to the brain.

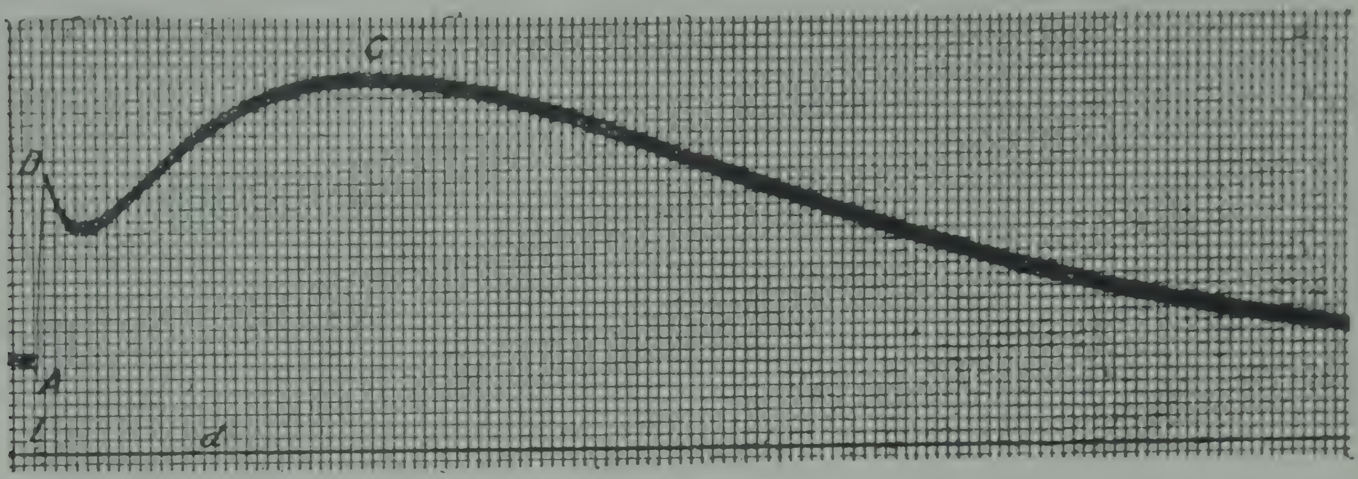

Fig. 272. Electrical Variation in Frog's Eye as recorded by the String Galvanometer. (Einthoven and Jolly.) On exposure to a single flash.

Chemical Changes in the retina on exposure to light are of two kinds: firstly a tendency of the retina as a whole to become acid in reaction, as shown in the change in its behaviour to certain stains; and secondly the bleaching of two pigments, namely the *visual purple* and *fuscin*. With regard to visual purple (or rhodopsin) a large number of facts have been made out. In the first place it is found in association with the rod retinal structures only, and is therefore absent from the human fovea centralis. It is a derivative of vitamin A, and when bleached by light liberates various products related to the carotenes.* Transient orange first appears and then indicator yellow (Lythgoe).† Bleaching on exposure to light occurs in solution as well as in the retina. According to Wald exposure to light causes visual purple to split into a yellow pigment "retinene" and a protein. Retinene on further exposure to light yields a colourless substance—visual white. When vitamin A is present in the retina the protein can combine with it to form visual purple.

The absorption of light by visual purple is greatest for the middle of the spectrum; the transmitted colour is therefore composed principally of red and violet rays.‡ Small variations of colour are found, however, in samples obtained from different animals; some are even rose-pink in colour. In the second place the most potent colours in producing bleaching are those near the centre of the spectrum, that is the rays which are most strongly absorbed. This pigment therefore obeys Draper's law, which states that those rays that are absorbed are those which produce chemical change.

It will be shown below that the retina when adapted for vision in dim light is not only colour blind, but also that the green rays of the spectrum appear to have the maximum luminosity. It will also be shown that the rod-containing parts of the retina, where visual purple is to be found, are the only regions that react to light of low intensity. Moreover, the curve which represents the rate of bleaching of visual purple by rays of different colour is very similar in shape to that which shows the visibility of lights of low intensity, as in Fig. 273. The obvious inference is that visual purple is concerned with twilight vision. Accordingly it is found that animals deprived of vitamin A, a precursor of visual purple, show deficient twilight vision (night-blindness).* When the visual purple in the retina has been bleached by exposure to light, there follows a gradual re-formation of purple, which is independent of nerve connections, but occurs only so long as the stratum pigmenti is in contact with the rod epithelial layer. If we suppose that the product formed by the bleaching of the visual purple stimulates the rod apparatus, causing it to send impulses to the brain, we have a plausible hypothesis of the mechanism for night vision. This we may briefly describe as follows :—When light falls on the retina, certain rays, particularly those near the middle of the spectrum, are absorbed by the visual purple. The pigment is bleached in proportion to the light absorbed, forming a new product : this acts on the rods, causing them to send impulses to the brain which continue so long as the light falls. When the light stops the stimulating product disappears again and therefore the stimulus to the rods ceases.

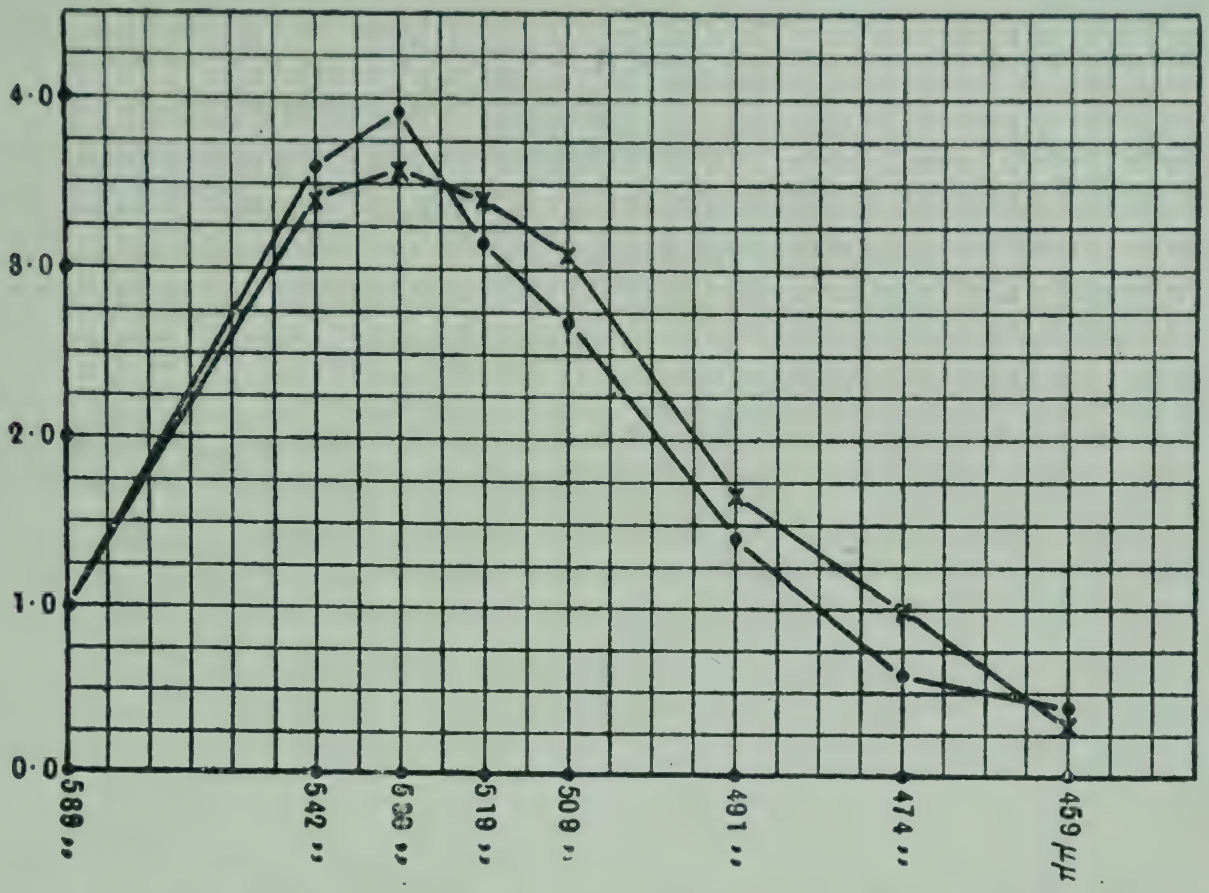

FIG. 273. Shows the Similarity between the Curve representing the Rate of Bleaching of Visual Purple by Light of different Wavelengths and the Luminosity Curve of Twilight Vision.

The work of Hecht (1920–21) is very strongly in favour of such a view. He has shown that the rate of bleaching of a solution of visual purple by light and the rate of light adaptation of the human eye both follow a logarithmic law : that is, the "reaction" in both cases appears to be one involving the splitting up of a single large molecule into components. On the other hand, the rate of dark adaptation of the human eye follows a curve similar in shape to that representing the rate of regeneration of visual purple.† Taken in conjunction these pieces of evidence point most strongly to the conclusion that a single large molecule of visual purple splits under the action of light into components, and that these when the light is removed combine again to re-form visual purple. Many analogous photochemical systems have been studied.

A picture, formed by the bleaching of the visual purple in those parts of the retina which correspond to the high lights of the image formed by the lens, can be fixed, much like a photograph, by immersing the retina in a solution of alum.

Fuscin is the pigment found in the form of needles, plates or prisms in the processes of the cells of the stratum pigmenti of the retina. The object of this pigment is apparently to absorb light, which might tend to spread from those retinal elements on which an image of a light source is falling to neighbouring ones. Some of this pigment is bleached by strong light, but so far as is known the break-down products have no visual function. The presence of other pigments has been described in the retina, such as visual yellow and the bright pigment granules found in birds. The presence of the latter is too variable for them to be considered to take any essential part in the visual mechanism.

* TANSLEY. *J. Physiol.*, 1931, **71**, 442.

† TANSLEY. *J. Physiol.*, 1931, **71**, 442 ; *Proc. Roy. Soc.*, 1933, **114B**, 79.

Physiological changes produced by light depend greatly on the region of the retina on which it falls, since this may contain rods only, cones only, both rods and cones, or neither rods nor cones. The peripheral parts of the retina contain numerous rods and very few cones. When stimulated by light of low intensity, this part of the retina is found to be exceedingly sensitive, particularly if the eyes have been closed or kept in the dark for a time. Tests with light of low intensity and of different colours show that the region is colour blind, but that rays in the middle of the spectrum are more readily appreciated than others. We have here well developed the so-called "twilight vision," which is associated with the rod-visual purple mechanism just described. Besides being very sensitive to light of low intensity, the periphery of the eye is also particularly perceptive of light of short duration. This part of the retina, therefore, appreciates movement at night very readily. Lastly, owing to the fact that a number of rods connect with one nerve fibre conveying the impulses to the brain, the periphery of the retina has a poor perception of detail.

THE FOVEA CENTRALIS is found to contain cones only. The vision in this region is therefore the antithesis of that found at the periphery. The appreciation of light of low intensity is bad, but when an image is sufficiently bright to cause stimulation, its colour is perceived. When light is poor, rapid motion is not so well observed as it is by the periphery. There is an extraordinary acuteness in perceiving fine detail. This is due to the fact that the cones in the fovea are very closely packed, so closely that they become flattened where they touch one another and thus have a hexagonal shape in transverse section. Further, each cone is connected to its own nerve fibre, so that no cyphering of the impulses can occur on the way to the brain. Experiments on visual acuity definitely show that the fineness of the detail, which the eye can perceive at the foveal region, is fully as great as that which we should expect to find, if each one acted quite independently of its neighbours. Parts of the retina around the macula lutea, since they contain both rods and cones, possess, as we should expect, both the power to perceive colour found at the fovea and the ability to react to light of low intensity, without colour vision, which is possessed by the periphery of the retina. The presence of rods scattered between the cones, however, naturally impairs to some extent the appreciation of fine detail. Rays of light which reach the fovea centralis by passing through the centre of the pupil were found by Stiles and Crawford to be more effective than rays which have passed through the periphery of the pupil. This phenomenon has been called by them the directional sensitivity of the

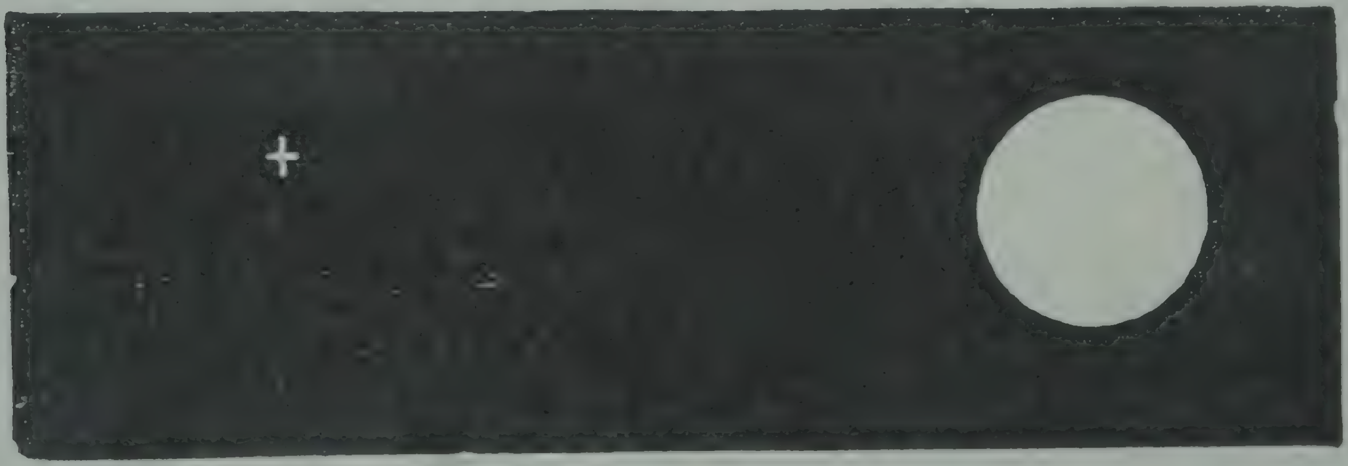

FIG. 274. Look at Cross with Right Eye, hold Book at about 10 inches.

retina. They suppose it to be due to the narrow cylindrical shape of the foveal cones (see p. 404).

At the papilla where the optic nerve enters the eye there are neither rods nor cones, and therefore, as we should expect, this region is quite blind. This fact can be readily proved by looking with the right eye at the cross in Fig. 274. If now the book be held about 10 inches from the eye the white disc will be found to disappear. By a simple calculation, it is found that the disc corresponds with the papilla of the optic nerve.

THE VISUAL FIELDS. Since the appearance of an external object will vary to a considerable extent, according to the region of the retina on which its image falls, it is a matter of considerable interest to determine the positions at which the appearances undergo change. This is also of practical value because the positions are found to be affected by disease. The determinations are usually made by means of an instrument called a *perimeter*.

This consists (Fig. 275) of a metal arm bent to the segment of a circle. This is so mounted in relationship to a horizontal bearing that the segment always has its centre in correspondence with a fixed pointer which is seen on the left of the diagram. If the eye of the patient is applied close to this pointer and looks towards the centre of the bearing, the degrees marked on the metal segment show the actual angle at which an index is situated in relationship to the eye axis, no matter in what meridian the metal segment may lie. The index mark usually consists of a disc 2 mm. in diameter, either of white or of coloured paper, according to whether the rod or cone area is to be examined.

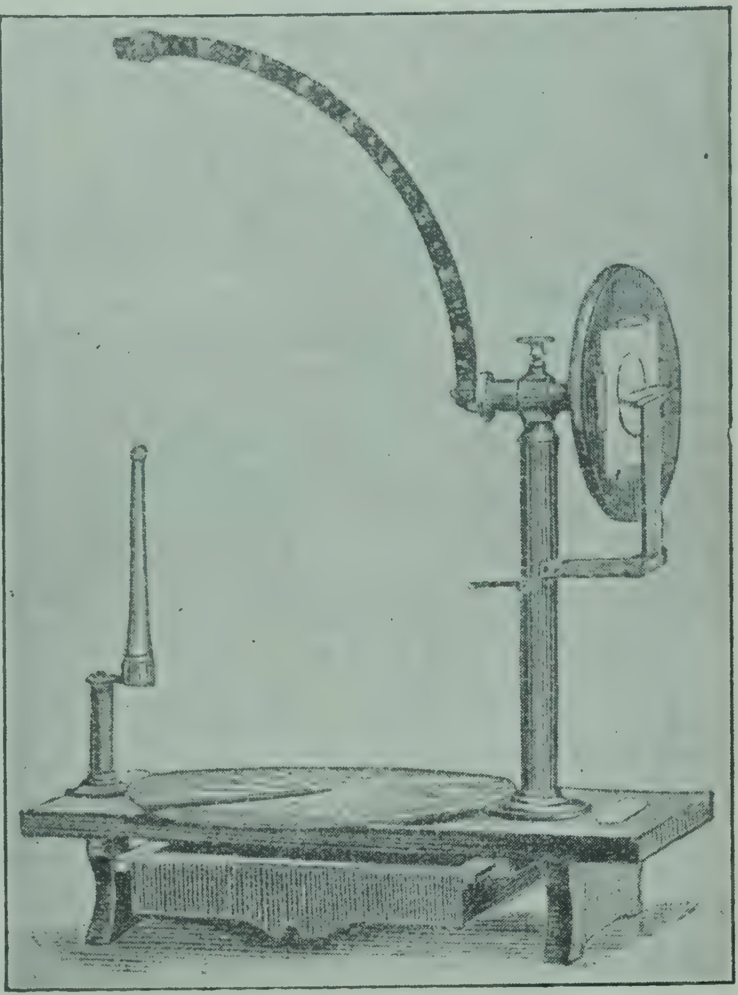

FIG. 275. Priestley Smith's Perimeter.

The results obtained by means of this instrument are shown in Fig. 276, which gives a typical curve for the right eye. The shaded area on the diagram is due to the obstruction of the eyebrow, nose and cheek of the patient. The visual field on the outer side will be seen to extend actually 14 degrees beyond the right angle. This result, which at first sight appears to be impossible, is in fact due to the considerable refraction of the light rays that occurs at the extreme edge of the cornea. The direction of the beam of light entering the eye under these circumstances is shown in Fig. 277, X.

It will be observed that, even when looking straight in front, a man can see to a considerable angle behind himself. By deviating the eyes only slightly to either side, this angle can be increased to 40 degrees in the average case, as shown at Fig. 277, Z. This ability to see to a considerable extent behind him is due to the narrowness of the head between the frontal processes and zygomatic bones. In those animals in which the eyes are placed on the sides of the head, and the visual axes are diametrically opposite to one another, the visual fields will actually overlap a short distance from the head, so that there will be no direction from which an enemy can attack without being observed (Fig. 277, Y).

UTILITY OF PERIPHERAL VISION. The high visual acuity of the fovea, and the great facility with which the eyes can be directed so that images form on this region, might raise the question as to the utility of peripheral vision. This question may be investigated experimentally by placing restricting screens in front of the eyes, or by ascertaining the experience of persons who are suffering from blindness in the periphery as the result of disease, *e.g.* retinitis pigmentosa. Both methods show that the periphery is of great value in

directing attention to outlying objects. Our attention being excited, we direct the gaze in the direction indicated, in order to bring into action the greater power of analysis of the fovea.

Central Connections of the Retina. The nerve paths by which the retina, itself a part of the central nervous system, connects with other parts of the central nervous system has been considered in detail (see p. 287). Briefly the optic nerves from the two retinæ converge and join at the chiasma. These fibres from the nasal halves of both retinæ cross, so that the optic tracts which convey the impulses from the chiasma to their destinations contain fibres which have come from the same side of the retinæ as that to which they themselves belong. The right-hand tract has fibres from the right-hand halves of both retinæ. The fibres pass chiefly to the calcarine region of the cerebral cortex *viâ* the lowest part of the optic thalamus and the most posterior part of the corona radiata for the sense of sight. But some pass *viâ* the superior corpora quadrigemina to the nuclei of the oculomotor nerves, thus causing reflex eye movements.

THE OPHTHALMOSCOPE. If the retina of a patient be illuminated by causing a beam of light to enter the pupil, the reflected light will cause the interior surface of the retina to be visible. In order to see the image distinctly, it is necessary either that both the eye of the patient and also that of the observer should be focussed for infinity (the direct method) or that both eyes should be focussed for one and the same intermediate plane (the indirect method). Both methods should be practised, since the indirect method gives a low magnification while the direct method gives a high one. The indirect method is carried out as follows :—A bright source of light having been placed behind and slightly to one side of the patient, the observer standing about half a metre in front of him reflects by means of a concave mirror an image of the light into his pupil. At the centre of the mirror is an aperture through which he sees the light which is reflected back from the patient's retina. The observer now holds a biconvex lens of about 6 cm. focal length about 8 cm. in front of the patient's eye, while he still directs the beam of light into the pupil as before. The image of the retina, which would normally be focussed by the lens system of the patient's eye at infinity, is now brought to a focus by the convex lens, forming what is called an aerial image (see Fig. 278). It is this image that the observer sees (Fig. 279) and in it are shown all the particular features of the vessels and nerves of the patient's retina. Beside its very great utility to the oculist, the ophthalmoscope is a very valuable instrument to the physician, for retinal vessels and nerves frequently show the evidences of constitutional disease, which are of great assistance to diagnosis. Ophthalmoscopes are usually fitted with a number of small lenses of graduated power, which may be introduced as required behind the mirror. For the indirect method they are seldom required. The magnification of the retina given by the indirect method is usually about 3, while that provided by the direct is 12. If a higher magnification is an advantage it may be obtained by the above method by using a biconvex lens of longer focal length (say 12 cm.).

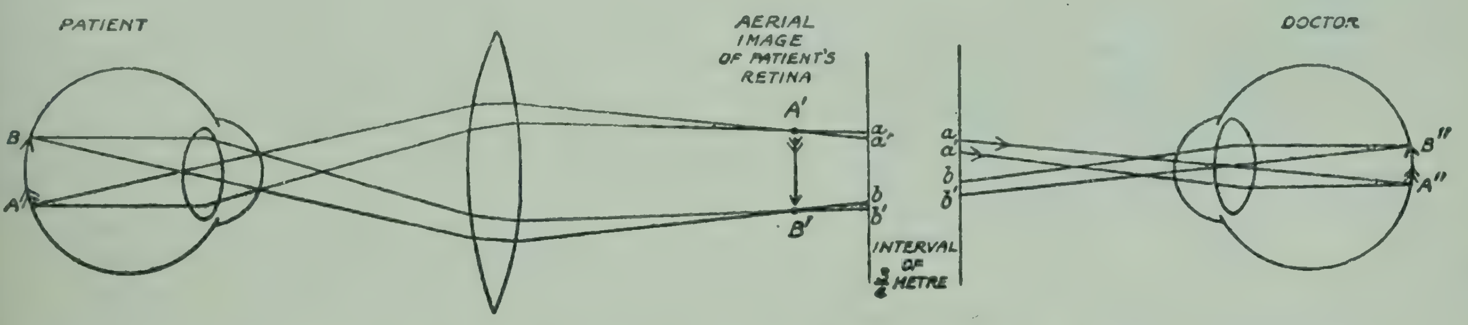

Fig. 278. Diagram to show Paths of Rays from Eye of Patient to Observer when the Indirect Method of Ophthalmoscopy is in use. (Hartridge.)

The image seen by the direct method is erect, that by the indirect is inverted.

On examining the back of the eyeball by either of these methods, the most prominent object is the optic disc or optic nerve papilla, which marks the point of entrance of the optic nerve. It is seen as a pale oval disc surrounded by a deep red background (Fig. 279). From the middle of the papilla the retinal vessels pass into the eyeball, and they are seen diverging from the papilla to ramify over the rest of the retina. The arteries can be distinguished from the veins by their brighter red colour as well as by the stronger reflection of light from their surfaces. The yellow spot is very difficult to see, except in atropinised eyes, since it comes into view only when the observed eye is looking straight into the ophthalmoscope. Under these conditions there is a strong "light reflex," and the pupil contracts up to a pin-point, unless paralysed by means of atropine. In order to see the blind spot, or optic disc, the observed eye must be directed inwards; thus if A is looking at the right eye of B, B must be told to look over A's right shoulder.

By projecting a highly concentrated beam of light on to the side of the eyeball, it is possible to cause sufficient light to pass through the wall for the retina to perceive the stimulus. When that is the case, it is found that the retinal arteries and veins are seen by the subject as dark images on a bright ground (Purkinje's figures). By moving the point of illumination and then measuring the apparent shift of the vessels which occurs, it has been found possible to estimate the depth below the vessels at which the receptive surface of the retina is placed, namely 0·17 to 0·36 mm. Now the average distance between the vessels and the layer of rods and cones is found to be 0·2 to 0·3 mm.; it must therefore be the layer of rods and cones which forms the sensitive layer. The directions taken by the light rays are shown in Fig. 280.

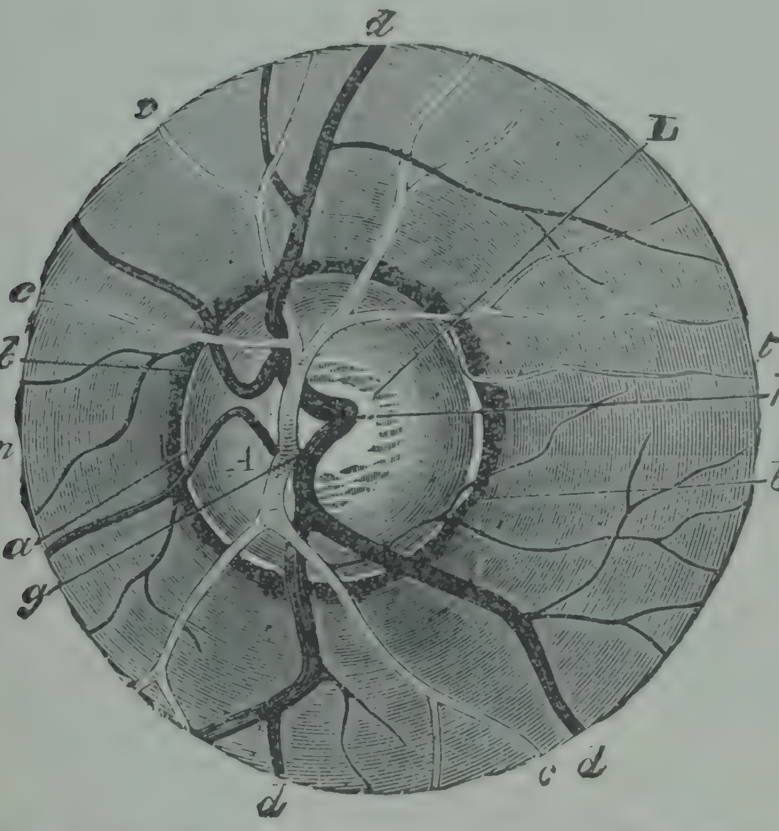

Fig. 279. Ophthalmoscopic View of Fundus of Eye, showing the Optic Disc, or point of entry of the Optic Nerve, with the Retinal Vessels branching from its centre.

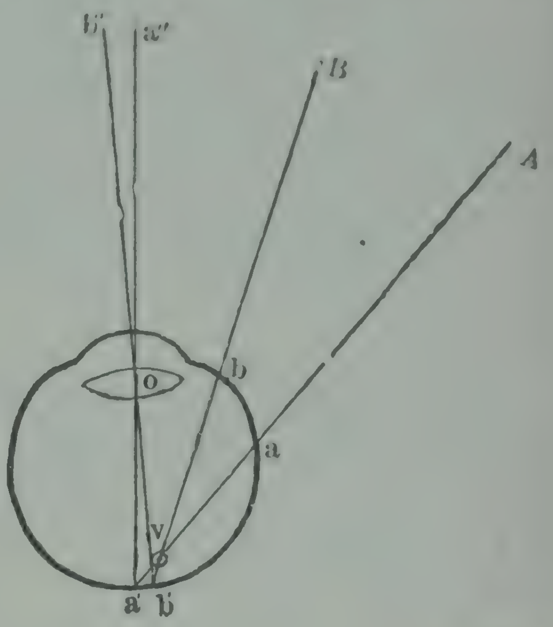

Fig. 280. Diagram of the Path of the Rays of Light in the Formation of Purkinje's Figures.

v represents a retinal vessel. When this is illuminated from A, a shadow is formed on the hinder layers of the retina at a′. This is projected along a line passing through the optic axis, and appears to come from a point (a″) on the wall. On moving the light from A to B, the image of the vessel appears to move from a″ to b″.

Another method of viewing the vessels in one's own eye is to look through a small hole in a metal plate at a smooth white surface. On oscillating the aperture in relationship with the pupil about once a second, the vessels will be seen as shadows on the bright background.

7. THE RELATIONSHIP BETWEEN STIMULUS AND SENSATION

Since we are unable to express our sensations in terms of physical units (we cannot say, for example, when one source is twice as bright as another), two methods of investigation are alone available, namely that which involves the determination of threshold values, and that which depends on the making of comparisons.

In order that a source of light shall be perceived, the image which is formed on the retina must have certain properties. In the first place, it must last for a certain finite time, for if it be of shorter duration than this it will not be perceived. Secondly, it must be larger than a certain size. Thirdly, its intensity must be greater than a certain limiting quantity. Fourthly, the rays it emits must have wavelengths which lie between certain limits. So that in the case of each of these four properties there are limiting values which must be exceeded; these values are called thresholds. The retina has, distributed over its surface, two different types of sensitive organ: the cone apparatus, which has the function of perceiving colours and is used in day vision; and the rod-visual purple apparatus, which is colour blind but very sensitive to light of low intensity and therefore used for twilight vision. Owing to the fact that the distribution of these organs is not uniform, we have to state the part of the retina which is being stimulated, when assigning a value to any of the above-mentioned thresholds. For example, the threshold for intensity may be that which just actuates the rods, that is the achromatic limit, or that which is sufficient to affect the cones and therefore causes an appreciation of colour. Moreover, the value of any one threshold is to a considerable extent controlled by the value of the other factors which have been mentioned ; for example, the time threshold is shorter the greater the size and intensity of the light source. The exact conditions must therefore be carefully stated in quoting the value of a threshold. Lastly, we must consider the personal equation of the observer, and also the state of his vision, for both are affected to an important extent by constitution, health, fatigue, etc.

Intensity Threshold for Light (Achromatic). If a spectrum be gradually reduced in intensity, it loses its colour and finally appears to the eye as a bright band which has its greatest luminosity in the green region of the spectrum and gradually fades towards both the red and violet ends. Since the band is colourless, any one part may be matched by any other part by suitably adjusting the intensities. But compared with the appearance under ordinary intensity, the red region of the spectrum has become greatly reduced in visibility, while the blue has become relatively brighter. The part of the spectrum with maximum luminosity is found to be the yellow when the intensity is high, but to be the green when it is low. It is therefore this shifting of the position of the maximum in the spectrum which has caused red to darken and blue to become lighter. The relative forms and positions of the luminosity (apparent brightness) curves for spectra of various intensities are shown in Fig. 281. If the spectrum of low intensity be still further decreased, a point will be reached at which the different parts become invisible to the eye ; this will occur first

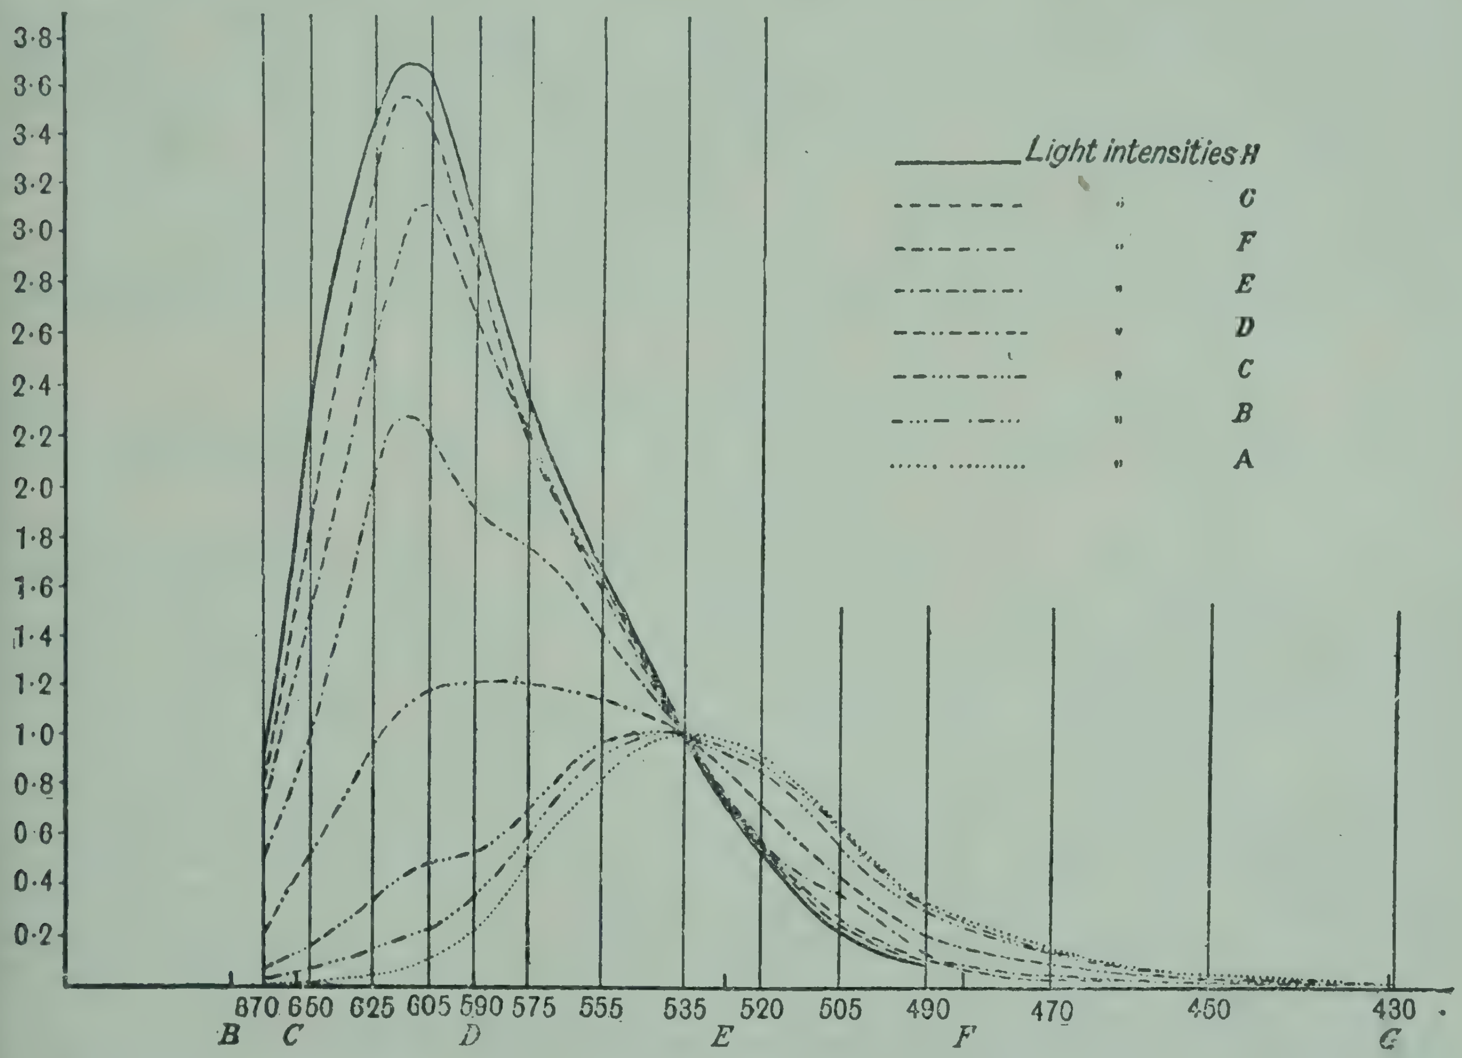

FIG. 281. Luminosity Curves for Spectra of different Intensity. (KÖNIG.)

H=highest ; A=lowest ; Abscissæ=wavelengths ; Ordinates=luminosities. The maximum of curve for light of high intensity is seen to be at 610 $\mu\mu$, that at low intensity 535 $\mu\mu$.

with the ends, and last with the middle (at about 5271 A.U.). It is found, however, that the intensity values at which visibility ceases decrease the longer the eye is kept in the dark—that is to say, the retina gradually becomes " dark adapted." The curves obtained for different degrees of dark adaptation are also shown in Fig. 281.

We must now consider the effects on the achromatic threshold, of size of light source, duration of stimulus and part of retina illuminated. With regard to size, experiment shows that, as the size of the source decreases, so the intensity at which extinction occurs increases, in fact that the area of the source multiplied by its intensity is a constant. With regard to the region of the retina that is stimulated, it is found that the rod-visual purple apparatus is responsible for the appreciation of the light of low intensity ; it is therefore found in all parts of the retina other than the fovea centralis from which rods are absent. The effect of time of stimulus will be considered shortly.

The Directional Sensitivity of the Retina. Stiles and Crawford found that a ray of light reaching the fovea through the centre of the pupil causes a greater stimulating effect than a ray which has reached the fovea through a more peripheral part of the pupil. This effect is not caused by the lens system of the eye and must therefore be due to a property of the retina. Recently Stiles (1939) has repeated the above test using light of different wavelengths and working with both the fovea and the periphery (extra fovea). Some of his results are given in the following table, which gives the light intensities which must be employed in order that a beam of light through the periphery of the pupil shall be as bright to the retina as one passing through the centre of the pupil.

		Nasal Side by			Centre of Pupil.	Temporal Side by		
		3 mm.	2 mm.	1 mm.		1 mm.	2 mm.	3 mm.
Fovea (light or dark adapted)	Red	4·8	2·7	1·5	1·0	0·9	1·1	1·6
	Yellow	3·8	2·3	1·4	1·0	0·9	1·0	1·4
	Green	4·7	2·6	1·4	1·0	0·9	1·1	1·7
	Blue	5·2	3·2	1·5	1·0	0·9	1·1	1·8
Periphery (Para-fovea) (light adapted)	Red	3·8	1·9	1·2	1·0	1·1	1·6	3·0
	Yellow	2·9	1·6	1·1	1·0	1·2	1·7	3·2
	Green	2·8	1·6	1·2	1·0	1·1	1·6	2·6
	Blue	2·8	1·6	1·2	1·0	1·1	1·6	2·6
Periphery (Para-fovea) (dark adapted)	Red	2·9	1·9	1·2	1·0	1·0	1·4	2·3
	Yellow	1·3	1·1	1·0	1·0	1·0	1·1	1·3
	Green	1·0	1·0	1·0	1·0	1·0	1·0	1·0
	Blue	0·9	0·9	1·0	1·0	1·0	1·0	0·9

Thus if two beams of red light fall on the fovea, one through the centre of the pupil, the other through the periphery of the pupil 3 mm. to the nasal side of the centre of the pupil, then for the beams to appear equally bright the peripheral beam must have 4·8 times the intensity of the central one. The conclusion is that light falling obliquely on the retina is less effective than light falling at right angles to the retinal surface.

Intensity Threshold for Colour. If a spectrum of low intensity, which appears colourless to the eye, be gradually increased in brightness, a point will be reached at which the colours begin to be recognisable, first yellow and green, then blue and lastly red and violet. If the intensity at which the colour just vanishes is measured, the curve obtained is similar to that shown in Fig. 282. As the intensity is increased, the point of maximum luminosity gradually shifts from the green to the yellow. As light is gradually increased in intensity, an object is first seen without colour, but on further increase the colour also is recognised; this is called the photo-chromatic interval. It follows from what we have said that the interval is greatest for colours of short wavelength (blue) and least for long (red) (the Purkinje phenomenon). The thresholds for light and colour differ in another important respect: whereas that of light varies with the degree of dark adaptation, that of colour is found by experiment to be nearly constant. With regard to the effect of area of light source, it is found that the same type of relationship exists in the case of colour as for light: that as the area is diminished, so the intensity must be correspondingly increased. The area and intensity, multiplied together, do not, however, equal a constant as they do in the case of light. The appreciation of colour is associated with the cones and is therefore most highly developed at the fovea. As the periphery of the retina is approached, the number of the cones very rapidly decreases, and we should therefore expect to find a limit to the size of the visual field for different colours. This may be tested by means of the perimeter (Fig. 275) and small coloured discs, or more accurately by suitable apparatus for employing spectral colours. By these methods it is found that the colour fields are smaller than those for light, but more or less concentric with them (Fig. 276). The actual size of the fields varies with the intensity and size of the test light source or object. The order in which the colours disappear varies somewhat, but appears to be usually as follows:—First green, then yellow, then red, and lastly blue. The determination of the size of the colour fields is a technique of considerable practical importance, because they are found to become restricted in those progressive lesions of the optic nerves which may finally lead to total blindness, and also in inflammatory conditions of the retina and choroid. Careful examination of the apparent limits of the blind spot by means of similar apparatus was found by Haycraft to show that there is a similar variation in the relative sizes of the fields for different colours (Fig. 283). The same phenomenon is also found round the blind spots formed in the retina by disease.

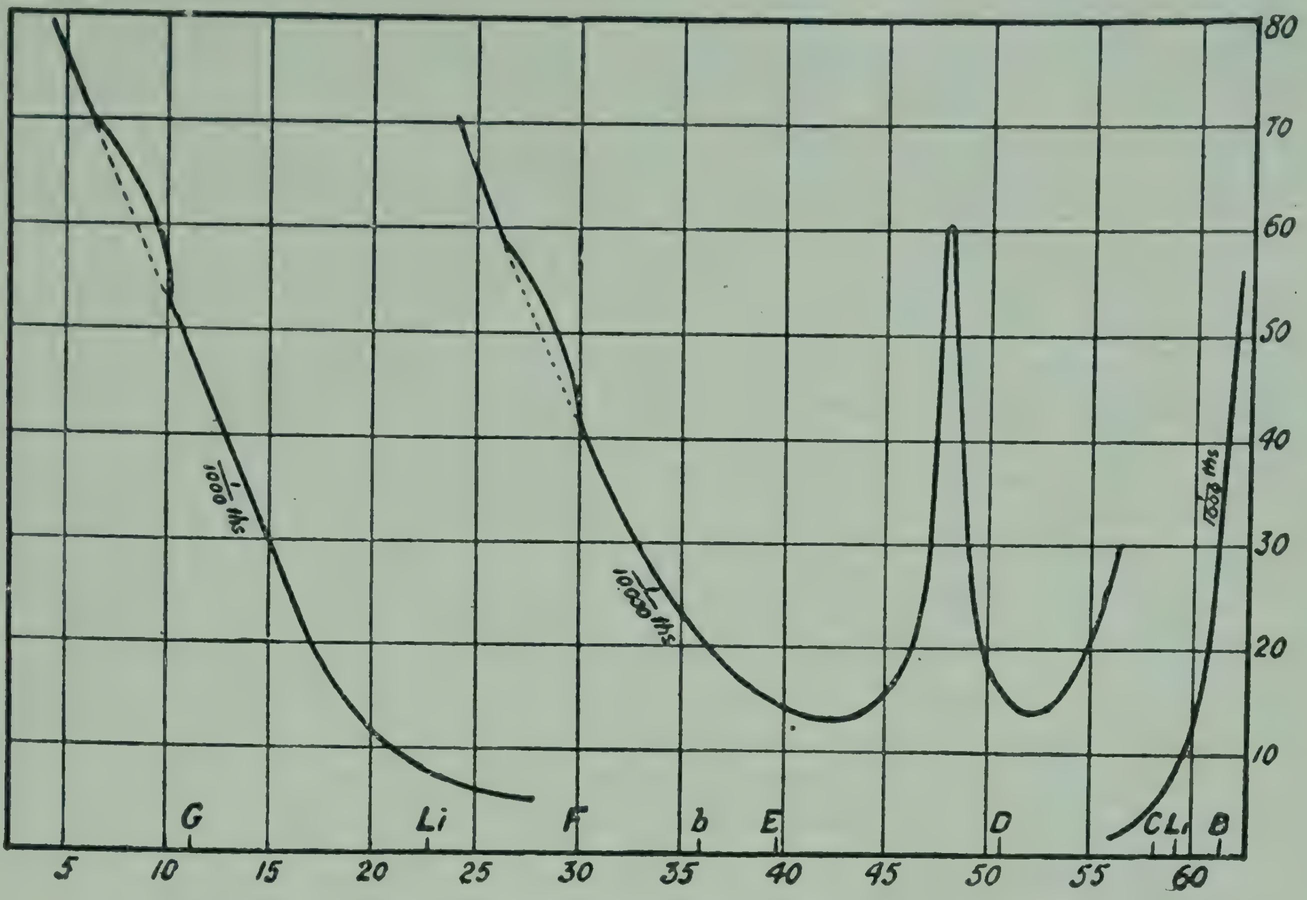

FIG. 282. "Extinction of Colour" Curve. (ABNEY.)
Abscissæ = wavelengths; Ordinates = intensity in candle feet when colour just vanishes.

Size Threshold or Visual Acuity. If a small source of light be gradually reduced in size, a point is soon reached at which it becomes invisible. If it is a coloured source, it as a rule shows a well-marked photochromatic interval, that is, it first loses its colour and then disappears later.

If the intensity of the source is very great, the size has to be much reduced before it becomes invisible: it is because of this that we see the stars. If the size and intensity at the point of disappearance be measured, it is found that when multiplied together they give a constant, so that as in the case of the light threshold, the determining factor appears to be the amount of light which falls on the retina. In the case of intermittent illumination a similar relationship is found.

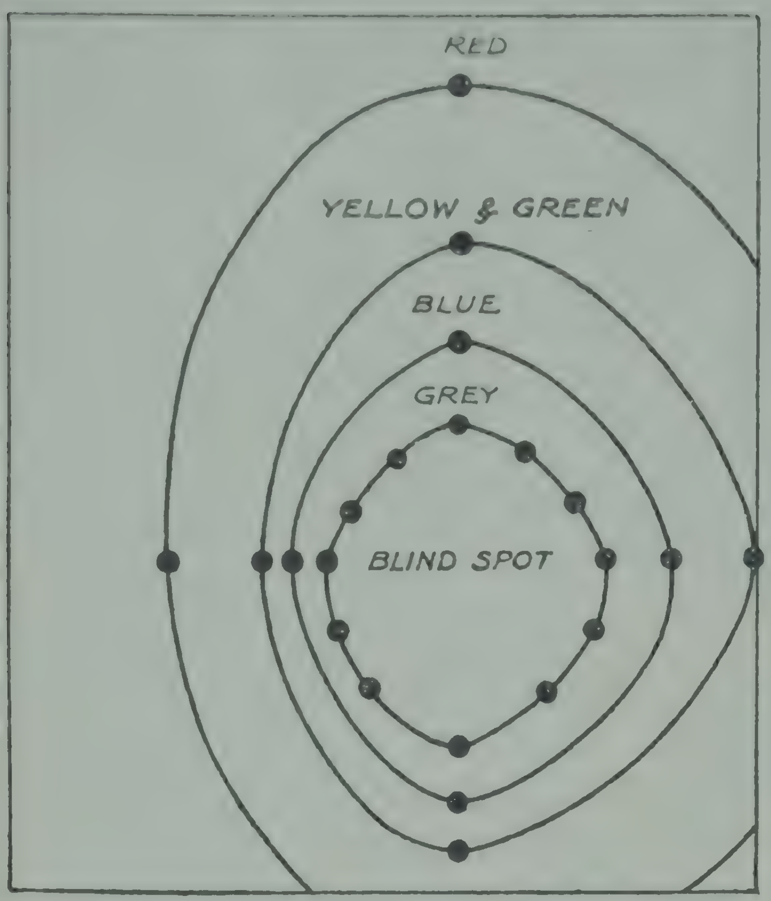

FIG. 283. Limitation of Colour Fields round the Blind Spot. (HAYCRAFT.)

Visual acuity is the ability to see as separate the images of small bright light sources of any shape placed very close together. Experiment shows that the distance between the sources must be increased as their distance from the eye is increased: in other words, that the angle which they make at the eye must be greater than a certain limiting value. The angle usually obtained is an angle of one minute, and on this the test types used in practice for testing the visual acuity of patients is based (see p. 396). Persons with exceptionally good vision are able to see the separate images, when the angle which the sources make at the eye is very much less than this, namely 24 seconds. Assuming that the posterior nodal point is 15·6 mm. from the retina (this being the distance in the normal eye), 24 seconds corresponds to a distance between the images at the retina of 0·0018 mm. The diameter of the cones is between 0·0020 and 0·0030 mm., and in the fovea they are very closely packed. The maximum visual acuity is therefore certainly as great as the size of the cones would lead us to suppose possible.

A dark spot on a bright ground is similar to the case just considered, because for the dark spot to be recognised it must subtend at the eye the minimal angle mentioned above. But increasing the intensity of the ground or the blackness of the spot will only make a very small difference, so that unlike the bright spot, an increase in the intensity does not make up for a difference of size.

The Dependence of Visual Acuity on Light Intensity. It is well known that visual acuity is very low when the eye is used under conditions of dim illumination. Even well-defined objects appear nebulous when seen in poor light. As the illumination is increased, definition improves with very great rapidity until at great intensities of illumination very high acuity is reached. When visual acuity is plotted against illumination an S-shaped curve is usually obtained.* Some observers, *e.g.* König, have reached the conclusion that visual acuity reaches a maximum value at about 100 ft. candles and that no improvement results from increasing illumination above this amount. Lythgoe, however, states that if care be taken to adapt the eye adequately, then visual acuity goes on improving as the illumination increases above 100 ft. candles. This relationship of visual acuity and intensity forms the basis of modern methods of artificial illumination, the brightness used depending on the visual acuity that is required of the observer. Thus, for passages and store-rooms 1/10 ft. candle may be sufficient. For coarse work not requiring detailed examination, 1 ft. candle may suffice. For clerical work, 10 ft. candles may b found necessary. For work where fine detail is to be seen, 100 ft. candles may be wanted, and 1,000 ft. candles will probably not be excessive for the finest work of all. Thus, for seeing very fine structures under a microscope, a bright microscope field is necessary.

---

* "Foundations of Experimental Psychology," 1929, p. 246, Fig. 15.

In order to double the visual acuity it is usually necessary to increase tenfold the intensity of illumination of the objects looked at, and their surroundings. The beneficial results of using bright lights appear to be due to two effects: (1) An increase in the discriminating power of the retina; (2) a decrease in the size of the pupil. The latter improves the definition of the image on the retina produced by the lens system of the eye, and at the same time increases the depth of focus, that is, it enables the eye to observe sharply objects at more than one distance from the eye. Two examples may make these points clear: A man mending a watch, and a woman sewing. When a watch is opened it will be seen that the works consist of two metal plates between which the gear wheels are pivoted. These are at different distances from the observer, in consequence if he focusses a gear wheel sharply the plates above or below it tend to be out of focus. The smaller the pupil, the greater the sharpness of definition of these plates owing to the increased depth of focus. Further, each bright metal surface reflects the light strongly, and therefore tends to look larger than its true size, because of the irradiation which is caused by the refractive errors of the peripheral parts of the lens system of the eye. The smaller the pupil the less the irradiation, and the more nearly do objects appear the correct size. An increase in the illumination causes the pupil to contract, and thus brings about an improvement both in the depth of focus and in irradiation. Sometimes in watchmaking and repairing it is necessary to detect extremely fine objects, such as specks of dirt or irregularities in the teeth of gear wheels. In this case the use of high illumination by reducing irradiation, and improving the defining power of the retina greatly increases the powers of observation. In the case of sewing, the material, unless it is stretched quite flat by the use of an embroidery frame, lies at different distances from the observer. The needle and thread is normally closer to the observer than any part of the material that is being sewn. In order to see needle, thread and material sharply at the same time, considerable depth of focus is required and this necessitates the use of a small pupil such as is obtained by illuminating the material brightly. Further, when the thread is extremely fine and great precision is required, for example when fashioning silk stockings by hand, then high visual acuity is necessary with the minimum amount of irradiation. This difficult work is found to be greatly facilitated by the use of high intensities of illumination. When the objects to be looked at are themselves dark in colour, for instance oxidised metallic surfaces or dark fabrics, then even greater light intensities should be made use of. Direct sunlight is not too bright for such purposes.

The Dependence of the Brightness Difference Threshold on Light Intensity. The ability of the eye to detect a difference of brightness is found to change considerably with illumination. When illumination is poor, quite big differences of brightness are not noticed. As illumination improves the differences which can be perceived get smaller and smaller until at very high illuminations, the differences become extremely small. If the difference, which can be detected by the eye, is plotted against the intensity, a curve* is obtained from which the conclusion is that, as in the case of visual acuity, the illumination required by an observer will depend on the differences of brightness that have to be visible to his eyes. If the differences of brightness are considerable, for example white objects lying on a black ground, a low degree of illumination will suffice. As the differences get smaller, the illumination required gets larger, so that where it is necessary to see objects which have nearly the same brightness as their surroundings then quite high intensities of illumination may be required.

---

* "Foundations of Experimental Psychology," 1929, p. 254, Fig. 18.

Much the same statement applies to differences of colour. The perception of small colour differences is very greatly facilitated by a high degree of illumination. In consequence, for the most perfect colour matching which the eye can carry out, a high degree of illumination should be employed.

Hecht's Theory of Vision. Hecht's theory is based on the duplicity theory, namely that the retinal receptors consist of both rods and cones; the rods occupying the more peripheral parts of the retina and being excluded from the fovea; the cones occupying the central part of the retina and having exclusive tenancy in the fovea. According to Hecht, these form two populations which differ considerably in the quantity of light required to stimulate them, the rods being, on the average, enormously more sensitive than the cones. Now according to Hecht the rod population consists of members which differ greatly in sensitiveness; a few have relatively low sensitivity, a few have relatively high sensitivity, and between the two come the main mass of the rod population. A similar statement, according to Hecht, applies to the cones. Now these two populations overlap so that as illumination is increased from zero, and therefore more and more rods are brought into play, some cones have commenced to act before the intensity has reached such a value as to cause a response from the least sensitive of the rods. This hypothesis is advanced by Hecht in order to explain the effects of increasing illumination on visual acuity and on brightness difference threshold. Thus, at very low intensities, only a few scattered rods respond, the consequence being low visual acuity and low discrimination of difference of brightness. A small increase in illumination will bring more rods into an effective condition, visual acuity will thus improve and, since the additional rods thus brought into play do not differ from one another so much in sensitiveness as the ones stimulated by the previous low degree of illumination, the discrimination of differences of brightness will also show an improvement. As the illumination is still further increased, more and more rods act until the brightness reaches a value at which the main rod population begins to function. At this point the difference of threshold between these individual rods is small, and so the ability to perceive differences of brightness has reached a much higher value than before. Now as the illumination is still further increased the cone population begins to be affected. The number of percipient elements, therefore, increase with a corresponding increase in visual acuity and, since the cones are more nearly alike in sensitiveness than the rods, the ability to discriminate small differences of brightness is also greatly improved. Further increases in illumination bring more and more cones into play until the stage is reached at which the main cone population begins to come in, and this causes an enormous increase in visual acuity and a correspondingly large improvement in the ability of the eye to perceive small differences of brightness.

There are three criticisms which can be advanced against this theory: (1) that it requires very high illumination indeed to cause the whole of the cone population to reach a functioning state. Which means that under ordinary conditions of illumination only a fraction of the cones are playing a part in vision. It may ultimately be found that such is actually the true state of affairs just as there may be sensory organs for pain which, for the greater part of our lives, are never called on to respond, but which are capable of functioning immediately a nocuous stimulus of adequate intensity is applied to the particular part of the body in which these pain end organs are situated. (2) That it assumes that the sensory structures of the retina obey the all or none law; that is that a rod or a cone can only be in one of two conditions, not responding at all or responding to the greatest extent of which it is capable. If the rods and cones obeyed this law they would differ from all the other sensory end organs which have been experimentally investigated. Moreover, experiments on the retina of Limulus have shown that its retinal receptors are graded in their responses. When illumination is low only a few impulses per second are transmitted to the brain by the optic nerve. As illumination increases, the number of impulses sent up the optic nerve increases.* In human beings, therefore, we should expect the impulses transmitted by the various fibres of the optic nerve to depend on the intensity of stimulation of the rods and cones to which the various fibres are attached. (3) That it does not consider cases where the visual acuity exceeds by a very material amount that which would be expected according to the law of geometrical optics. The position with regard to these cases will now be examined.

The Diameter of the Cones of the Fovea. A large number of investigators have determined the dimensions of the cones taken from the fovea centralis of the eye. They vary considerably as the following table shows. The mean value being about $3{\cdot}2\mu$.

Observer.	Diameter of cones.
Max Schultze	$2{\cdot}8\mu$
H. Muller	less than $3{\cdot}0\mu$
Merkel	$3{\cdot}0\mu$
Welcker	$3{\cdot}1$–$3{\cdot}5\mu$
Wadsworth	$2{\cdot}5\mu$
Kühnt	$2{\cdot}0$–$2{\cdot}5\mu$
Kölliker	$4{\cdot}5$–$5{\cdot}4\mu$
Koster	$4{\cdot}4\mu$
Greeff	$2{\cdot}5\mu$
Dimmer	$3{\cdot}0$–$3{\cdot}5\mu$
Mean	$3{\cdot}2\mu$

If the focal length of the eye be assumed to be 15 mm., then $3{\cdot}2\mu$ corresponds to an angle of 44 seconds of arc.

The Resolving Power of the Human Eye. The values obtained for the resolving power of the eye differ according to the type of test which is used. Thus, Hooke found that two stars must be separated by approximately 60 seconds of arc in order that they may be seen separately by the eye. The distance between the bright bars of a grating, in order that resolution shall occur, have been found in general somewhat less, as shown in the following table.

Observer.	Value at retina in		Angle in seconds of arc.
Lister	$4{\cdot}6\ \mu$	...	64
Hirschmann	$3{\cdot}6\ \mu$	...	50
Bergmann	$3{\cdot}8\ \mu$	...	52
Helmholtz	$4{\cdot}6\ \mu$	...	64
Uthoff	$4{\cdot}0\ \mu$	...	56
Cobb	$4{\cdot}6\ \mu$	...	64
Mean	$4{\cdot}2\ \mu$	...	58

For some other test objects the acuity of the eye exceeds, by a considerable margin, the above values. Thus, Volkmann, in 1863, found that the smallest difference that can be perceived between the breadth of two white objects on a black ground was as little as 10 seconds of arc. Wulfling, in 1892, confirmed Volkmann's observations. Hering, in 1899, showed that the edges of two rectangles did not appear in line with one another if they were shifted sideways by as little as 10 seconds of arc. He named this ability to identify small displacements as "the position sense." Hartridge confirmed Hering's value. Bryan and Baker, 1912, found that one line of a vernier can be set into coincidence with another line of a vernier with an accuracy of between 8 and 10 econds of arc. Hartridge found that objects with diffuse contours (like bsorption bands) can be set into line with an accuracy of approximately 1 seconds of arc. It will be observed that all these experiments indicate an ccuracy of observation of approximately one-sixth of the diameter of a foveal one. Even greater accuracy is found when the acuity of vision is determined for the narrowest black line that can be perceived on a white ground. The values obtained for several observers is given in the following table.

---

* *J. Cellular & Compar. Physiol.* (1), 1932, p. 277, Fig. 6 (p. 291).

	Seconds of arc.
Aubert	6
Smith Kastner	3·5 Spider's web.
Hartridge	3·6 Bright brass wire.*
Hartridge and Owen	3.1 Black brass wire.*

Recently Hecht and Mintz, using as test object a black line whose length was many times its width, obtained values for visual acuity even better than those quoted in the above table. They obtained values as low as 0·5 seconds of arc.

The acuity of stereoscopic vision has also been found to be extremely high. Thus, Bowden found an accuracy of 5 seconds of arc, while Breton, 1920, found an even greater accuracy of 4 seconds of arc ; which would correspond to an accuracy of one-fifteenth of the diameter of a foveal cone. It is clear that some theory is required which will account for the very great acuity that experiment shows that the eye possesses for these kinds of test.

Hartridge's Theory of Visual Acuity. On the basis that the eye suffers from chromatic aberration and diffraction, Hartridge calculated the distribution of light intensity in the image formed on the human fovea. This calculation was done for (*a*) a grating test object, (*b*) for a narrow black line on a white ground, (*c*) for the coincidence of two black lines on a white ground (or two white lines on a black ground), and (*d*) for the stereoscopic sense of position. From the distribution of light thus calculated, it was possible to ascertain the average illumination falling on the cones of the retina. It was found, for example, in the case of a single black line on a white ground, that that cone which according to geometrical optics corresponds with the centre of the black line, receives 13 per cent. less light than the cones on either side of it. If, then, this cone sends impulses up the optic nerve fibre connected to it which are noticeably less in number than the impulses on the cones on either side, the existence of this narrow black line will be identifiable and its position in space can then be observed. Similar calculations for the other types of test mentioned above have given the values shown in the following table.

A. Cases in which there is a constant difference of intensity without eye movements.	
Single black line on white ground	13 per cent.
Grating	20 ,,
Double line	12 ,,
B. Cases in which there is a variation of intensity when movements of the eyes occur.	
Coincidence of two lines	22 per cent.
Position of edge of contour	32 ,,
Stereoscopic vision	12 ,,

If the figures on the table above be examined, it will be noticed that the values obtained when there is a constant difference to be observed are somewhat smaller than when with movements of the eyes a comparison has to be made between the intensity at one moment and that at another. Otherwise these values are fairly concordant if allowance is made for experimental error, for the fact that the observations of the different test objects have been made by different observers, and for the difficulty of making even approximate calculations of the intensity of light falling on the retina.

We may summarise what has been stated above as follows : for certain kinds of test object the acuity of the eye is such as to correspond to the employment of an area considerably less than that represented by the diameter of a cone. This acuity can be accounted for if the intensity of light falling on a certain cone is noticeably different to that on the cones on either side of it. The illumination on the central cone must be from 12 per cent. to 32 per cent. greater or less than that on the two cones next to the central cone.

---

* Both mounted in front of white paper at such a distance that no shadow was cast.

Now the question which presents itself is this: "is there any evidence that such differences of intensity can be observed?" because, if they can, then the above theory is substantiated.

Now, when large retinal areas are being stimulated and the intensity of illumination is high, the smallest difference of intensity that can be perceived as given by various observers is as follows:—

König	1·56 per cent.
Helmholtz	0·6 ,,
Aubert	0·68 ,,
Hartridge (with absorption bands)	about 0·5 ,,

But experiment shows that the smaller the area of retina that is being tested, the greater must be a difference in intensity for it to be perceived. For so small a retinal area as that corresponding to one or two cones it would be quite possible that the difference threshold would have fallen from the high values given in the table above to the lower values of 12 per cent. to 32 per cent. required to explain the acuity of the eye mentioned previously in this section.

Hecht and Mintz, employing a similar method of calculation, found for a black line test object a difference of illumination of 0·95 per cent. between the row of cones corresponding to the centre of the geometrical image of the black line and the rows of cones on either side of the central row.

Now all the above experiments were probably performed under approximately ideal conditions of illumination. As the intensity of illumination decreases there will be a deterioration in the performance of the eye which is due to the fact that the ability of the eye to detect a small difference of brightness depends on adequate illumination, and falls progressively as illumination decreases.

Time Threshold. In considering the time threshold, two different sets of conditions require description: firstly, the minimum time during which a given stimulus must act in order to reach consciousness, and secondly, the minimum rate at which a series of stimuli must follow one another in order to give a uniform impression without flicker. Both are of considerable importance, since the first enters into such problems as the determination of the length of time during which a lighthouse beam should be projected in a given direction; the second because it gives a reliable method of comparing the intensity of lights of different colour. Experimental investigation of the first type of time threshold is effected by measuring the length of stimulus necessary to cause a source of a certain intensity to affect the retina; and it is found that the lower the intensity the longer must the image fall on the retina. But if the eye be dark adapted, if the time and the intensity values be multiplied together, then within limits a constant is obtained. On the other hand, in the light adapted eye, the value is found to vary somewhat, but is sufficiently constant to show that the relation between intensity and time is approximately the same. Within limits, therefore, we find that at the threshold the total amount of light is constant, whether it be of high intensity for a very short period of time, or of low intensity for a correspondingly longer one. This relationship ceases to be true if the time of stimulation is longer than about one-tenth of a second, and this is apparently due to the fact that the retinal apparatus reaches a steady state in about one-quarter of a second in the dark adapted eye (rod-visual purple apparatus). A lighthouse flash should therefore be visible to the eye for this length of time, in order to make the greatest possible impression. For coloured lights, approximately the same values are found, provided that allowance is made for the comparative intensity of the colour. Since the time required for the retina to reach a steady state is nearly that at which a series of stimuli must fall on the retina in order to produce a uniform sensation, for intensities near the threshold the rate at which flicker disappears is one stimulus every quarter of a second. But it is found that as the intensity rises, the rate must be increased in order to abolish flicker. The rule which most nearly expresses the relation appears to be that geometrical increase in the intensity requires an arithmetical increase in the rate. Sherrington showed, however, that the results are affected by simultaneous contrast. This phenomenon of flicker, as has been said, is used in practice for measuring the intensities of light sources. Two methods are employed: firstly, that in which the two light sources to be compared are measured separately for the intensity at which flicker ceases when the same rate of stimulation is used for both; and secondly, that in which the two sources are caused to fall alternately on the eye, and are adjusted in intensity until flicker ceases. Of the two methods, the latter is the more accurate. The value of these methods lies in the fact that they measure brightness independently of colour. The shape of the curves obtained by plotting the luminosity of different parts of the spectrum has been shown in Fig. 281.

Lastly, we have to consider the relationship between time, intensity and apparent brightness, in the case of an intermittent source, the rate of which is sufficiently great to avoid flicker. Experiment shows that the brightness increases in proportion as either the intensity or the time intervals are increased, and further that equal brightness is obtained if the time multiplied by the intensity is constant. This statement is true of both the cone and the rod apparatus, and is known as the Talbot Plateau Law. Use is made of this law in the sector method of controlling intensity (see p. 424) because the intensity is proportional to the time during which the light is allowed to pass through, which is in its turn controlled by the angle between the blades of the sector.

Colour Threshold. On testing the violet end with a photographic process, or the red end by a thermopile, it can readily be shown that the spectrum extends at both ends far beyond the visible limit. The visible limit at the red end under the most favourable conditions has been found to be 8350 A.U., while under ordinary circumstances it is difficult to go beyond 8000 A.U. Since rays beyond this reach the retina in considerable amount, the limit cannot be caused by opacity of the eye media, and must therefore be due to an actual inability on the part of the retina to record their presence.

Of several hypotheses which might be advanced for this inability, the most probable is that the retinal pigments are unable to absorb rays in the infra-red part of the spectrum, and therefore, according to Draper's law, such rays cannot produce photochemical change and cannot be perceived by the eye. It may be mentioned in this connection that few organic pigments absorb strongly in the infra-red.

The limit at the violet end is less easy to determine, because the eye media, in common with a large number of other bodies, have the property of fluorescing when the ultra-violet rays fall on them, *i.e.* they convert them into rays of longer wavelength and therefore make them visible. The resulting impression is, however, quite different, because, since these rays are generated in the eye media themselves, they are spread over the retina as a haze without there being any proper image formation. The limit of the visibility of the violet end of the spectrum appears to be at about 3,800 A.U., while the portion which is seen because of the fluorescence, which it produces, and which appears a pale lavender, ends at about 3,200 A.U. Since the wavelength of the extreme red rays is a little more than double that of the extreme violet, the eye is sensitive to a little over an octave. The range of appreciation of the eye is therefore very much smaller than that of the ear, which is about 10 octaves. As age increases, the eye media become yellow in colour; this change particularly affecting the lens, the violet end of the spectrum becomes shortened owing to absorption. On removing the lens of the eye, as in an operation for cataract the sensitiveness to the violet end of the spectrum is considerably increased It would therefore seem certain that the limitation of the spectrum at the viole end is largely due to absorption by the eye media, and not to inappreciatio on the part of the retina. The causes of the limitation of the two ends of the spectrum are therefore different.

Difference Thresholds. Beside the thresholds for light, colour, time and wavelength, which may be called absolute thresholds, there are certain difference thresholds that must be considered. Thus, for example, a certain finite difference must exist between the intensities of two sources of light of the same colour for a difference between them to be appreciated by the eye. There are four principal types of difference threshold: that of intensity, that of colour, that of saturation, and that of size.

Difference Threshold of Intensity. It is found by experiment that a just perceptible difference between the intensities of two surfaces varies with the mean value of their intensities. Thus, supposing that it had been found by one experiment that a difference of intensity of one foot candle was necessary in order that two sources should be just distinguishable, the average intensities of which were one hundred foot candles, then in another case in which the average was 25 F.C. the least perceptible difference would be found to be one-quarter F.C. This is one illustration of the principle known as Weber's law. It appears to be true for light of medium intensity, and for sources not separated by more than a small interval. But the least perceptible difference is found by most observers to be less than that taken for purposes of illustration above, namely one-hundreth part of the mean intensity; thus Helmholtz found it to be a $\frac{1}{167}$th, other observers have obtained even smaller fractions. It is interesting to find that the results are not influenced by the size of the pupil.

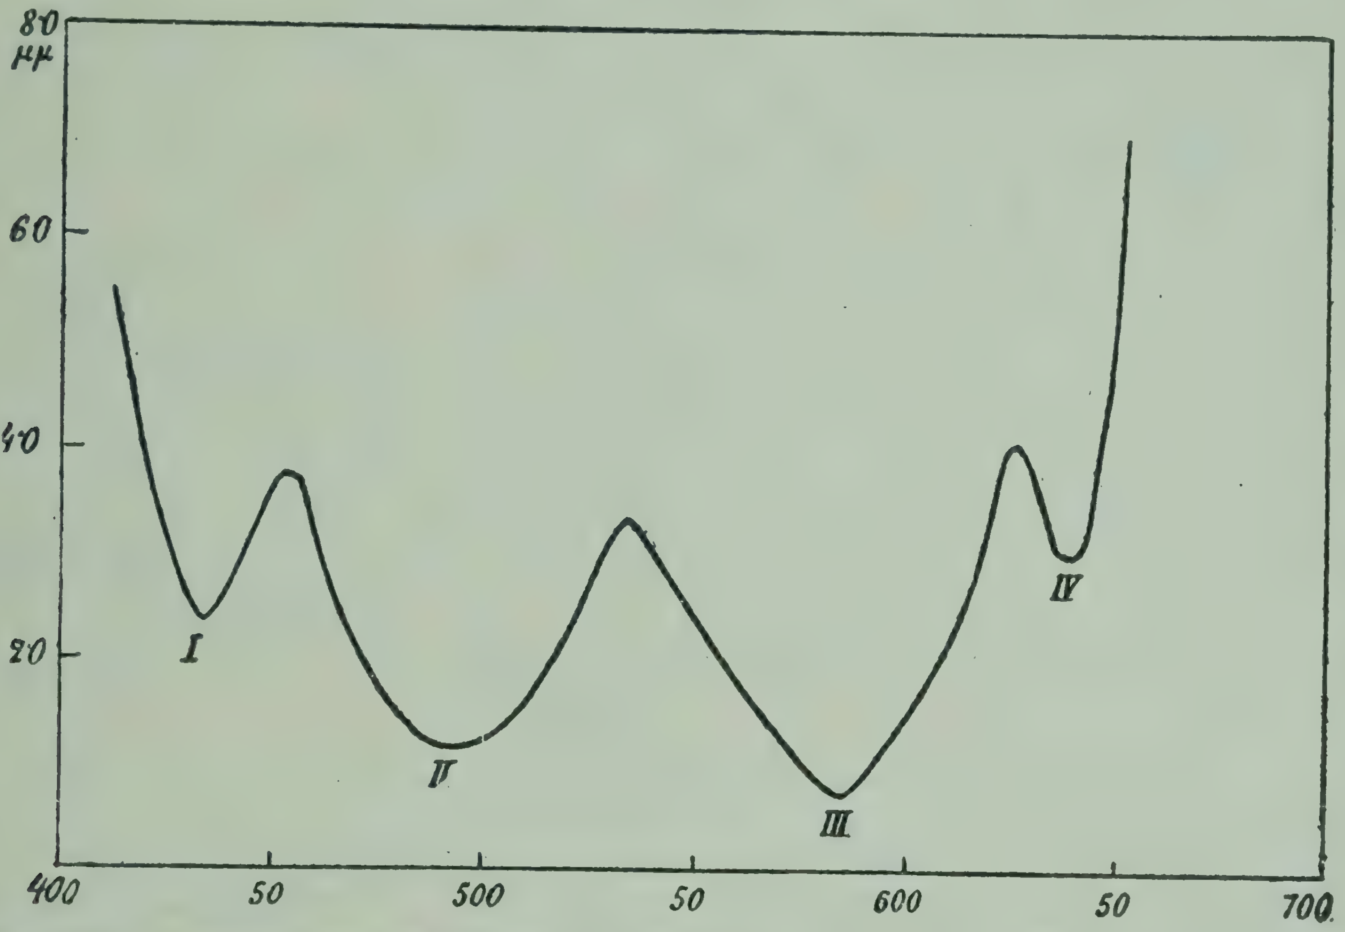

Fig. 284. Curve showing Difference Threshold of Colour at different parts of the Spectrum.

Abscissæ = wavelengths. Ordinates = difference between wavelengths capable of being discriminated. (Steindler.)

Difference Threshold of Colour. If the range of colours exhibited in the spectrum be carefully examined, it will be seen that there are certain parts, notably at the red and violet ends, at which the change of colour with wavelength is a very gradual one. At other parts, on the contrary, the change of hue is very rapid; the yellow region at 5,800 A.U. may be given as example. If therefore we determine by experiment what difference of wavelength is just perceivable by the eye, we find that it varies with the part of the spectrum under observation. We may therefore conveniently express the difference threshold in different parts of the spectrum in the form of a curve, as in Fig. 284. In persons with normal vision the total number of different hues in the spectrum is calculated to be 165. In persons with colour blindness the number is greatly reduced.

This fact has been applied by Edridge Green for the detection of colour blindness. It should be pointed out that, since in this method the spectrum itself is presented to the observer, so that there is a gradual change from one colour to the next, it is the threshold of rate of change of colour that is determined, and not difference threshold of colour. Edridge Green's method gives only from 21 to 28 monochromatic patches in the spectrum.

Difference Threshold of Saturation. By saturation is meant the amount of white light which is present with, and is therefore diluting, a colour. The threshold would appear to be of the same order as that of intensity given above, namely that a difference in the amount of white light diluting a colour by $\frac{1}{180}$th of the total intensity present can be just appreciated by the eye.

Difference Threshold of Size. If two objects are the same distance from the eye, and are close to one another and in similar positions, a difference of one-hundredth the mean size can, as a rule, be appreciated. If they are at different distances from the eye, or are far apart, or are not in similar position (*e.g.* one perpendicular and the other horizontal), then considerable errors may occur.

The Flicker Method. The majority of observers can obtain consistent measurements of intensity with the above method only when the colours of the two patches are exactly alike. Thus it is difficult to adjust a green light to be of equal apparent brightness (luminosity) with a red because the difference in colour makes the judgment of brightness inaccurate. Abney found that in his own case practice greatly increased the certainty with which the measurement could be made. A more reliable technique is given by the flicker method. The two patches are viewed through a rotating sector, the speed of rotation of which can be controlled. The intensity of one of them is now adjusted so that, when the speed of the sector is altered, both commence to show and to cease showing flicker at the same time. By applying this method to the colour mixing apparatus, the luminosity of the different parts of the spectrum can be determined. The curves obtained at different luminosities have already been given in Fig. 281. Tested by this method, different observers show individual peculiarities, which amount in some cases to a greatly diminished perception of a certain part of the spectrum. Some of the types met with will be described later.

The Method of Comparisons. In the application of this method three different series of investigations have been carried out: (1) To determine the intensities of three primary colours which, when mixed together, will match the different spectral colours or white light. (2) To determine the intensities and wavelengths of the complementary colours. (3) To ascertain the intensities and wavelengths of red and green rays which, when mixed together, match a pure spectral yellow.

A colorimeter of some form or other is used for these tests. Abney's apparatus may be described as a typical example. Light from an arc lamp is focussed on to the slit of a powerful spectroscope, which consists of a collimator, a train of prisms and a telescope. The spectrum thus produced is caused to fall on three slits, one of which corresponds with the red, another with the green, and the third with the blue. The light having passed through the slits falls on a lens which forms an image of the prism faces on a screen. The light from the slits thus recombines on the screen to produce a bright patch, the colour of which alters according to the intensities of the three components. To one side of the patch a second patch of light can be thrown from the arc lamp, and this also may be varied in different ways according to the nature of the experiment. The intensities of the different beams could be modified by altering the widths of the slits; a preferable method is to employ rotating sectors, the angles between the blades of which can be varied at will (see Fig. 285).

Colour mixing experiments performed with this apparatus give results that have already been briefly considered in Section I. It is found that not only do the three primary colours, when mixed together in the right proportions, form a white light that is indistinguishable from ordinary white light, but they can also be made to match the whole range of colours both of the spectrum and of pigments. It was also described how that certain pairs of colours when mixed in the right proportions are able to match white, and that these pairs are called complementary colours. If the colours that are mixed are farther apart than are the complementary colours, then the mixed colour is found to

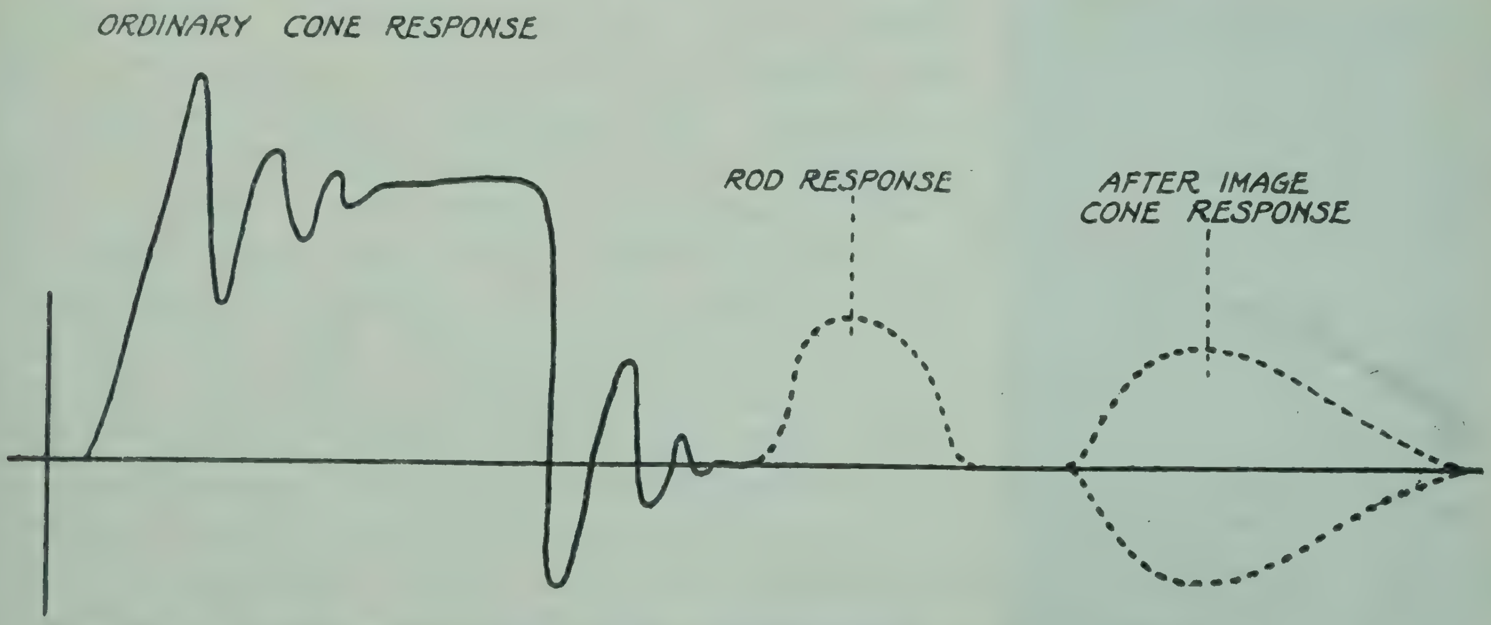

Fig. 286. Curve representing diagrammatically the Sensations aroused when the Eye has been Stimulated by a Flash of Light.
Intensity of Sensation vertical. Time horizontal. (Hartridge.)

be a shade of purple; but if nearer together than the complementaries, then the colour formed by the mixture corresponds to an intermediate part of the spectrum. Thus, if the colours mixed are red and green, the intermediate yellow and orange portions of the spectrum can be matched. As a rule the mixed colour is not so pure as the corresponding spectral colour, being less saturated (that is, diluted with a certain amount of white light). These facts can be expressed diagrammatically in the form of a geometrical figure, the colour triangle, in which the three fundamental colours occupy the corners and white the centre (see p. 373). Matches made by light of one intensity require readjustment if the intensity be changed, and matches made by one observer are different from those made by another.

8. THE SUBJECTIVE PHENOMENA OF VISION

By "subjective" we mean that the sensations under consideration cannot be traced solely to the stimulus which initiated them. Thus intermittent stimuli presented to the eye at a certain rate form a continuous sensation, so that flicker appears to have ceased. But the carrying on of the sensation from one stimulus to the next is performed by some part of the visual mechanism, and has nothing to do with any physical peculiarity of the light. It is, therefore, an example of a subjective phenomenon.

The Sensation Curve. When a light stimulus enters the eye a certain period of time elapses before a sensation is perceived. This latent period may be compared with that which occurs between the stimulus and contraction of a muscle. After its commencement the sensation rapidly rises to a maximum (see Fig. 286) and then shows several rapid fluctuations as it reaches its mean value. These fluctuations are called Charpentier's bands (Fig. 287), and are well seen after stimulating the eye by means of the flash from an electric spark. They have been compared with the oscillations which occur when an electric current is passed down a telegraph cable, and which are caused by the inductance and capacity of the circuit. Similar oscillations occur when the telegraph circuit is broken. Oscillations have also been witnessed and described by Bidwell at the end of the primary visual response. The time taken for the sensation to reach its maximum varies from 0·16 to 0·07 secs., being shorter the greater the intensity of the stimulus. This so-called primary image is followed under certain conditions by a less definite and less intense image, which has the following characteristics: (1) It is not seen when the eye is light adapted. (2) It is strongest for green light, and is absent for red. (3) It is absent from the fovea. (4) It is not seen by persons suffering from night blindness. (5) It is always of a bluish-grey colour. All the above facts fit in with the view that, whereas the primary response corresponds with the reaction of the cones to the stimulus, the image which is sometimes seen to follow belongs to the rod apparatus.

Fig. 287. Charpentier's Bands as seen when a disc with a narrow radial slit is rotated in front of an illuminated screen about once a second.

The After Image. Following these responses of the cone and rod end organs is the so-called secondary image, which certainly concerns the cones and may concern the rods as well. This image is of longer duration than those already considered, and it is of much lower intensity. It has, however, the peculiarity that, so long as it lasts, the part of the retina affected gives a diminished response to a stimulus of the same type as that which it had previously received. For example, if the first stimulus was one of white light, then a second white light stimulus falling in the period occupied by the after image of the first would not be recorded by the retina with the normal intensity. It has been pointed out that the after image period in some ways resembles the refractory period which follows the activity of muscle and nerve. If the second stimulus affects a larger area of the retina than that affected by the first stimulus, then a dark patch is seen lying on a bright ground, the dark patch corresponding in size to the first stimulus, the bright ground corresponding in size to the second stimulus. If the first stimulus is coloured, and no stimulus follows, the secondary image is found to have the same colour ; but if a second stimulus of the same colour, but rather larger size, falls on the retina during the secondary image, then, as before, a dark patch is seen lying on a bright coloured ground. If, on the other hand, the first stimulus be coloured light, say red, and the second stimulus be one of white light, the sensation received is one of the complementary colour, the reason being that the red constituents of the white light are partially excluded by the after image of the first stimulus, but not so the other spectral colours, and the image which is seen is therefore a blue-green one. Because of these peculiar properties the after image is said to have two phases : being called positive when the eye receives no second stimulus, and the appearance of the after image is the same as that of the first stimulus ; and being called negative when, owing to the incidence of a second stimulus, the after image shows the opposite intensity or colour to the stimulus which originated it. Since absence of the second stimulus causes the after image to be positive and the presence of a second stimulus makes it appear negative, we should expect a second stimulus of the right intensity to cause the after image to disappear altogether, since it would stimulate the surrounding retina with the same intensity as does the after image of the first stimulus. Experiment shows that this result can be achieved. Because of the importance of these properties of the after image, we may with advantage recapitulate as follows :—As a result of a stimulus the region of the retina affected gives a response which is followed by a second or after image. During this after image, this area is incapable of reacting with the normal intensity to a like stimulus, but shows increased excitability to a stimulus of the opposite kind. For example, after a green stimulus the retina is unable to respond fully to another green stimulus unless it falls either before or after the period of the after image. Therefore, if during that period a white stimulus be arranged to fall on the retina, it will cause a purple sensation (purple being white minus green) in that part of the retina first stimulated. The duration of the after image is variable, but is found to correspond roughly with the intensity and duration of the stimulus. Thus, after a few seconds' exposure to a bright light the after image may be noticeable for two or three minutes, its intensity waxing and waning in an irregular manner. Successive images are often found to show a series of colours ; a common series is bluish-green, violet, rose, and finally orange or green. The phenomenon is, however, very variable. The colours may be explained by assuming a difference in the rate of oscillation for the after images of the different colours. For example, the above series of colours would be obtained if green were more rapidly, and red less rapidly, perceived than blue.

Flicker and Visual Persistence. A study of the characteristics of the sensation curve provides an explanation of a number of the subjective phenomena of vision. For example, if a cardboard disc, marked as shown in Fig. 288, be caused to rotate slowly, while the black and white sectors are readily recognised, their radial margins appear blurred. This blurring is due to the slow rise and fall of the primary image of the sensation curve. If the speed be increased, a point is reached at which the disc gives an unpleasant glittering appearance ; this would appear to be due to one stimulus occurring during the after image of the previous one, and thus becoming suppressed, but being followed in its turn by a fresh stimulus which is caused by contrast (see later) to have a greatly increased intensity. If the rate of rotation of the disc be still further increased, a point is reached at which a stimulus falls during the primary image of the previous one. The persistence of the primary image after the cessation of the stimulus causes the stimuli to fuse to give a uniform sensation without flicker, which may be compared with the complete tetanus of a muscle. Since the primary response is more abrupt the greater the intensity of the stimulus, a more rapid rate of rotation is required to produce fusion at high intensities than at low.

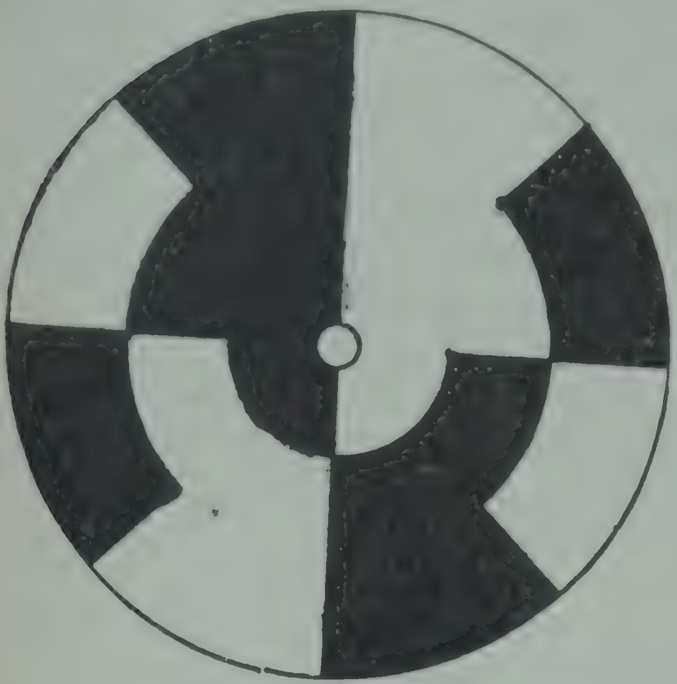

FIG. 288.

PERIODIC STIMULI. We have seen that, if a stimulus falls during the after image of a previous one, its character is altered. If the two stimuli are similar the second stimulus tends to be suppressed, but if dissimilar the second stimulus appears to be increased. If, on the other hand, the second stimulus falls either before or after the after image, it appears to be unaffected. But the experiments on flicker show us more than this, because even in a case where a second stimulus comes before the after image of the first, it is clear that the third would at a certain speed coincide with it, and should therefore be modified. Experiment seems to show no evidence for such an effect, and we must therefore conclude that the occurrence of the second stimulus in some way inhibits the after image of the first, so that its results are not apparent. Further evidence for this view is to be obtained from continuous stimuli, for we do not find a sudden diminution in the intensity of the response a moment or two after a continuous stimulus has begun, such as we should expect if the after image of the commencement of stimulus were suddenly after a short interval to assert itself. What happens to these suppressed after images? Are they entirely destroyed, or are they caused to accumulate until the end of the stimulus? The evidence appears to be in favour of the latter view, because an after image has a more definite character the longer the stimulus. Moreover if the gaze be directed towards a fixation point, and the inclination to blink be rigidly suppressed, after a few seconds the images of objects which fall on the periphery of the retina begin to appear milky, particularly in the shadows. At the same time the brightness of the high lights seems to be reduced so that it approximates more and more closely to the milkiness of the shadows. When this stage is reached, objects appear in outline, the contours being produced and renewed by imperfect fixation. If fixation can be retained for a short period, it will be found that the whole field becomes blank with the exception of the fixation mark. If this also disappears momentarily, then fixation is lost, the eye makes an involuntary movement, and the whole field immediately fills with detail again. In this experiment, two processes seem to be going on: firstly, in the shadows, the disappearance of the after images of previous impressions, the replacement of the visual purple previously bleached and possibly also the recovery of these parts of the retina from the effects of previous stimulation, all of which will increase the sensitiveness of the retina so that it now responds to the light reflected by the shadows; secondly, in the high lights, the accumulation of after images, the bleaching of the visual purple, and possibly the effects of fatigue, all of which tend to reduce the intensity of the impression. So that these processes, tending to increase the brightness in the shadows, and to decrease that of the high lights, finally bring them to the same level. In these processes the accumulation and removal of after images would appear to take a considerable part. The conclusion to which we are forced is, that at the beginning of a continuous stimulus, the after images are effectively removed until such time as the stimulus shall cease, when they can be permitted to assert themselves. But if the stimulus be prolonged, the suppression becomes more and more difficult, until the accumulation of after images is so extensive that they begin to obtrude more and more on the impression conveyed to consciousness.

Fate of After Images. If the conclusion drawn from the above experiments is valid, the question arises as to the apparent unimportance of the after image in ordinary vision. The answer is to be obtained from experiments like the following :—If fixation be continued until the images formed on the retina appear in outline as in the previous experiments, and the gaze be then quickly turned to a second fixation mark placed some distance from the first, it is found that, on returning to the first mark, some time has to elapse before the appearance in outline is obtained again ; in fact the time taken is not very different from that required to reach this stage at the beginning of a new experiment. The second impression had effected an almost complete removal of the after image of the first, so that on returning to the first again, the slate had, as it were, been wiped clean, and the first impression therefore acted as if it were a new one. This conclusion is entirely in agreement with our previous conclusions with regard to the after image, namely that it corresponds to a period in which a stimulus, similar to that to which the after image belongs, is inhibited, while that of a different kind is favoured. If, therefore, during fixation the gaze be momentarily directed elsewhere, the after image that had been set up is quenched by the new impression, and on returning the gaze to the fixation point the old image behaves almost like a new one. The non-intrusion of the after image in ordinary vision is therefore due to a considerable extent to the continual and rapid replacement of one impression by another, by the shifting of the gaze, and also to the spreading of the accumulation of partially effaced after images more or less uniformly over the retina. It has been suggested that impulses may be originated from the external eye muscles on movement, which on reaching the brain assist in the removal of the after images of previous stimulation.

Adaptation. If the eye after being in the dark is rapidly exposed to the light, at first the sight is confused and the eye dazzled, in spite of the powerful constriction of the pupils. The eye, however, very quickly becomes accustomed to the greater intensity, or, as we say, it becomes light adapted. In a similar manner, on entering the dark from the light, the eye can at first see nothing, but by degrees it becomes accustomed to the new conditions, and objects begin to be recognised : the eye has therefore become dark adapted. In the first case, the initial light stimulus reduced the sensitiveness of the eye to light to such an extent that the eye ceased to react to an excessive degree as it had done at first. Dark adaptation appears to consist of two separate processes : (1) the removal of after images from the cone light-receiving mechanism, and (2) the replacement of visual purple for the rod apparatus ; the former predominating at high intensities and the latter at low.

Fatigue of the Retina. If the eye has been exposed to a very bright light for a considerable time, there is at first inability to see with the dazzled part of the retina. If a field is looked at, a black spot appears to lie in front of it ; if, on the other hand, the field subsequently looked at is dark, this same area of the retina appears to be filled by a bright haze. If the dazzling light be restricted to one colour, there is an inability to see the same colour, if of lower intensity, immediately afterwards. The power to see other colours is apparently quite unaffected ; in fact Burch stated that the complementary colour actually appears to be more vivid than usual. These changes are similar to those caused by after images. The negative after image causes diminished appreciation of colours similar to itself, while the positive shows itself as a bright image similar in colour to the original stimulus when a dark field is looked at.

Contrast Phenomena. SUCCESSIVE CONTRAST. Visual impressions are affected by the previous history of the retina ; thus, after the eyes have been directed towards a red surface, a grey surface appears to be tinted green, a green surface seems a more vivid colour than normal, while a red colour is relatively dull. In other words, after stimulation by one kind of source, another of a similar nature is inhibited, while that of a different nature is either unaffected or may be even increased. This effect is called successive contrast. Experiment shows that the change of the second stimulus is such that it favours the colour complementary to the first stimulus. These effects are similar to those already described under adaptation and fatigue, and the causation of the phenomenon is the same as that given above, being due to the presence of an after image.

SIMULTANEOUS CONTRAST. If the retina is stimulated by two separate impressions, any differences between the impressions will be found to be accentuated. Thus if a small grey surface be placed on a white ground, the grey will become darker, and to a less extent the white ground will become lighter. If now the same grey surface be placed on a dark ground, it will be found to become lighter and the field darker. The nearer the surfaces are together the greater are the effects of contrast, the edges showing the effects of contrast most. In the case of colours, similar changes take place : thus two similar colours of different intensity placed together appear to be more different ; two colours of different saturation change, the one to greater, the other to less saturation ; while two colours of different wavelength appear, under the influence of contrast, to suffer a variation towards the complementary colour. A similar change is observed if contrast is occurring between a colour and a grey surface of approximately the same intensity, for we find that the grey is obviously tinted with a colour that is very nearly the complementary of the colour in question. It has been stated that the light which reaches the eye other than through the pupil (*e.g.* the sclera), and which is coloured an orange-pink in consequence of its partial absorption by the blood pigment in the capillaries, is responsible for the contrast colours not being strictly complementary to those which produce them. It is also found that separation of the surfaces, or the demarcation of the junction of the two surfaces by means of a narrow black or white line, or even the existence of small marks or creases, reduces the effects of contrast to a considerable extent.

We can summarise the effects of simultaneous contrast in the following way :—if one part of the retina is being stimulated, the part surrounding it not only tends to discourage a similar stimulus but also favours one of a complementary nature (black in this connection being considered as complementary to white). But this statement is similar to that which we have already made with regard to the effects of the after image on the same part of the retina which has received stimulation. Simultaneous contrast would therefore appear to be simply an extension of the after image phenomenon into a region of the retina outside the confines of the original stimulus. Experiment shows that this extension does not go far from the excited area, for the contrast effects, which may be considerable near the contour, rapidly decrease as the distance from the contour increases.

BIDWELL'S EXPERIMENT. If a brief white light stimulus be caused to fall during the after image period of a previous red stimulus, we should expect the white light to be tinted blue green, because red light is suppressed and its complementary increased. If the intensity and time intervals are carefully chosen, the blue green sensation may be made stronger than the original red stimulus to which it owes its colour. The persistence of vision causes this blue green response to last an appreciable time, and therefore if another red stimulus rapidly succeeds the white one (the one which is coloured blue green) it will tend to be suppressed from consciousness. But a white stimulus succeeding this second red one will be coloured blue green by its after image, because it has left its impression on the visual mechanism, although that impulse has not been conveyed to consciousness. If therefore a series of such red and white impulses be caused to fall on the retina, each white one will be tinted blue green, and each red one will be suppressed, the result being that the complementary colour alone is seen. This interesting phenomenon was discovered by Bidwell. He took a disc of tin plate about 8 inches in diameter, and arranged so that it could be rotated by an electric motor 6 to 8 times a second. From this disk a sector was cut of approximately 60 degrees; half the remainder was covered with black velvet and the other half with white paper. Behind the disc were mounted two pieces of silk: one red, the other blue green (Fig. 289). The order in which the images were presented to the eye on rotation of the disc was: (1) coloured silks, (2) white sector, (3) black sector, and so on. The result was found to be that the red silk appeared pale blue green, and the other pink; that is, in both cases the complementary colour alone was seen. This experiment brings out very clearly the fact that the after image process is entirely subconscious. The following observations confirm this conclusion.

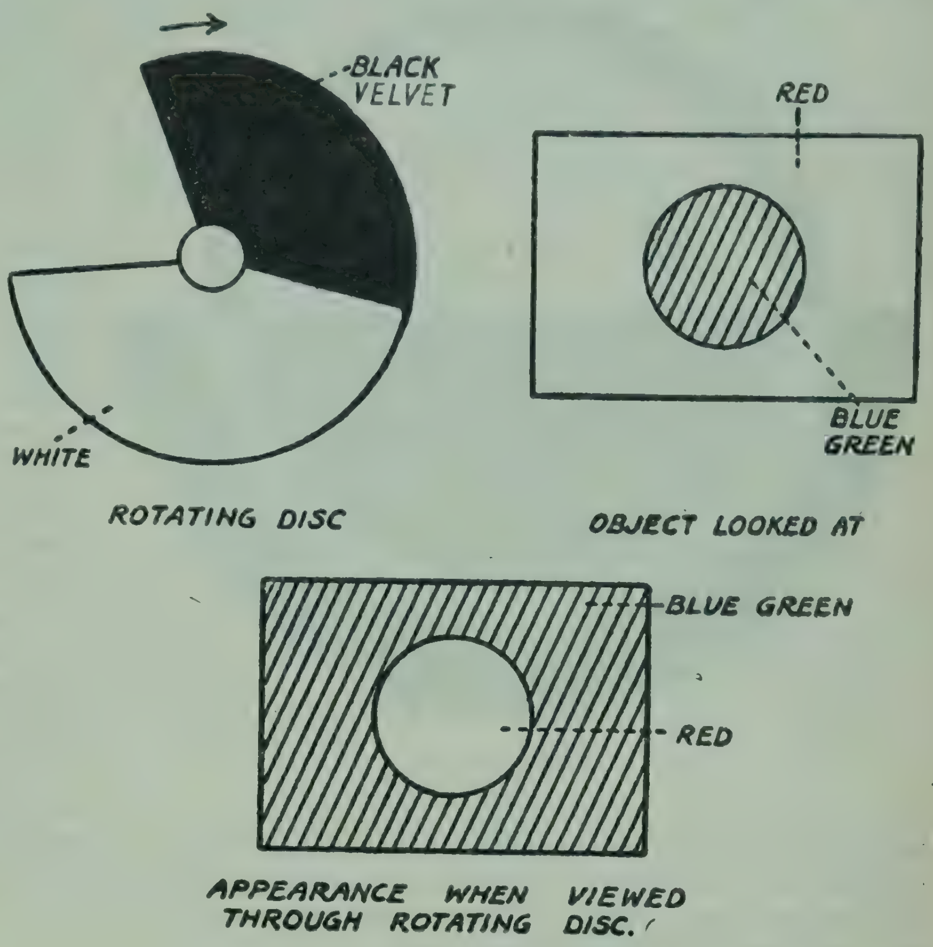

Fig. 289. Bidwell's Rotating Disk.

An object looked at through the disc appears in complementary colours.

Burch's Experiment. It has been much discussed in the past whether contrast phenomena are due to errors of judgment, as Helmholtz supposed, or due to physical or physiological changes taking place in the retina or in the conducting paths leading from it to consciousness. Burch disproved Helmholtz' view by the following simple experiment. A box (Fig. 290) is divided into two long compartments, *a b* and *c d*. At *a* the compartment is closed by a red glass-plate and at *c* by a blue glass-plate. Apertures are provided at *b* and *d* for the observer's eyes. At + and + two small grey crosses are fixed about the middle of the compartment on sheets of transparent glass. On looking through the openings *b* and *d* and converging the eyeballs, so as to fix the point *o*, we get a fusion, more or less complete, of the two colours red and blue, so that the background appears purple; or there may be a struggle between the colours, at one time blue, at another red predominating. To the judgment, however, there is one background and not two, and therefore, according to the theory of Helmholtz, the grey crosses should by contrast both acquire the same induced colour, which would be complementary for purple. But it is found that the two crosses are perfectly distinct in colour, that which is seen by the eye against the blue ground being yellow, while that on the red ground is green, showing that the phenomena of simultaneous contrast are not due to an error of judgment.

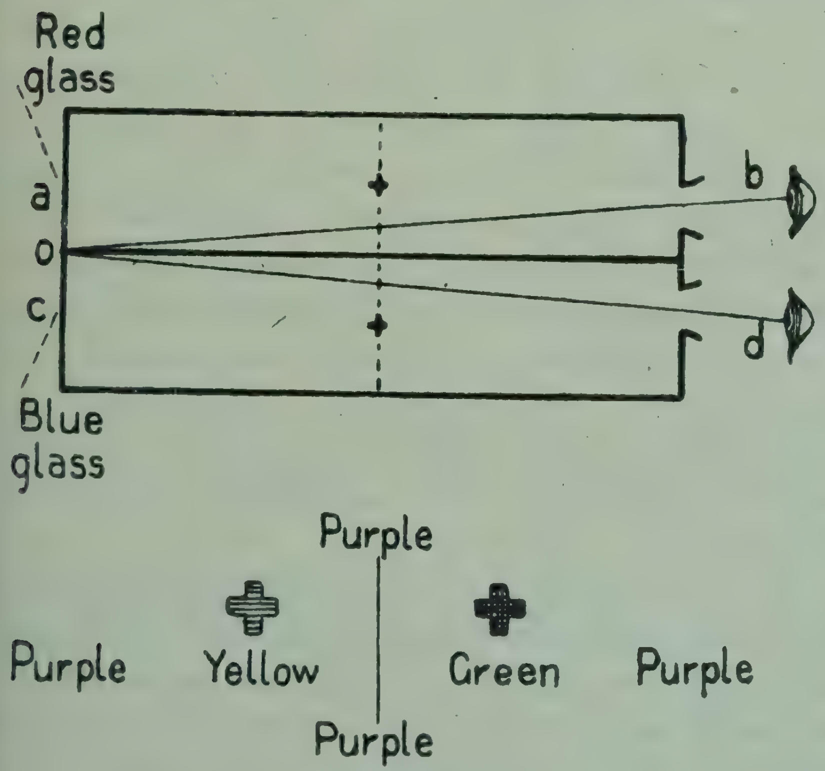

Fig. 290.

Sherrington's Experiment. The same fact is very definitely established by the following experiment devised by Sherrington. The disc (Fig. 291) presents two rings, each half-blue and half-black. The outer ring is intensified when at rest by simultaneous contrast, the black half being seen against the surrounding yellow, while the luminosity of the blue half is increased by the effect of the surrounding black. In the inner ring the blue half is darkened by contrast with the surrounding yellow, while the black half is not evident at all. If the disc be rotated, we get two concentric rings on an apparently homogeneous field. It is found however that the outer ring flickers long after complete fusion has taken place in the inner ring, showing that the stimulation of the retina by the outer ring is increased under the influence of contrast.

Allen's Monocular Experiments. By means of two independent monochromatic illuminators, Allen illuminated one eye with a small flickering light source of one colour lying on a background of a large non-flickering source of another. He varied the rate of flicker until a smooth sensation was perceived. He then made the justifiable assumption that, when an increase in flicker rate is required for smoothness, it demonstrates an increase in the sensitiveness of the retina at that point and *vice versâ*. Allen found that a red background caused a decreased sensitiveness of the retina to red, but an increased sensitiveness for green and blue. A green background on the other hand made green minus, but red and blue plus, while a monochromatic yellow background made both red and green minus, but blue plus plus. Now these results fit in exactly with older ones in simultaneous contrast. They show, however, more than these could do, namely that both facilitation and inhibition are at work. They show, moreover, a trichromatic subdivision of the spectrum such as Young's theory of colour vision postulates.

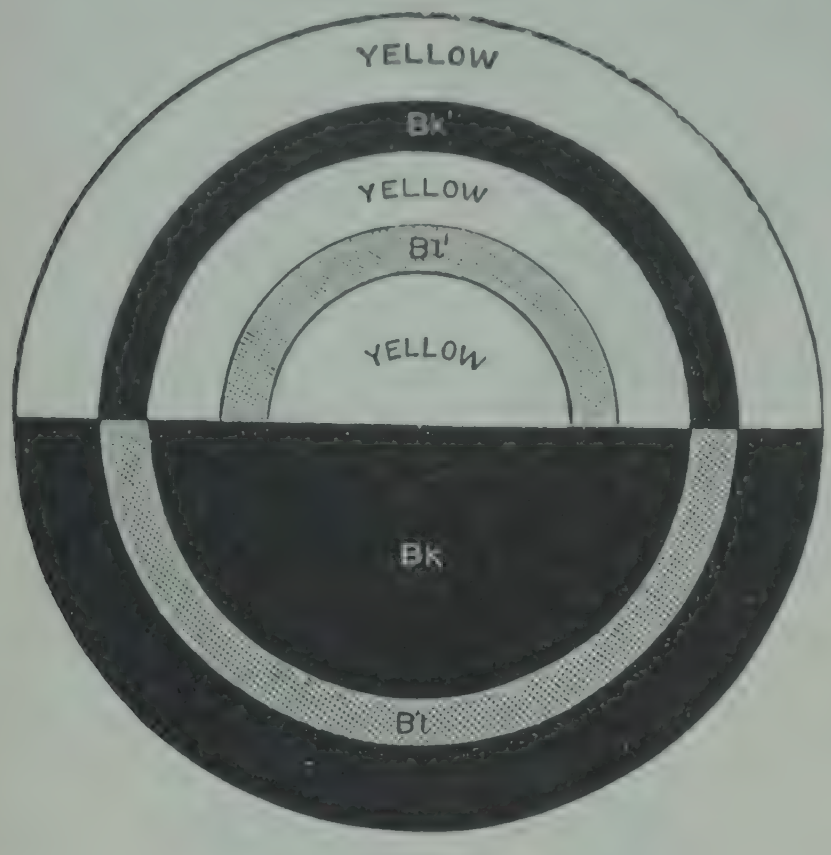

FIG. 291.

ALLEN'S BINOCULAR EXPERIMENTS. By a similar arrangement to that used above, the constant coloured field was presented to one eye, and the small flickering coloured source of light to the other eye. These experiments also demonstrate a trichromatic sub-division of the spectrum, since a stimulus of red, green or blue to one eye enhances the perception to the whole spectrum, but especially to the corresponding colour in the other eye; there being two invariable regions between these at 0·655 and 0·500μ respectively.

CAUSE OF AFTER IMAGE. Sherrington has shown that in the case of muscles there is what is called reciprocal innervation. Thus stimulation of the cortex which causes the contraction of one muscle also brings about a corresponding relaxation of its antagonist, in order that rapid and economical motion may take place. The contraction and corresponding relaxation are therefore analogous to the response of one part of the retina, which is accompanied by an inhibition of the surrounding parts of the retina to the same kind of stimulus (simultaneous contrast). In a similar manner the inclination to extension, which is found to accompany the prolonged flexion of a limb, finds its analogy in the phenomena of after images and adaptation of the eye, since the tendency is to suppress a similar stimulus in the part of the retina stimulated and to encourage its complementary. The inference to be drawn from these analogies is that the after image and its allied phenomena are caused by changes in the conducting paths of visual impressions which are similar to those found to exist in paths belonging to the motor system. What the nature of these changes in the conducting paths may be is at the present time undecided. McDougall has suggested that they are fatigue effects in the synapses of the higher conducting paths. If this view is correct, it would seem difficult to explain why after images and contrast phenomena are best seen with a rested eye.

UTILITY OF THE AFTER IMAGE. We have seen that the effect of the after image is to inhibit the possible reception of a second stimulus, and at the same time to favour the reception of one of a different nature. The process is therefore one which favours change, for not only is there a tendency to efface an old impression but also to welcome a new one. Such effects must be of great value to an organ such as the eye, the function of which to a considerable extent in everyday life is to present to consciousness the greatest number of impressions in a given time. For example, by measuring the time taken to read a passage in which almost every word was of importance, it was found that on an average eight words were read in each second, and that the eight words had an average of forty letters. It is clear from this that from eighty to forty different impressions must be presented to consciousness in each second. The function of the after image in preparing the retina for the reception of new impressions would therefore appear to be a very important one. The effects of simultaneous contrast are equally important to vision, because the changes produced by it are such that the images falling on contiguous portions of the retina are made as unlike as possible. Not only are the intensity and colour of adjacent parts of the image made more definite (this process being comparable to the effects of intensification on a photograph), but the blurring at the edges of contours due to imperfections in the image formed on the retina, is also largely eliminated (this comparing with retouching in photography).

Binocular Rivalry must be briefly referred to here, because of the similarity which it shows with the phenomena described above. If for any reason the images formed on the retinæ have dissimilar contours, rivalry ensues, first one image and then the other reaching consciousness. This process usually occurs independently in different parts of the field, so that the visual impression consists of a patchwork of the two images (Fig. 292). Seldom, if ever, are both images seen in the same part of the retina at the same time. It is found that a number of factors can cause one image totally to suppress the other : these are interest, novelty and brightness. The importance of this suppression can be appreciated by picturing the confusion which would occur if two different images were simultaneously presented to consciousness, as would happen in animals in which different images are formed in the two retinæ and in cases of strabismus in man. The parallelism between this process and those which we have already described can be traced by regarding for one moment one of the images as the primary one. This causes impulses to travel to the visual centres unaffected at first by the effects of other images, but these tend to accumulate more and more until the primary image is overcome, and that of the other eye put in its place. But this image in time suffers in the same way, so that the images alternate. The fact that a new image can suppress an old one, is due to the absence of after images in the first and their presence in the second. The predominance of a bright image can be explained by the longer time required for the after image to reach such a level as shall cause suppression. The preference for an image with contours would seem to be due to the greater ease with which the after image may be removed by small deflections of gaze.

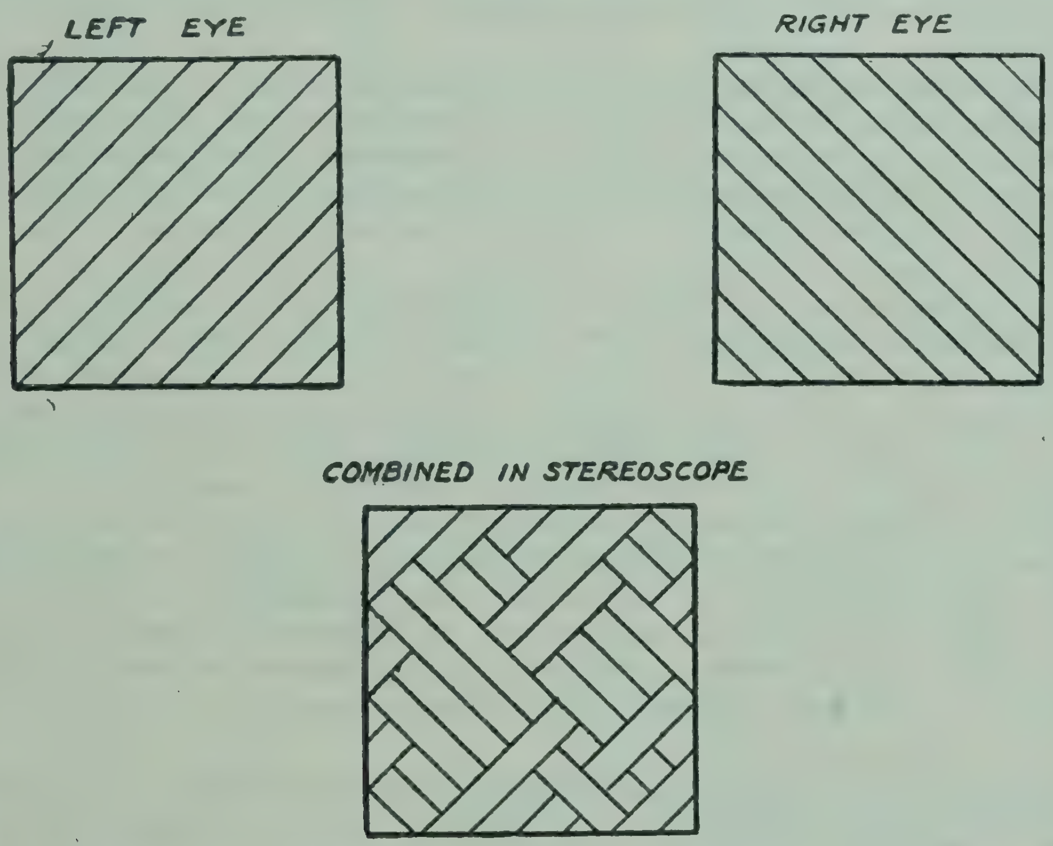

Fig. 292. Diagram to show how the Binocular Combination of two Dissimilar Images produces a Fluctuating Image containing parts of both of them.

9. ERRORS OF APPRECIATION

Under this heading we include all types of abnormality in the retinal apparatus or in its central connections. The class therefore includes cases n which the image formed on the retina is in every way normal, and those n which the optical defects do not adequately explain the whole of the visual disability which experiment shows to be present. The class is found to include ases which range from slight impairment to complete blindness.

The following classification may be used :—

Group 1. Both rod and cone vision are affected, and there is thus both night blindness and total colour blindness.

Group 2. Rod vision is either affected alone, or there is slight defect in cone vision as well.

Group 3. Rod vision is unaffected, while cone vision is either altogether absent, or is found to show abnormality which affects certain colours only.

Note that any one of the above groups may be found to affect either one or both eyes, and may involve the whole or only a limited part of the retina.

Complete Blindness (group 1) may affect the whole of one or both eyes, or may occur in half the visual fields only. It may be limited to irregular-shaped islands or patches, or it may be found associated with central or peripheral vision. The shape of the affected area frequently gives a direct clue to the cause of the condition. The shape is best determined by means of the perimeter.

(*a*) The whole of one or both eyes is found to be blind. The disease may be congenital or may be the result of inflammation affecting the posterior parts of the eye (ophthalmoscope will confirm). Injury involving the whole of the optic nerve trunk will also cause blindness of the corresponding eye.

(*b*) The blindness involves the right or left halves of one or both retinæ only. The lesion in such cases involves the optic tracts. Tumours are the commonest cause.

(*c*) The blindness is limited to a segment of the retina when the retinal vessels are affected (*e.g.* by embolism). The ophthalmoscope will confirm.

(*d*) Blindness which affects only the periphery of the retina is due either to deficiency of blood supply (as may occur in glaucoma), defective blood (severe anæmia), or the presence of poisons in the blood.

(*e*) If blindness affects chiefly the centre of the retina, the cause is probably poisoning by either tobacco, alcohol or both. At first vision is impaired for certain colours only but the blindness quickly becomes complete if the absorption of the poison continues.

(*f*) If irregular blind islands called *scotomata* are found in the visual fields, the cause may be inflammation of the choroid or of the retina itself, or the detachment of the retina from the choroid.

Night Blindness (group 2) is found in four different types of case.

(*a*) As an inherited condition. (*b*) In diseases of the liver in which bile salts are found to circulate in the blood, since these dissolve the visual purple out of the retina and therefore impair rod vision. (*c*) As a symptom of inadequate diet (lack of Vitamin A). (*d*) In disease of the retina or choroid (*e.g.* retinitis pigmentosa). In the last two cases it is usual to find colour vision affected to some extent.

The symptoms of night blindness are well described by the name. The eye does not possess the power of becoming fully dark adapted, and even a moderate degree is only attained after a prolonged stay in the dark. A photochromatic interval is not found, that is to say, when the intensity of a colour is reduced, it does not pass through an uncoloured stage (due to the rods). Purkinje's phenomenon is usually poorly developed or is not seen at all. There is no cure in the congenital cases.

Colour Blindness. The detection of this condition is important because of the use of coloured signals in the railway, the marine and other services. The employees of such services should be tested at frequent stated intervals, because colour blindness may develop (*e.g.* from tobacco or alcohol poisoning) in a relatively short space of time.

The methods of testing colour blindness fall roughly into three classes : (1) those of historic interest ; (2) those used by ophthalmologists for practical tests ; (3) those used for research. Holmgren's wool test is an example of the first class. It consists of a large series of coloured worsteds, the number of different shades being very great. In using the test the doctor hands to the patient selected skeins which have been found by experience to give difficulty to colour blind persons. He then instructs the patient to select from the box all the skeins that appear to him to have the same colour. His visual defect is judged by the mistakes which he makes. Since coloured wools readily fade and get dirty in use, slips of coloured glass or beads, etc., have been used in a similar way. These tests are however no longer employed, because parts of the test may so easily be lost or damaged.

Of practical methods the lantern test would appear to yield the best results, because it gives a close imitation of a signal light as seen at different distances and under various atmospheric conditions. In using the test, the examiner shows the subject a series of different coloured lights in turn, and in each case asks him to state what he sees. If he makes no mistakes, the colours are shown through modifying glasses which give the effect of a signal when seen through mist, fog, rain, etc., and the answers noted. One definitely wrong answer should reject the subject, particularly if red, green or white be one of the signals misnamed. Objections have been raised to this test, because it is possible for a man ignorant of colour names "to be failed" even if he has normal colour vision. The objection is readily met, however. When the driver of a train sees a signal, he says to himself "that is a green signal and therefore my train may proceed." But supposing all the time it were a red signal, and that he called it green through ignorance of the name, that man is as much a danger to the community as if he were in fact colour blind. No test can be too searching, and no borderline case should ever be passed; the risk is too serious.

Of tests of theoretical importance some have already been described, namely the measurement of the thresholds for light and colour, the colour-mixing apparatus and the flicker method of photometry. There is, however, another test which is found to give valuable information, namely the spectroscope test of Edridge Green. The instrument consists of a spectroscope to which is fitted two shutters, one of which may be caused to shut off the spectrum from the red end and the other from the violet. The patient commences the test by placing the shutter on the red side at the place where he sees the red begin, and this position on the wavelength scale of the shutter is noted. The patient is then told to move the other shutter until it reaches the place where red changes to orange. This wavelength also is noted. The red side shutter is now moved until it occupies the position of the violet side shutter, and the violet side shutter is now moved until a difference in colour at the two sides of the spectral area, which is thus isolated, is just not able to be seen. The wavelengths are again noted, and the next area measured off, and so on until the violet end of the spectrum is reached. A person with normal vision using this instrument will map out between 20 and 30 distinct strips. Abnormal vision may be shown in three ways: firstly, by the ends of the spectrum being found in abnormal positions, the spectrum being shortened at the red or the violet, or both; secondly, by the isolated strips being too large and too few; and thirdly, by wrong names being applied to some of them. The value of the method is considerable because it shows the presence of all three classes of defect, those due to blindness, those caused by ignorance of colour names and those in which the appreciation of colour is deficient.

Cases of colour blindness, when tested by the above methods, are found to show every possible variation between complete blindness and slight impairment of the colour sense. Their classification is as a rule complicated by the fact that cases are usually described in terms of one of the theories of colour

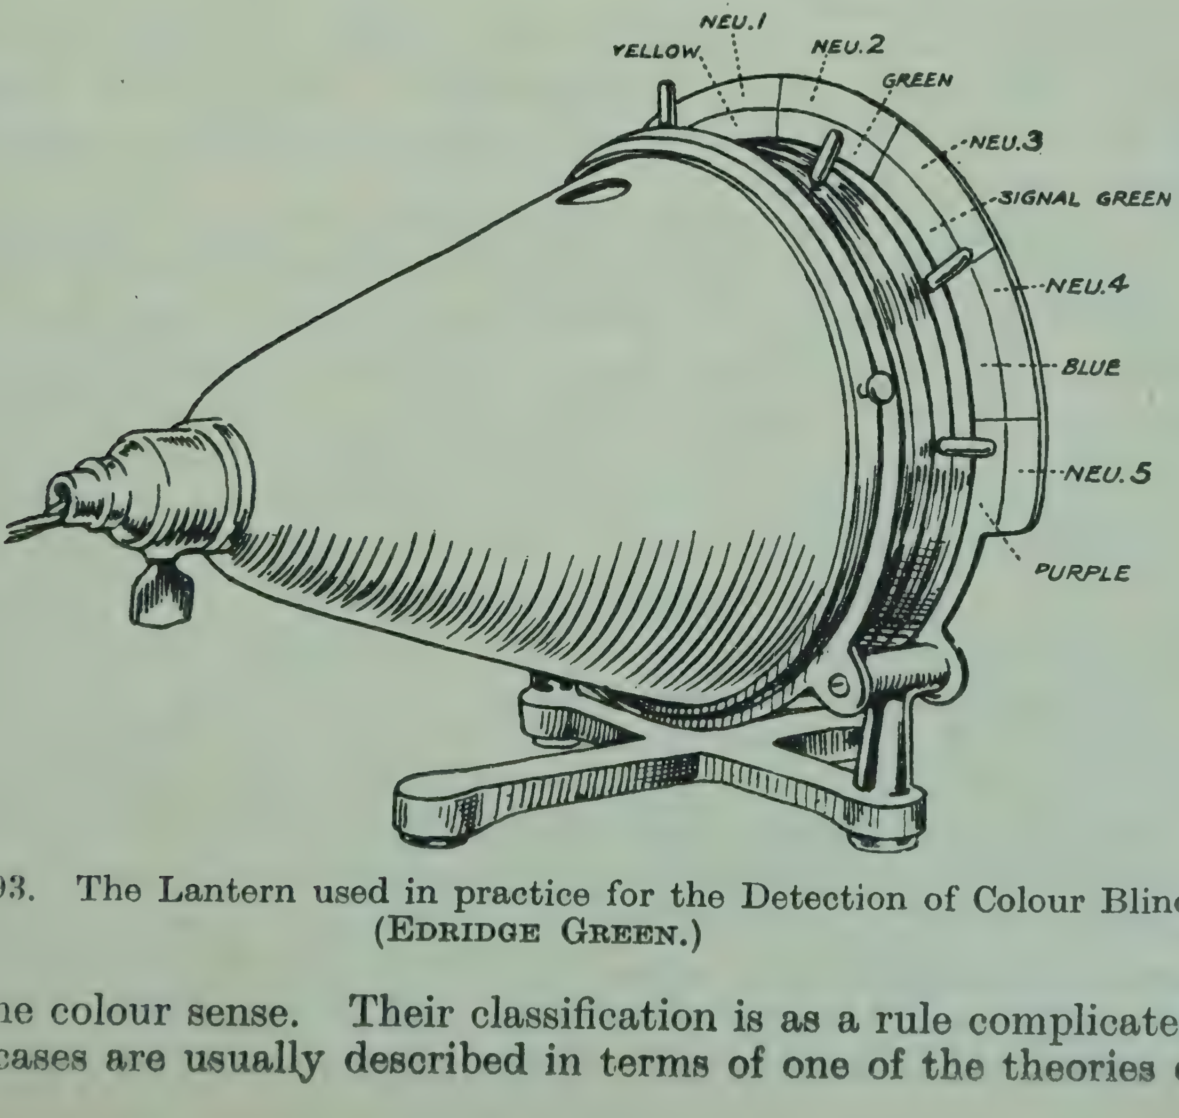

FIG. 293. The Lantern used in practice for the Detection of Colour Blindness. (EDRIDGE GREEN.)

vision. Most varieties of colour blindness are inherited, and are commoner in men than in women. But it may also be acquired, as explained above, in poisoning by alcohol and tobacco. Cases of colour blindness may be grouped as follows :—

(1) Cases in which the cone mechanism of the retina is not functioning. The patient is found to be colour and day blind ; red is not seen at all, while the other colours are seen as different shades of grey. Vision at night is good, vision by day is complicated by the fact that the patient must not expose his eyes to a bright light, for otherwise his visual purple will become bleached and his rod apparatus therefore cease to function. Owing to the absence of rods from the fovea, this part of the retina is blind. Visual acuity is therefore low. When tested by the flicker method, his luminosity curve is found to correspond with that of twilight vision. His condition may be improved by using neutral tinted glasses fitted with a sky shade.

(2) Cases in which the cone apparatus is apparently normal, that is to say, there is no avoidance on the part of the patient of strong light, no diminished visual acuity, no foveal blindness and no inability to see red light. Yet there is absolute inability to recognise all colours, any one part of the spectrum being able to be matched by any other. Tests by means of the flicker method show a luminosity curve which corresponds to that of day vision. It would seem clear that the retinal apparatus is in every way normal ; one is therefore forced to the conclusion that the defect concerns the brain centre which subserves the appreciation of colour. This view is supported by the fact that, between this extreme type and normal colour perception, there are a large number of cases which show various grades of defect. Some, for example, see two colours at the ends of the spectrum only, the intermediate portion being a neutral colour ; others see three only, at red, green and blue, and so on. Since in all these cases the cones are apparently normal, there would appear to be a parallel with cases in which there is no trace of deafness, and yet there is an inability to appreciate harmony, or to tell when two notes are in tune. In both types of cases, it would seem that the higher centres of perception and appreciation are either absent or are undeveloped. As might be anticipated, therefore, instruction and practice at colour naming and colour matching benefit a certain number of these cases, so that it is sometimes found that after such instruction the less abnormal cases are not readily detected. If, however, they are tested in a poor light, they are found to make mistakes which a person with normal vision would not commit. As these are the circumstances under which signals have frequently to be recognised, it is for this reason that the lantern test with its modifying glasses is so valuable.

(3) Cases in which certain parts of the spectrum are not seen at all. This condition frequently affects the red end of the spectrum, but it may be found in other parts. The principal effects to be noted are : (i) an abnormal type of luminosity curve, as examined by means of the flicker method ; (ii) the requirement of different amounts of the primary colours in order to match a given spectral colour, as compared with individuals of normal vision ; (iii) inability to recognise the normal number of different hues in the part of the spectrum affected, as shown by the spectroscope test ; (iv) shortening of the spectrum, if either of the ends of the spectrum is affected. These cases therefore show quite distinct features, which at once differentiate them from those of class 2. A typical example of a case belonging to class 3 will now be described, namely that in which there is shortening at the red end of the spectrum. The flicker test shows that the luminosity curve for different parts of the spectrum has its maximum in the green, instead of in the yellow. Further, the curve does not extend so far into the red, or show such high values in the orange as the normal curve. This curve therefore explains the apparent shortening of the spectrum. Colour mixture experiments show that the patient can match mixtures of green and blue with white light. When required to match yellow, he uses an excessive amount of red, and correspondingly less green than the

normal sighted; this test again shows the deficiency of the red sensation. Tested by the spectroscope, it is found that, besides the shortening at the red end of the spectrum, there is also an inability to distinguish the normal number of hues at the green and yellow. This effect is readily explained, because the difference between green and yellow shades largely depends on the varying extent to which they stimulate the red sensation. When the red sensation is absent, it is clear that the differentiation of greens and yellows must suffer.

10. THEORIES OF COLOUR VISION

The value of a theory to science is as much due to the fresh lines of research which it indicates, as to the explanation which it offers of the already ascertained facts. The theories of vision, therefore, are of value in spite of the fact that they do not at the present time offer a complete account of the retina and its functions.

THE DUPLEX THEORY of von Kries states that the retina shows two different types of response, one for low illumination and one for high, *i.e.* twilight vision, which is colour blind, and day vision, which responds to colour. The view that the rods with the visual purple supply the former, whereas the cones provide the latter, is one widely held and is already familiar, because it has been made the basis of the description given in previous sections. The evidence on which this opinion is based may with advantage be repeated because of its importance.

Twilight vision is found in those parts of the retina where there are rods; it is not present, therefore, at the fovea centralis, which consists entirely of cones. If a spectrum be examined, it is found that the colour with the greatest luminosity is the green, but that red rays are not seen at all. The form of the luminosity curve is identical with the bleaching curve of visual purple, and this pigment occurs only where there are rods. The acuity of twilight vision is low, and is explained by the fact that many rods as a rule send their impulses through one and the same nerve fibre.

Day vision is most highly developed in the fovea, from which rods are absent. Not only are the cones at the fovea placed very closely together, but it would appear that each cone connects to one nerve fibre only; in this way the high visual acuity is explained.

It has been suggested recently that the following modifications should be made in the duplicity theory of von Kries:—

1. That the cones do, in certain cases, function to some extent in night vision, thus retaining one of the primitive characteristics of rods, from which on morphological grounds they appear to have been developed.

2. That the fovea contains some visual purple, this being necessary in order that the cones may function in night vision as above, or possibly for the green sensation of vision.

3. That the rods play some part in day vision, adding their response to that of the day cones.

These modifications of the duplicity theory concern detail more than they do the basis of the theory, and do not appear to detract at all from the strength of its position. Hence, so far as the relative rôles of the rods and cones are concerned, there would not appear to be any room for speculation. Such is not the case, however, with regard to colour vision because, of the various hypotheses that have been so far advanced, none has been found to offer a feasible explanation of all the known facts, or to leave no other possible alternative. A brief account of the rival theories may with advantage be given.

YOUNG'S HYPOTHESIS states that there are cones of three different kinds, namely red, green and blue. The impulses from these cones are so combined in the brain that they give a complete picture of the separate coloured images. When all three types of cone are stimulated by white light, a colourless sensation results. Each visual unit may therefore be regarded as consisting of three cones, one of which responds to each of the fundamental colours. From this we should expect that the limit to the acuteness of vision would be reached when the separation of the images on the retina is not less than the diameter of such a unit. But the diameter of the foveal cones is approximately 0·0025 mm., and therefore that of a unit would be roughly 0·004 mm.

When the visual acuity of the eye is measured using monochromatic light it is found hat the limit is reached when the retinal images are separated by about 0·002 mm. The conclusion from this is, that the unit of response cannot be larger than one cone, and this uggests the idea that each of the cones of the fovea must be capable of responding to all hree of the funamental colours. There are thus two rival views for trichromatic vision : 1) Young's original hypothesis that there are three different kinds of cone; (2) the modified ypothesis that there is only one kind of cone, but that this is capable of responding to all hree fundamental sensations. These hypotheses will be considered in detail and then their elative advantages and disadvantages will be considered.

THE MULTIPLE CONE HYPOTHESIS. According to this hypothesis every cone f the retina is capable of responding to one colour sensation only. Thus in the fovea entralis there must be at least three different types of cone, those responding to red, those o green, and those to blue.

According to this hypothesis the brain receives nerve impulses which inform it of the colours which are present in the images formed on the retina. The possibility that every one of these cones behaves in an all-or-none manner was suggested by Hecht, but it is also possible that each of these cones responds in a graded manner sending impulses along the optic nerves which vary in frequency according to the intensity of light falling on the cone in question. This view, which was suggested by Hartridge, has been supported experimentally by Granit, by Hartline and others.

THE SINGLE-CONE HYPOTHESIS. According to this hypothesis every cone of the retina is capable of responding to more than one colour sensation, so that, for example, in the fovea centralis every cone can give responses to three colour sensations.

So far as is known no single nerve fibre is capable of transmitting more than one kind of nerve impulse. Moreover, each cone of the retina connects with one fibre of the optic nerve and no more. In consequence every cone must be capable of transmitting up its nerve fibre three different sensations, and this can only be done by variations either in frequency or in the pattern of the nerve impulses which are sent up to the brain. Suppose, for example, that when a cone responds to red rays it sends up its nerve fibre 100 impulses per second, whereas when responding to green it sends up 300, and for blue 1,000. Then provided that the brain has the necessary structure for recognising these three different frequencies, recognition of red, green or blue may be satisfactorily explained. When, however, two colour sensations are simultaneously being perceived there would have to be a transmission of two separate frequencies to the brain. It does not seem easy to picture the simultaneous transmission of two or more such frequencies.

Now since the type of colour sensation is determined by frequency, it is impossible for intensity of light to be transmitted by any variation in the number of nerve impulses per second sent up the particular nerve fibre. In consequence, it is a corollary of this hypothesis that each cone performs in an all-or-none manner and that different cones have different thresholds so that as the intensity of light increases the number of cones responding to that light increases, thus the active cone population will be small when light intensity is small and will increase to a maximum number as light intensity increases. Sooner or later, as this increase in light intensity continues the whole of the cone population will have been brought into a state of activity and no further increase of light intensity which may take place will cause a corresponding increase in the intensity of the sensation received by the brain.

EVIDENCE AGAINST THE SINGLE-CONE HYPOTHESIS. Granit found irrefutable evidence against the single-cone hypothesis when he discovered that a micro-electrode applied to the different fibres of the optic nerve of an anæsthetised or decerebrate animal picked up differences of electrical potential, when the retina as a whole was exposed to light. Thus one fibre might be connected to a receptor with a marked green response while another fibre might be connected to a receptor with a markedly orange response. Thus in the frog's retina there were found to be one type of receptor with a broad response, which he called a dominator, and five different types of receptors with responses in narrow spectral regions, which he called "modulators." (See Table on p. 440).

It will be shown later that we have strong evidence for postulating a similar arrangement in man's retina. Now this idea meets with difficulties concerning the acuity of the eye by white light and by coloured lights, because it would be expected that acuity for fine detail would be superior when white light is in use to that found when coloured lights are in use instead, because white light acts as a stimulus for all receptors irrespective of colour property, whereas coloured lights act as stimuli for only a few. Thus if the acuity by white light be made equal to unity, that by red or by green light might be expected to have a value of one-half, or perhaps one-third. But experiment demonstrates no such large differences, as is clearly shown in the table below.

RELATIVE ACUITIES BY LIGHTS OF DIFFERENT COLOUR

Observer	Test object	White	Red	Green	Blue
Shlaer *et al*	Grating	1	0·91	1·02	1·00
,,	Landolt's C	1	1·00	—	1·00
Hartridge	Letters	1	0·82	0·96	0·90
,,	Landolt's C	1	0·84	1·00	0·92
	Mean values	1	0·89	0·99	0·92

Thus acuity, when using red light or blue light, appears to be slightly less than that obtained when using white light or green light. But in fact the differences are within the experimental error of the method.

We see then that expectations from the multicone hypothesis, that acuity by white light would be superior to that by coloured lights, is not fulfilled. How can this discrepancy be explained ? An explanation can be obtained on the basis of the cluster hypothesis.

THE CLUSTER HYPOTHESIS. In any random distribution of several different populations there are always places to be found where one population predominates over the others. An excellent example of this is the colour screen of the Lumiere photographic plate. In this there are distributed irregularly three different coloured groups of starch grains, red grains, green grains and blue grains. When such a screen is looked at with the naked eye, red, green and blue dots are clearly visible. On examining these dots with a microscope it is seen that they are not due to isolated starch grains but to quite large groups of grains of almost entirely one colour. Now if the cones of different colour-response are distributed irregularly in the same way, we should expect to find places where the red cones predominate, other places where green cones are in excess, and other places again where blue cones are nearly exclusively present, and so on. In consequence, when high visual acuity is wanted for any one colour it might be obtained if it were possible by slightly rotating the eyes, to cause the image of the object in question to fall on a part of the retina where the cones predominate, which are sensitive to that particular colour. In the case of yellow light, a spot where there is a predominance of both red and green cones with the almost complete exclusion of blue cones, would be most suitable for the purpose.

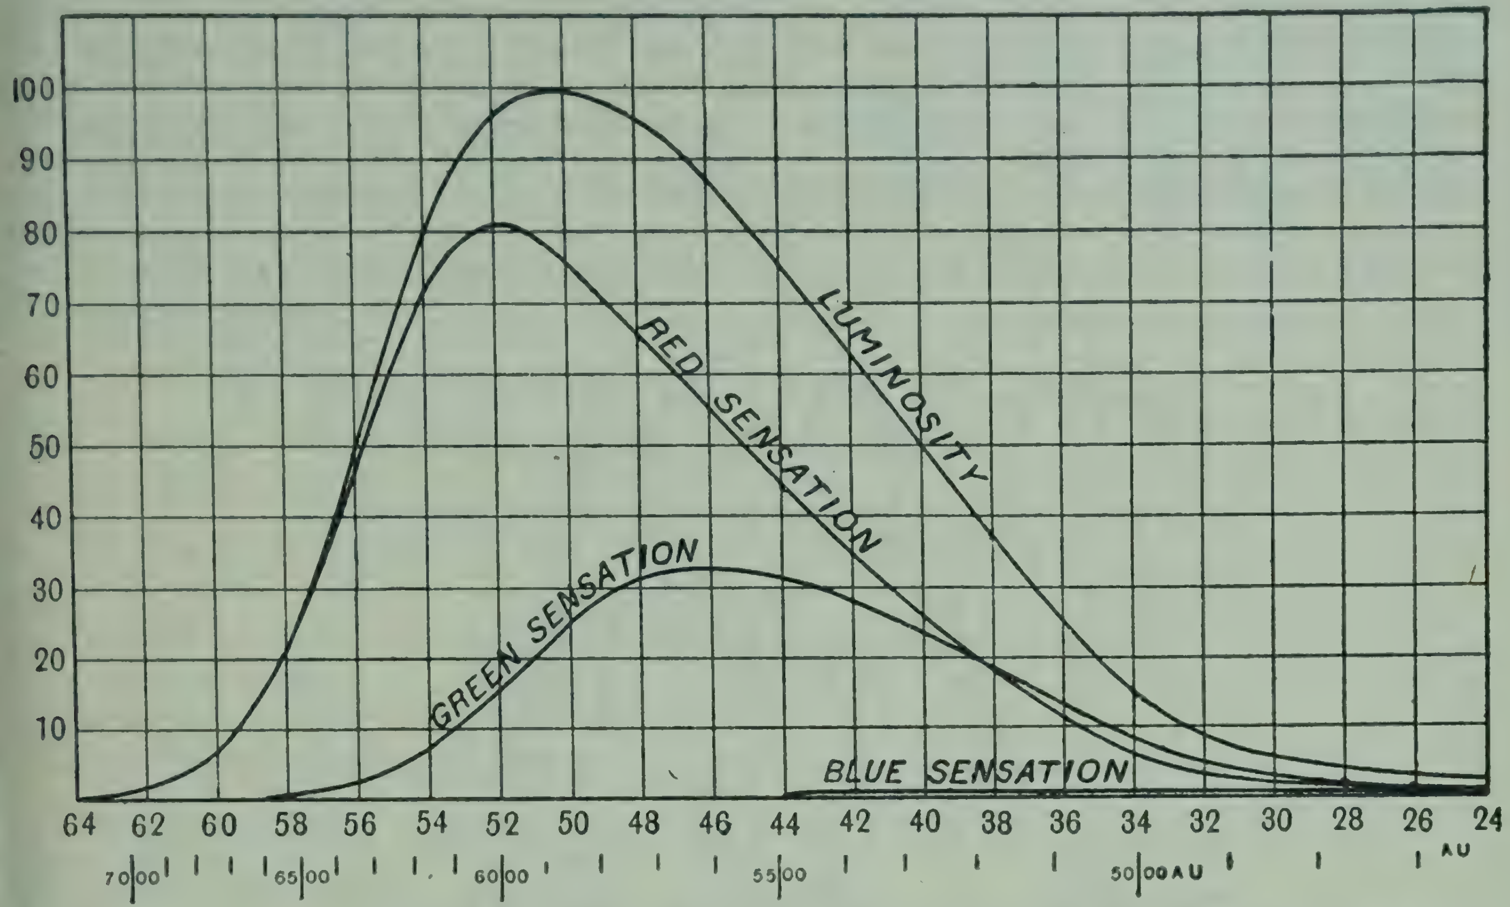

FIG. 294. The red, green and blue Sensation Curves and the Luminosity Curve of white Light. Luminosity vertical, wavelengths horizontal. (ABNEY.)

THE POLYCHROMATIC THEORY. Three independent lines of research give support to the view that human vision is polychromatic and not trichromatic as has long

been supposed, and that the three-colour theory is an approximation which is applicable solely to foveal colour vision at medium light intensities and visual angles. The three lines of research are: (1) the micro-electrode experiments on animals, of Ragnar Granit; (2) the biochemical experiments on vitamin A derivatives, of Morton and his associates; and (3) the human experiments of Hartridge.

Granit's technique, which is illustrated diagrammatically in Fig. 295, consists in removing the anterior eye structures from a deeply anæsthetised or decerebrate animal and in applying to the fibres of the optic nerve a fine wire electrode which is coupled to a valve amplifier of high gain, the output of which is either connected to a loudspeaker or to a cathode ray tube according to requirement. The retina is illuminated by means of a monochromator, the experimenter's object usually being to determine for the different parts of the spectrum the minimum light energy required in order to produce a noticeable response on the part of the optic nerve fibre with which the electrode is in contact. After the examination of one nerve fibre the electrode is raised and is placed into contact with another, and so on.

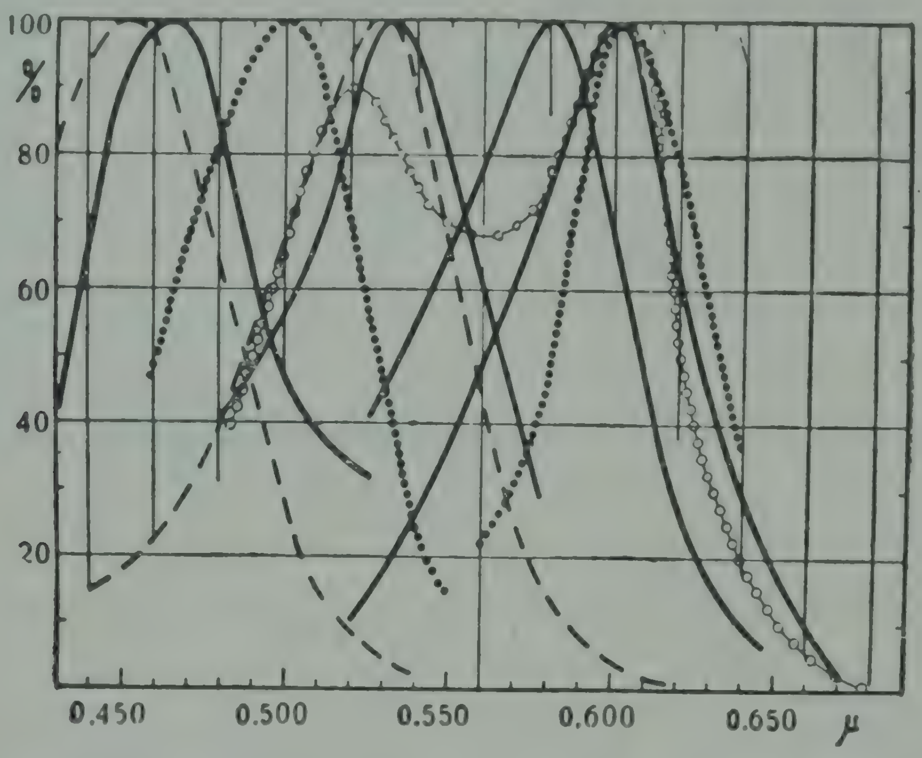

FIG. 296. Granit's Modulator. From "The Sensory Mechanisms of the Retina," 1947.

Granit has discovered in this way two essentially different kinds of receptors which he has called "dominators" and "modulators." The former exhibit wide response curves which extend over the greater part of the visible spectrum. The latter exhibit narrow response curves which are restricted to a particular spectral region; see Fig. 296. The positions of the crests of the latter in the spectrum are shown in the table below.

Ball, Collins, Morton and Stubbs (1948),* on applying strong acids such as concentrated sulphuric acid and syrupy phosphoric acid to vitamin A_1 or to retinene$_1$, which is itself an aldehyde of the former, find that they obtain a number of pigmented substances which have narrow modulator-like absorption bands which occupy characteristic positions in the spectrum. Moreover these pigments resemble visual purple in being sensitive to light. The positions of the crests of their absorption bands are shown in the following table.

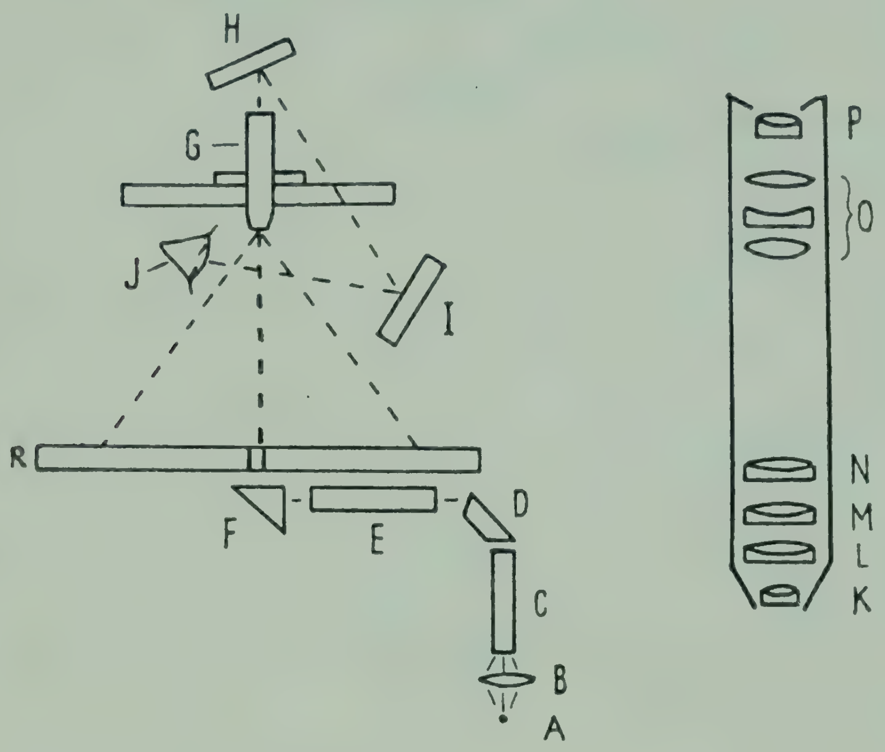

FIG. 297. Hartridge's Microstimulation Apparatus.

Light from the source A is focussed by the lens B into the monochromator C, D and E. The coloured rays emerging from the latter are reflected vertically upwards by the prism F. These coloured rays, together with rays from other sources placed on the board R, are greatly reduced in visual angle by means of the optical system G, some details of which are shown on the right at K to P. The reduced images are viewed by the eye of the observer J via the two plane mirrors H and I.

Hartridge, using a microstimulator, which presents to the observer's eye one or more minute points of coloured or monochromatic light (see Fig. 297), finds evidence for modulator-like receptors in the human retina, occupying certain characteristic spectral regions. These are shown in the table below.

Wave-length	Animal modulator	Human fixation point	Human subjective colour	Receptor	Unit	Wave-length
0·66		0·66	0·64	Red . .	R–BG–R	0·660 ?

* Found in the guinea-pig and the rat.
† Found in the cat, at 0·44μ.

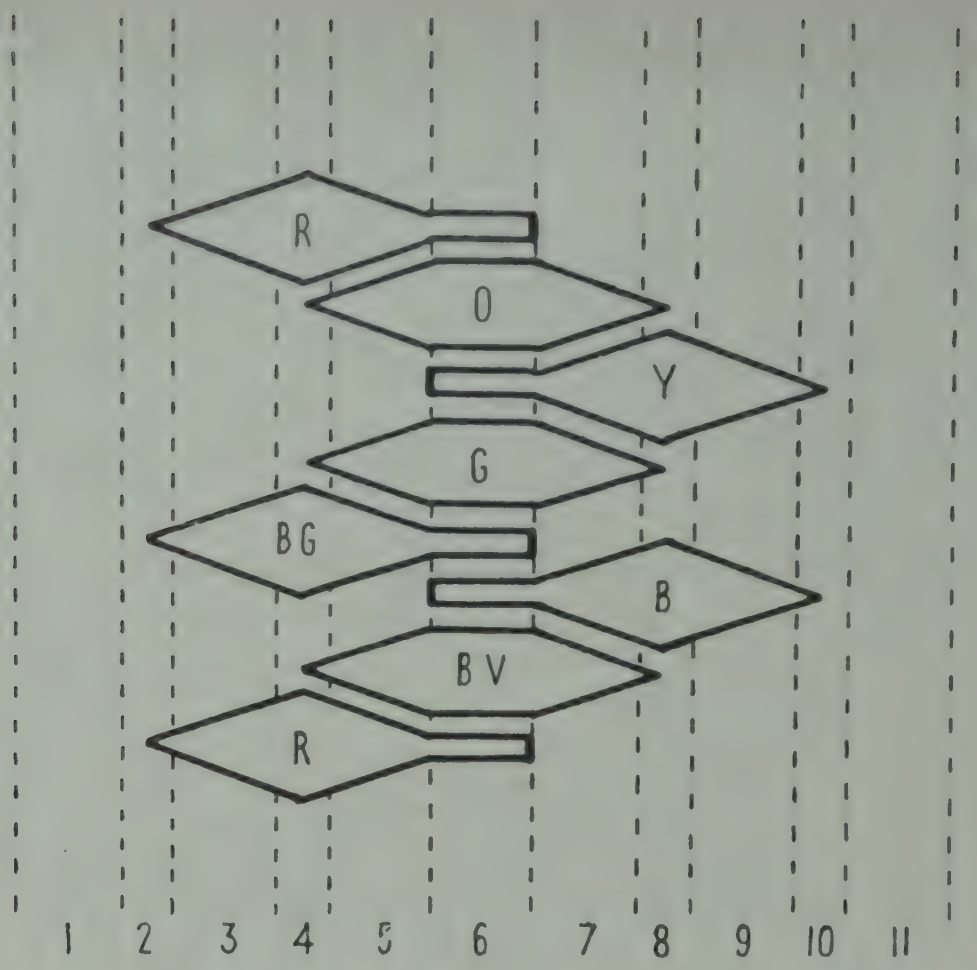

FIG. 298. The areas R, O, Y, G, BG, B, and BV indicate approximately, by their widths, the degree of activity of the receptors for red, for orange, for yellow, for green, for blue green, for blue and for blue violet, under different conditions of vision. (1) For the fovea at very low light intensities or very small visual angles. (4) For moderately low light intensities and rather small visual angles. (6) For the fovea at ordinary light intensities and visual angles of two degrees. (8) At the fovea for high light intensities, and in the near periphery of the retina for ordinary light intensities. (11) At the fovea for excessively high light intensities and at the extreme periphery of the retina for ordinary light intensities.

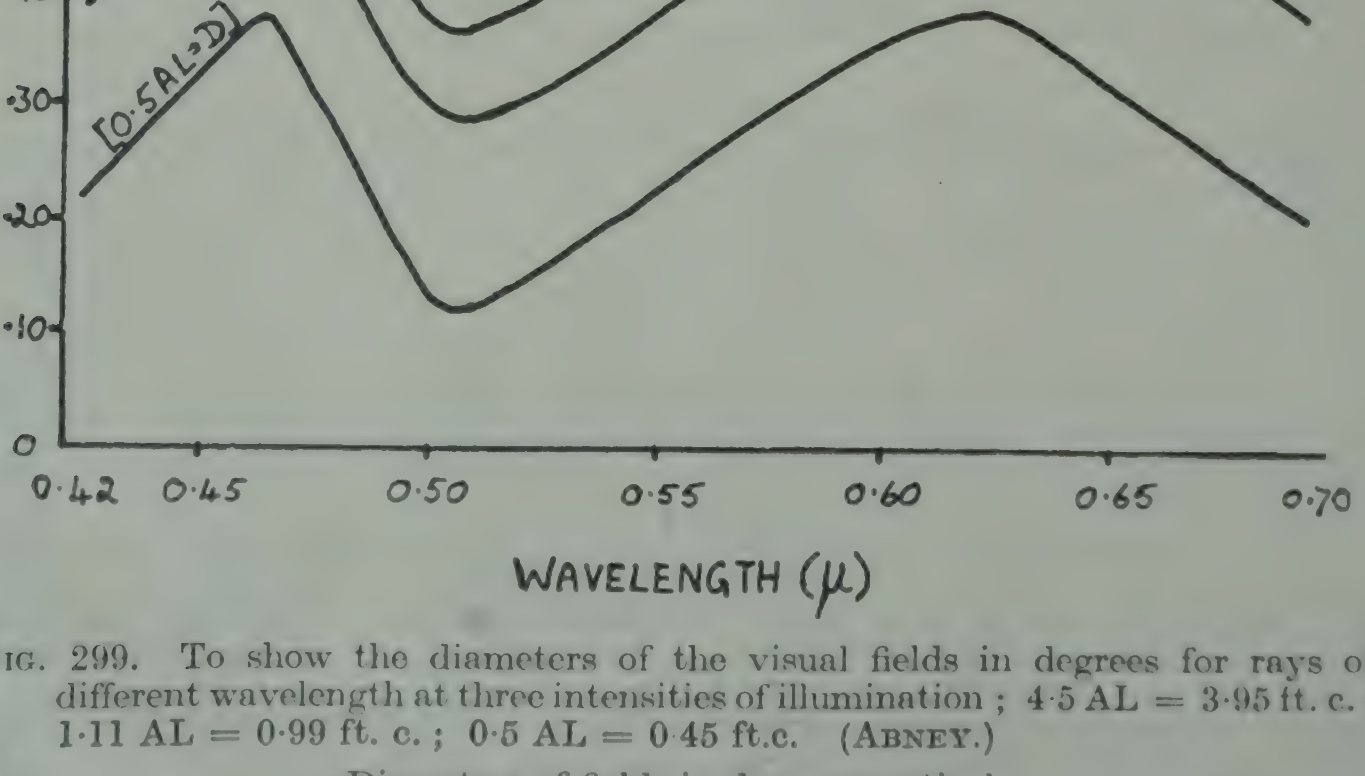

FIG. 299. To show the diameters of the visual fields in degrees for rays of different wavelength at three intensities of illumination; 4·5 AL = 3·95 ft. c.; 1·11 AL = 0·99 ft. c.; 0·5 AL = 0·45 ft.c. (ABNEY.)

Diameters of fields in degrees vertical.
Wavelengths (μ) horizontal.

Thus there are seven varieties of receptor in man, six of which have simple modulator-like response curves resembling those found in animals (see Fig. 296); the seventh one has twin responses, one in the extreme red and one in the extreme violet. If this receptor by itself was stimulated by light it would produce a sensation of a crimson or mauve light.

According to the polychromatic theory these receptors are arranged in three units: (*a*) a tricolour unit comprising the orange (0·600μ), the green (0·547μ), and the indigo (0·450μ) receptors; (*b*) a dichromatic Y–B unit comprising the yellow (0·578μ) and the blue (0·476μ) receptors, which are complementary in colour to one another; and (*c*) a dichromatic R–BG–R unit comprising the red (0·66μ and 0·42μ) and the blue green (0·50μ) receptors. These also are complementary in colour to one another. At the normal fovea, at medium light intensities and average visual angle, the tricolour unit has the greatest activity, but it is assisted by both the other units; see Fig. 298 at "6."

At high intensities of illumination the fovea exhibits a yellow-and-blue dichromatism due to the Y–B unit, the other two units having become inactive; see Fig. 298 at 9. At higher intensities still all colour vision disappears and there is colourless foveal vision; see Fig. 298 at 10 and at 11.

At low intensities of illumination the fovea exhibits a crimson-blue green dichromatism due to the R–BG–R unit, the other units having gone out of action; see Fig. 298 at 4. At lower light intensities still, all colour vision ceases and there is colourless foveal vision; see Fig. 298 at 2 and at 1.

Peripheral colour vision bears strong resemblances to foveal vision at high intensities of illumination; that is, there is a yellow-blue dichromatism at medium perimetric angles, and colourless peripheral vision at large ones. In Fig. 299 are shown the sizes of the perimetric fields as measured by Abney at four colour brightnesses. It will be noticed that the blue-green and the red and violet ends of the spectrum are the colours with the smallest fields, due to the R–BG–R unit having a small field. On the other hand, the yellow and blue regions of the spectrum have the largest fields, due to the large field of the Y–B unit.

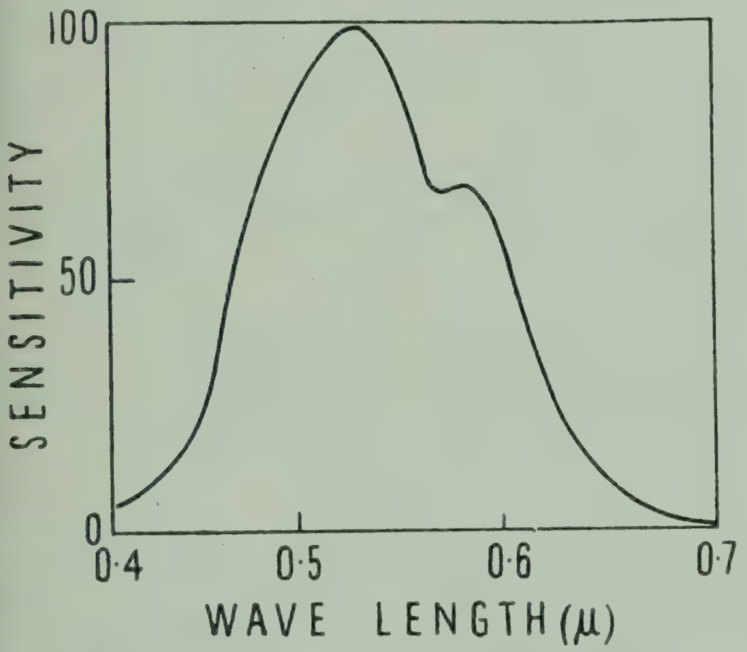

FIG. 300. Wright's notch in the foveal luminosity curve in the yellow part of the spectrum due to the use of a test object subtending a small visual angle at the observer's eye.

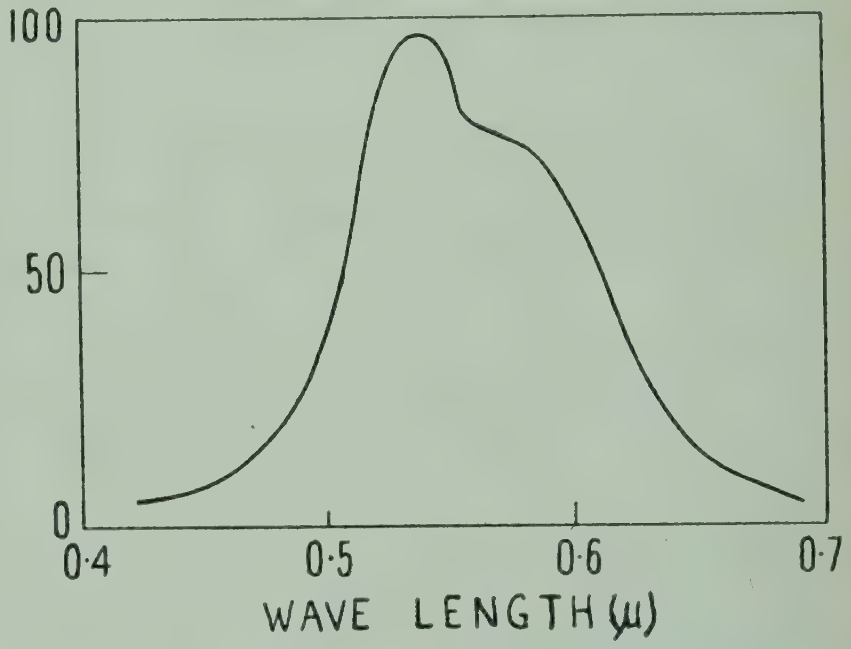

FIG. 301. Sloan's notch in the foveal luminosity curve in the yellow part of the spectrum due to the use of a low intensity of illumination.

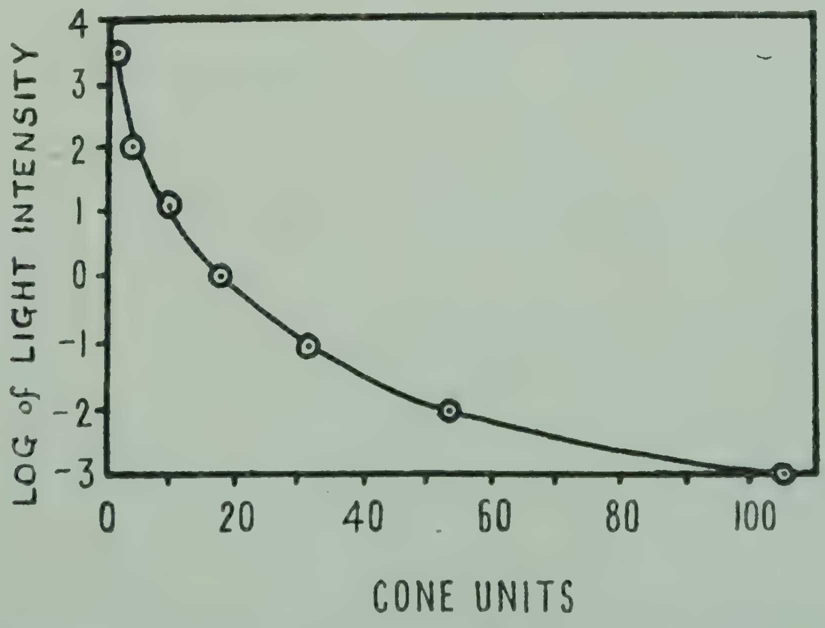

FIG. 302. Relation between light intensity and visual angle subtended by test object (see text).
Log of light intensity, vertical. Visual angle, in cone units, horizontal.

At small visual angles, the fovea exhibits a type of vision which is similar to, if it is not identical with, that found at low light intensities. Here are some points in favour of this view : (*a*) Both cause in an early stage the replacement of yellow by pale grey or white, and of blue by dark grey or black, and at the same time notches develop in the luminosity curve : Sloan's notch with reduction of light intensity ; see Fig. 301 ; and Wright's notch with reduction of visual angle ; see Fig. 300. (*b*) The visual angle at which the change takes place, either of yellow to white or of blue to dark grey, is altered by changes in light intensity. A high intensity causes a smaller visual angle to be required, and *vice versá*, as shown in Fig. 302. (*c*) With sufficient reduction of visual angle, or light intensity, or both, a red-blue-green dichromatism develops. And lastly, (*d*) with a still further reduction of light or angle, or both, all colour vision is lost and there is colourless foveal vision. In these and other respects the two changes in foveal vision resemble one another closely, if they are not identical.

With regard to the red-blue green dichromatism mentioned above, Fig. 303 shows the spectral coefficient curves obtained by Willmer and Wright for this type of foveal vision.

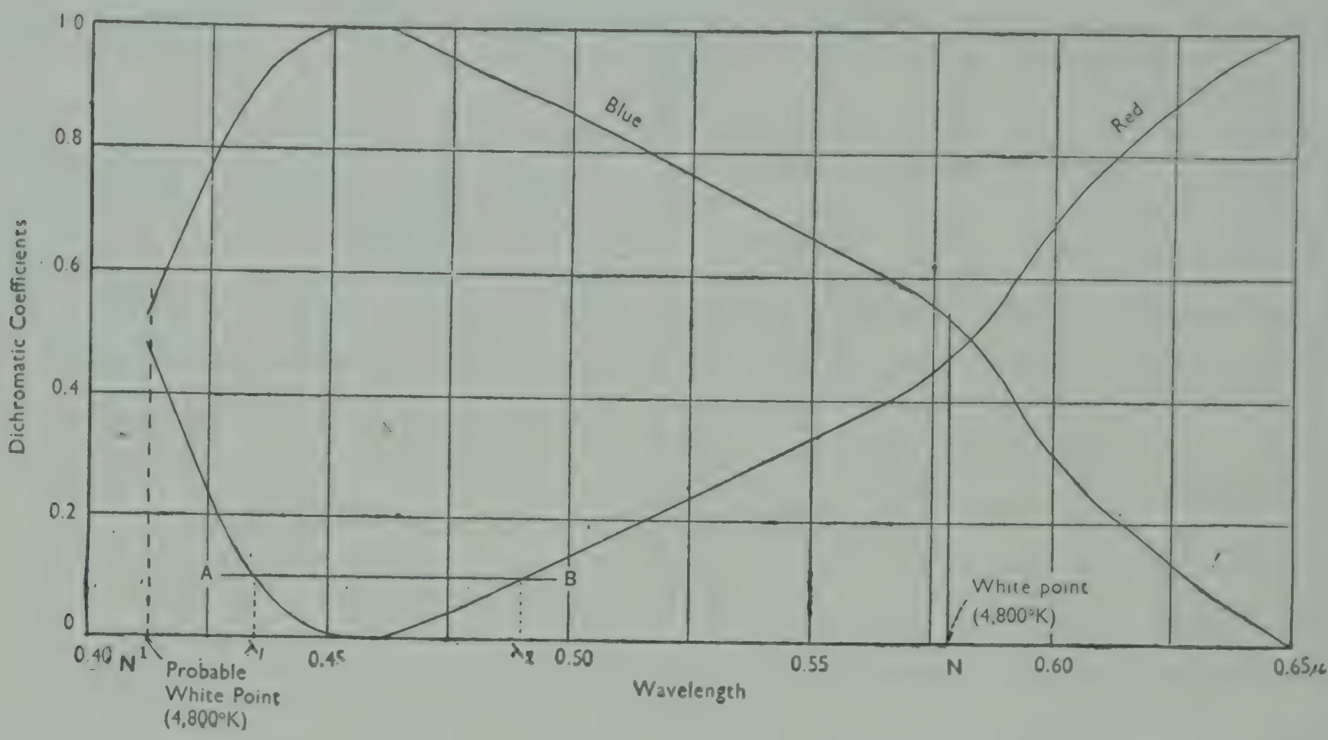

FIG. 303. Spectral coefficient curves for the fovea using 15 minute fields. Two neutral points are found ; one in the yellow at N and one in the blue at N¹. Arbitrary units vertical. Wavelengths in μ horizontal. (WILLMER AND WRIGHT.)

It will be observed that the red curve which falls to a low value at the medium wavelengths of the spectrum rises towards both the long and the short wavelengths. This is typical of the R receptors of the R–BG–R unit. The green curve gives its maximum response at medium wavelengths and decreases in activity toward either end of the spectrum. There are two neutral points in the spectrum, one in the yellow, the other in the blue, which are marked by N and N′ in Fig. 303. It will be recollected that yellow and blue are the two colours which are replaced by grey when either visual angle or light intensity are reduced.

THE CORRECTION OF THE CHROMATIC ABERRATION OF THE EYE. It will be remembered that the chromatic aberration of a lens causes the production of narrow yellow and blue fringes, which surround large objects and which replace small ones. The same statement applies to the lens-system of the eye. It might be supposed, therefore, that the correction of this aberration of the eye by means of a Helmholtz lens consisting of a combination of crown and flint lenses, or its elimination by means of monochromatic light, for example sodium light, would bring about the removal of these fringes and would therefore improve the acuity of the eye. But experiment shows no improvement, and moreover the fringes are invisible when the eye is used for normal vision. The causes of these apparently contradictory statements have long been under discussion. The true explanation is as follows : In the case of a test object constituted of a white dot on a black background, chromatic aberration causes the retinal image to be a yellow dot surrounded by a blue halo. But owing to the small visual angles which both dot and halo subtend at the eye, yellow is replaced by white and blue by black, so that the original appearance is returned to. In the case of a black line on a white background, chromatic aberration substitutes a blue line surrounded by a yellow halo on a white background. Now, as before, yellow becomes white and blue becomes black, and the original appearance is restored. By means of lens systems of special design it is possible to increase the chromatic aberration of the eye. When this is done it is found that the correcting effect present in the case of the eyes of one observer is sufficient to correct about double the natural aberration present. This is the probable reason for being able to use simple convex lenses, uncorrected for colour, in conjunction with the eye, as spectacles and as magnifying glasses.

The Colour Responses of the Human Eye. We have seen that the colour fringes which are introduced into the retinal image by the aberrations of the lens system of the eye are removed again by a process which consists essentially of an alteration in colour vision. Thus yellow and blue test objects viewed at large visual angles are seen in the proper hues, but the yellow and blue fringes, being viewed at small visual angles, are not. How are these changes in colour vision brought about ? Hartridge investigated a number of possible mechanisms and decided that the only feasible one was neurological in nature, that is, a nervous process alters the normal polychromatic vision of the fovea to a red-blue-green dichromatism. Now it is obvious that identical questions arise with regard to the other changes in foveal colour vision which occur, for example, with change of light intensity or of adaptation. Moreover at the periphery of the retina alterations of light intensity or of visual angle also alter the type of colour vision met with. How are these brought about ? Are they also caused by some neurological " response " ? Only further research can supply us with the answers to these and related questions.

11. BINOCULAR VISION

Binocular vision may be defined as the co-ordinated employment of two separate visual organs in order to produce a single mental impression. The advantages of binocular as opposed to monocular vision are :—

(1) Optical defects of one eye are less important, since they are masked by the well-defined images of the other eye.

(2) Defective vision in parts of the visual fields of both eyes is hidden, so long as the defects do not affect the same parts of both fields. Thus under ordinary circumstances, each blind spot does not obtrude itself because in the other eye the image of the same part of the field falls on functional retina.

(3) The combined fields of the two eyes are larger than either alone because, while the features restrict the nasal halves of the fields of both eyes, the combined field contains the unrestricted temporal areas of both retinæ.

(4) Binocular vision under certain circumstances provides a very accurate perception of depth, size and distance, which is called stereoscopic vision.

In order that there should be binocular vision the following conditions should be complied with :—

(1) The fields of the two eyes must overlap. Animals in which the eye axes are parallel have the greatest overlap, and therefore possess the most perfect binocular vision.

(2) Approximately similar images must be formed on the retinæ, because if this condition is not satisfied, antagonism between the images will occur, as described above, and first one image and then the other will be presented to consciousness.

(3) The retinæ must possess physiologically corresponding points, in order that similar images formed on them may produce one conscious impression.

(4) The external eye muscles must so adjust the visual axes, that the centres of the fields of the two eyes coincide with the images of one and the same object. This adjustment is called fixation. It is sometimes described as the intersection of the visual axes at the point fixated.

(5) The oblique muscles must rotate the eyes about their axes, until corresponding retinal points occupy corresponding meridians.

The rotation adjustment is necessary because otherwise identical points of the retinæ might not correspond, even when the centres did, so that one image would appear tilted at an angle with the other.

The Horopter. Theory shows that, even when fixation is properly effected, so that corresponding retinal points occupy the same meridians, images formed on the retinæ do not necessarily fall on corresponding points. For this to be the case, it is necessary also that the objects from which those images are formed should occupy certain definite positions in relationship with one another. For example, if an object 10 feet from the eye is fixated, the images of other objects on either side will only fall on corresponding points if they lie on a circle of 5 feet radius, the centre of which is between the observer and the object fixated. For calculation shows that only then are the images formed on the two retinæ at the same distances from the centres. The form of the curve, which is called the horopter, is found to change with the different directions of the gaze. When the gaze is directed to a point on the floor, it is stated that the horopter almost corresponds with the plane of the floor.

Monocular Depth Perception. The perception of depth with the single eye is found to depend on a number of different factors, which as a rule operate together :—

(1) The apparent size of objects, the dimensions of which are known. Thus the size of a man being approximately known, his distance away is deduced from the size of the image which is formed on the retina. The further away he is, the smaller his image will appear.

(2) The colour of an object being known, the effect of distance in modifying that colour is used in depth perception. Thus trees, which when near look yellow-green, when seen at a distance through an intervening layer of haze appear blue-green or even blue. This fact is made use of by artists for expressing distance (" ærial perspective ").

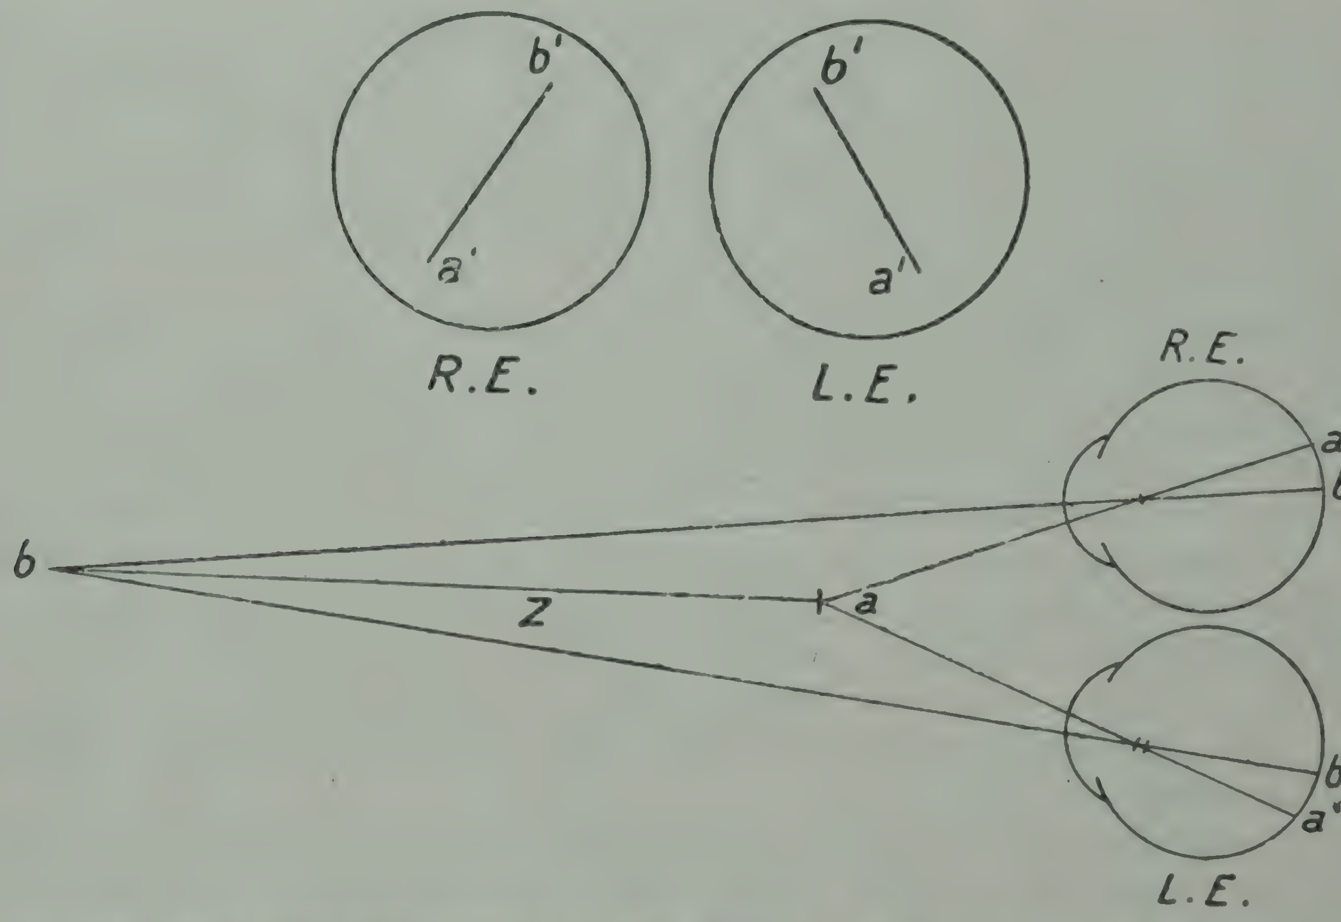

Fig. 304. The eyes are directed to the point *b*. A thread hung obliquely at *a* gives rise under these circumstances to the images shown in the upper figures —*i.e.* two images which do not lie on corresponding points. Nevertheless the thread is seen as single.

(3) The partial obstruction of a distant plane by objects nearer to the observer.

(4) The shadows which one plane casts upon another.

(5) The intensity of the light which is reflected by the object frequently varies with its shape and position. For example, the shape of a solid sphere can be accurately inferred from the distribution of intensity over its face.

(6) By linear perspective, which may be defined as the geometrical arrangement of lines in the image formed on the retina. Thus the lines of a tennis court seen diagonally from one side are all found to converge to one or other of two points on the horizon.

(7) By the intersection of objects with the horizontal plane. Thus the positions of trees in a field may be inferred with some accuracy, if the positions of the roots of the trees in relationship with the boundaries of the field be observed.

(8) By parallax, that is, the apparent movement of objects in relationship with one another. Thus if a middle plane be looked at, and the observer moves, it will be noticed that objects in a plane behind appear to move in the same direction as the observer, while those in a plane in front appear to move the opposite way. Even when we are standing still, we are all the time making involuntary movements which cause the development of parallax. This process is probably one of the most important in producing the monocular effect of depth.

(9) By the effort of accommodation required to focus an object sharply. In man the accommodation is found by experiment to give little or no perception of depth, possibly because the function is involuntary. It is thought that in birds, in which the ciliary muscles are striated and are under voluntary control, the accommodation may give valuable information of distance.

All the above factors operate together to produce an appreciation of distance which as a result of experience reaches a very high order, and with the exception of the last two, are used by the artist to produce the effect of solidity and reality. Any good picture shows us that the result can be very convincing.

STEREOSCOPIC VISION is the binocular perception of depth. It consists of all the factors which operate in the case of each eye separately, and in addition uses :—

(1) The convergence of the eye axes which is necessary in order to cause images of near objects to form on the fovea simultaneously.

(2) The dissimilarity between the images which are formed on the two retinæ (Fig. 305).

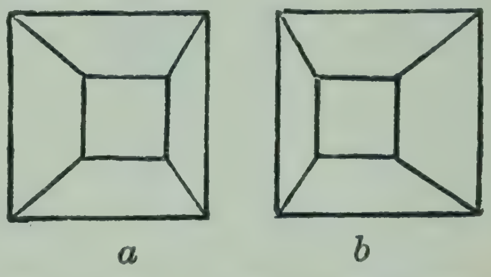

FIG. 305. To show the difference in the Images of a Truncated Pyramid as given by the right and left eyes.

That convergence has very little effect on the perception of distance can be proved by placing weak prisms, either base in or base out, in front of the eyes and in this way changing the convergence of the eye axes without changing any other condition. It is found that the apparent positions of objects are unaffected.

That there is dissimilarity between the images formed on the retina can easily be proved by experiment. Thus, if the gaze be directed towards a distant point, and the finger be held a short distance from the nose, the finger appears to be to the right of the distant point with the left eye and to the left with the right. If two photographs be taken of the same scene, but with the camera for the second photograph three inches to one side of its position for the first, it is found that, when the two negatives are placed so that objects on the horizon correspond, there is a lateral difference of position in the case of all other objects situated nearer to the camera. Measurement shows that the nearer the object the greater the difference in position. Since this is the case, it is clear that only images in one plane can be formed on corresponding retinal points ; images in all other planes must fall on points which are discrepant. Two questions therefore arise : (1) Do we see such objects doubled ? (2) If we see a single image only, is it because one of the images is displaced from consciousness by the antagonism of the other ? An answer is given by the following experiment : A Brewster's stereoscope is taken, the optical arrangement for which is shown in Fig. 306. At B and B′ two similar lantern slides are placed which show a view of any distant objects. On looking through the instrument towards the point S, the directions of the rays are changed, so that the images of the slides are seen to overlap one another. By shifting one of the slides the images may be made to fall on corresponding points of the retinæ, and they then form a single combined picture. In front of these slides is now placed another pair of slides which show the photograph of an index mark. If the indices are adjusted so that they occupy corresponding positions in relationship with the objects on the slides below them, on looking into the instrument it will be seen that these marks appear to lie in the same plane as the distant objects placed on the slides below them. If one of the index marks be moved towards the axis of the instrument, it will be seen on looking into the eyepieces that the indices now appear to lie in a plane considerably in front of their previous position, in fact that the closer they are placed together, the nearer do they appear to the observer. But the indices do not show double images unless they are moved a considerable distance together, and then the effect of distance ceases. If one of the index slides be removed and the other be moved towards and away from the axis of the instrument, the index is not found to shift its plane towards or away from the instrument. This shows that for position to be appreciated both images must be presented to consciousness simultaneously without appearing double.

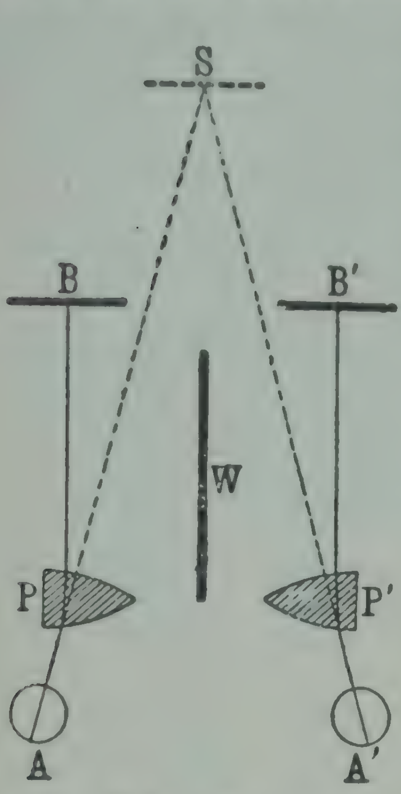

FIG. 306. Brewster's Stereoscope.

THE ACUITY OF STEREOSCOPIC VISION has been investigated in such a way that other factors which normally assist distance perception were excluded. Two methods have been used: (1) to adjust the position of a thread which lies between and parallel with two other threads until they all appear at the same distance from the observer; (2) to observe the fall of small coloured bodies of unknown size, and then to state the position of the line of fall in relationship with a fixation mark. The former method at 2 metres distance shows an average error of 1·5 mm., the latter method at the same distance an error of 40 mm. The difference between the results of the two methods is considerable; but it should be noted that in the fall method the object is seen only for 0·2 sec. If in the thread method the threads be placed horizontal it is found that the appreciation of distance is greatly impaired. The greatest acuity is found when the threads are vertical. If, however, the head is turned so that the line joining the two eyes is vertical, the greatest acuity is found when the threads are horizontal. This would be expected if the appreciation of distance is greatest when the parallax of the objects at the two eyes is greatest. Experiment shows that the recognition of position in relationship with a definite fixation mark is much more accurate than recognition of absolute distance in which there is no point of reference. Thus it is well known how inaccurate the estimation of the distance of a single source of light at night may be.

HYPOTHESIS OF DEPTH PERCEPTION. Javal's view was that the movements of the eye muscles, which are necessary in order to direct the gaze from objects in one plane to those in the next, caused impulses to travel to the brain which are interpreted in terms of distance. This view was ruled out by the fact that images which are formed on the retina for a short length of time only (0·02 sec.) can be perceived in relief.

HERING'S HYPOTHESIS was that it is the formation of similar images on points of the retinæ that do not correspond which causes distance perception. If the disparation is crossed, the object appears nearer than the fixation mark by an amount which depends on the amount of the disparation. If, on the other hand, the disparation is uncrossed, the object is recognised as being farther away. Hering supposed, moreover, that crossed disparation acts as a stimulus to convergence and accommodation, while uncrossed produces the reverse effect. We may now inquire how this hypothesis fits in with the facts. To commence with, if depth depends on disparation, it is clear that, when we perceive objects lying in different planes, we must subconsciously group them according as they fall on corresponding retinal points, or on points which are discrepant by one, two, three or more cone widths, and whether the discrepancy is crossed or uncrossed. The amount of the discrepancy must be some whole number of cone widths, because it is clearly impossible to stimulate half a cone with one impression and the other half of the same cone with a different one and obtain two distinct sensations. It is clear that space must be divided, so far as stereoscopic vision is concerned, into a number of concentric shells, the centres of which correspond with the position of the observer. Now the thickness of these shells can be readily calculated; at 1 metre they are found to be 2 mm. thick, at 10 metres 200 mm. thick, and at 100 metres 17 metres thick. If we are looking at a fixation mark 10 metres away, objects 100 mm. nearer to and 100 mm. farther from the observer will lie in the thickness of one and the same shell, and will therefore appear the same distance from the observer. Objects between 100 and 300 mm. nearer to the observer will lie in the shell corresponding to one cone discrepancy, and will therefore be appreciated as being at a different distance from the observer, appearing nearer if crossed, and farther if uncrossed. The same reasoning applies to objects at other distances. If this calculation is correct, it should be necessary to place objects more than 100 mm. from a fixation mark, which is itself placed at 10 metres, in order that a difference in the distance from the observer should be appreciated. Greeff found by experiment that $\frac{1}{50}$th the distance of the fixation mark was necessary (*i.e.* 200 mm.), the observations being instantaneous ones. If time be allowed for prolonged observation, greater accuracy in the appreciation of distance is obtainable, because different points of fixation can be used. Suppose for example that two objects 20 mm. apart be examined at a distance of 10 metres, under instantaneous observation they will appear identical as described above ; but if the examination be made more carefully, it will be found that, on fixating a point a mean distance of 100 mm. away from the objects, the distance between the two is suddenly appreciated because the demarcation between two shells now falls between them. It is in this way that the accuracy of extended observation becomes greater than that obtainable with instantaneous. The limit reached by experiment is stated to correspond to a displacement at the retina corresponding to $\frac{1}{10}$th the diameter of a cone. The corresponding values for the acuity of stereoscopic vision would be $\frac{1}{10}$th those given above, namely 0·2 mm. at 1 metre, 20 mm. at 10 metres, and 1·7 metres at 100 metres. Hering's view would therefore appear to agree well with the results of experiment. It remains to consider the type of cortical mechanism that would be necessary for the estimation of the discrepancy between the images. One type may be briefly described as follows :—To a number of parallel " planes " in the left side of the cortex are connected the terminal ends of the nerve fibres from the left halves of the two retinæ. At the middle plane fibres from exactly corresponding retinal points are connected together. At planes which lie superficially to the middle plane are connected other terminations from the same fibres but with a crossed lateral discrepancy of one cone in the 1st plane, two cones in the 2nd plane, three cones in the 3rd plane, etc. At planes which lie deep to the middle one other terminations from the same fibres are connected, but with an uncrossed lateral discrepancy of one, two, three, etc., cones as the case may be. On looking at a fixation mark on a uniform background, therefore, a series of impressions of the mark will be formed on all these planes, but in the central one only will they exactly agree, for in all the others the lateral discrepancy will cause the impressions to be duplicated. In all these other planes there will thus be antagonism, first one image and then the other predominating. When these images are combined in consciousness, the stable image from the central plane will suppress the unstable ones from all the other planes, the result being a single picture of the fixation mark. If there are in front of the fixation mark other objects lying in planes at different distances from the observer, the impulses sent up by the cones to the cortical plane will not correspond at the central plane, because their images no longer fall on corresponding points, but they will correspond in the superficial planes where the discrepancy of their images agrees with the discrepancy of the nerve-connections. These other planes will therefore predominate according as each contains the identical images, and when they are combined in consciousness these planes will suppress all the others. Since each cortical plane represents a certain lateral discrepancy, it must also represent a certain distance from the fixation mark. If consciousness recognises the plane in which a stable image is formed, it also must appreciate the distance of the object lying in that plane from the fixation mark. This would not seem any more difficult than the localisation of a touch on the skin. So far as we are able to judge there is nothing inherently impossible in the arrangement of the hypothetical cortical mechanism which has been outlined above, and therefore Hering's theory would appear to be very plausible.

CHAPTER XXVI

HEARING AND SPEECH

1. THE ORGAN OF HEARING

SOUND is conducted in the form of a wave motion. When sound is conducted through the air each sound wave consists of two phases ; during one phase the pressure in the air is above the atmospheric pressure, during the other phase it is below the atmospheric pressure. These alternate variations of pressure are conveyed to the drum skin of the middle ear *viâ* the external auditory meatus when sound waves reach an observer.

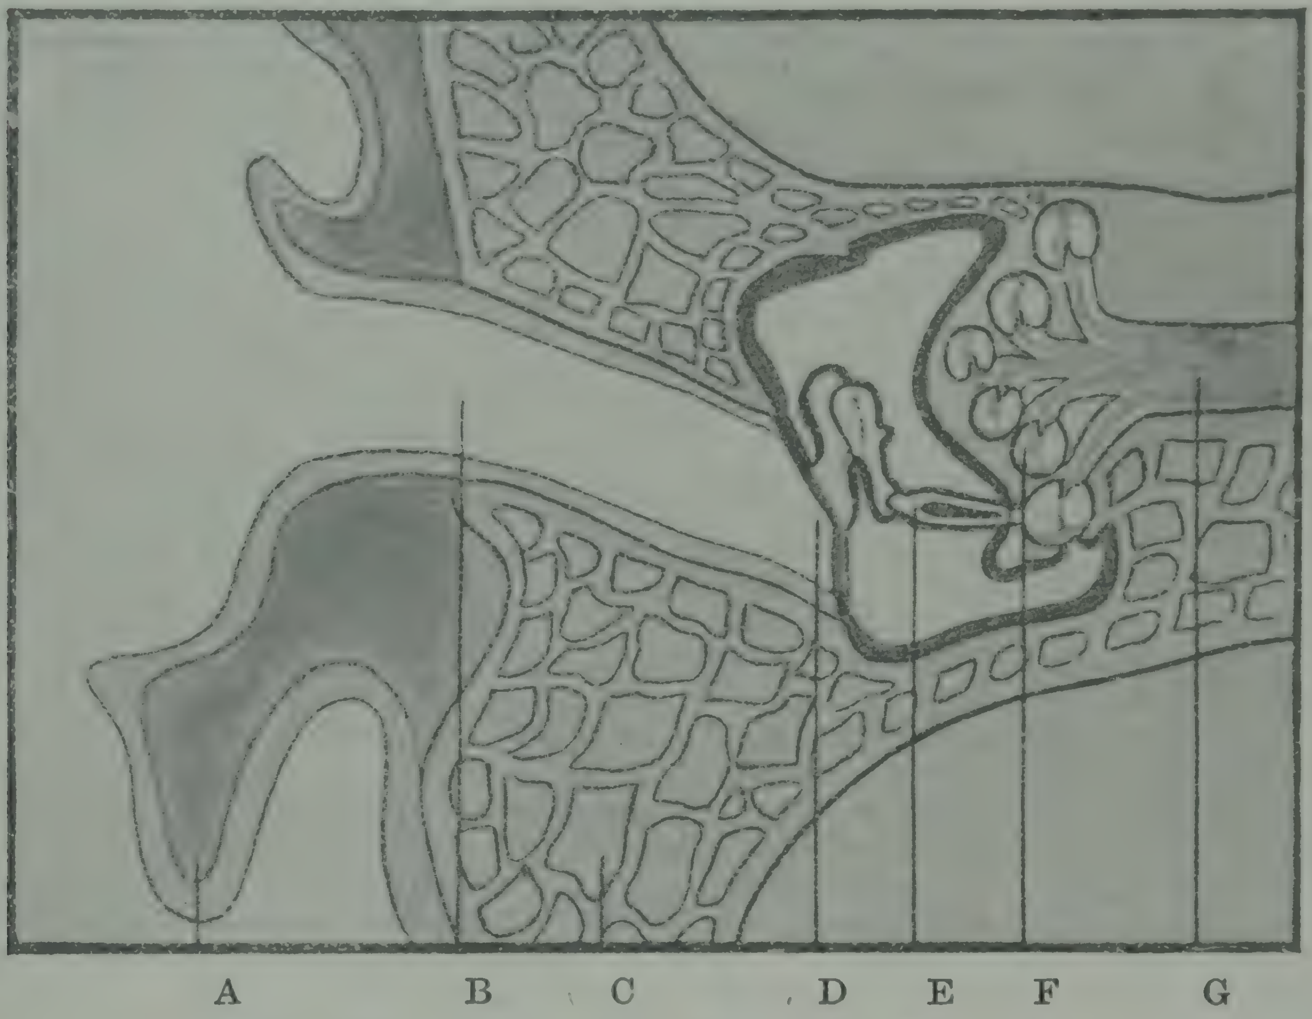

FIG. 307. Diagrammatic View of Auditory Organ.

A = Lobule of Pinna.
B = External Auditory Meatus.
C = Mastoid Air Cells.
D = Drum Skin.
E = Ossicles.
F = Cochlea.
G = Acoustic (Auditory) Nerve.

RECTIFICATION BY MEMBRANA TYMPANI. It should be noted that the drum skin has a different mode of attachment to that provided for the cone of a moving coil loud speaker. The latter is so flexibly mounted that it can move with equal facility both inwards and outwards, and so can perform a sine wave motion. The pull of the tensor tympani muscle, however, stretches the attachments of the drum skin to the meatus, so that it is only possible for the drum skin to move inwards if there is stretching of these attachments, whereas it is possible for it to move outwards by stretching the tensor tympani muscle. Of these two movements, the former is much more difficult than the latter, and thus the movements of the drum skin tend to be asymmetrical about the position of rest, so that a sine wave motion applied to it would become distorted. In consequence of this asymmetrical movement of the drum skin, which is called "rectification" by physicists, certain tones not originally conducted by the air to the ears may be generated in the ears themselves and thus be heard as if they were conducted to the ears by the air.

When a weak tone is being heard (below an intensity level of about 45 decibels) the movements of the drum skin and ossicles are linear, that is, the variations of pressure in the air cause corresponding movements according to Hooke's law. Under these conditions no ear-produced tones are heard. When a stronger tone is being heard the movements of the drum skin and ossicles become asymmetrical since Hooke's law is obeyed for an outward movement from rest, but is disobeyed for an inward movement from rest. Ear-produced tones are now heard consisting of even numbered harmonics. When a still stronger tone is being heard, such that Hooke's law is disobeyed both for movements inwards and for movements outwards, then odd numbered harmonics appear in addition to the even numbered ones.

When two pure tones are simultaneously received by an ear, then, in addition to the even harmonics for both tones and (if the tones are loud enough) the odd harmonics of those tones, it is found that there are also present both summation tones and difference tones. Suppose the two pure tones to be 700 and 1,200 cycles per second, then the following summation tones can usually be identified (700 + 1,200) = 1,900; (700 × 2) + 1,200 = 2,600; (1,200 × 2) + 700 = 3,100; (700 × 2) + (1,200 × 2) = 3,800; (700 × 3) + 1,200 = 3,300, and sometimes others as well. The following difference tones are also usually present 1,200 — 700 = 500; (700 × 2) — 1,200 = 200; (1,200 × 2) — 700 = 1,700; (1,200 × 2) — (700 × 2) = 1,000; and others generated by the ear in a similar manner. Consequently the brain receives a somewhat distorted sound picture owing to this rectification by the drum skin. This subject will be found referred to in greater detail on p. 462 under "combination tones."

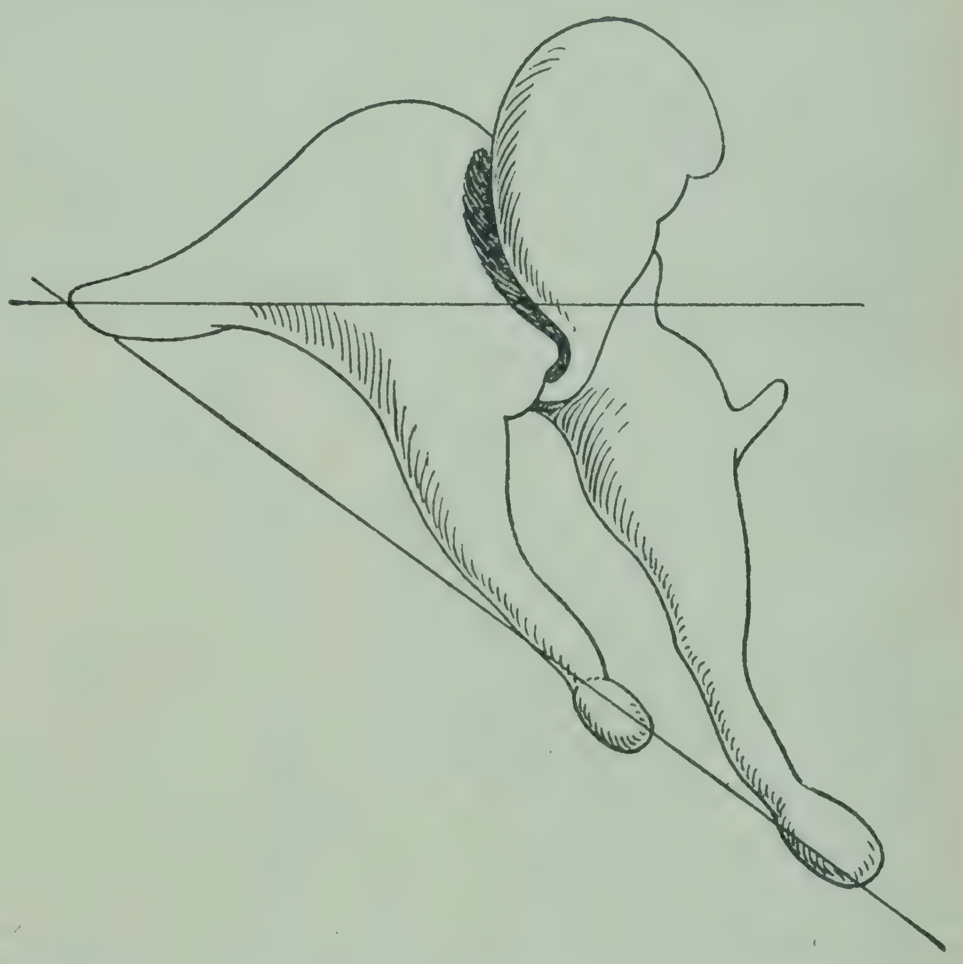

FIG. 308. To show the Relations of the Malleus and Incus to one another.

The shaded area between the two bones shows the articular surfaces which connect them. The overlapping of the two bones at the lower part of these surfaces is well shown. It is this arrangement which causes motion to be conveyed from one to the other.

THE OSSICLES. Stretching across the tympanum, from the membrana tympani to the outer wall of the internal ear, is a chain of ossicles, which are named respectively the malleus, the incus, and the stapes (Fig. 308).

THE MUSCLES found in the tympanum are the tensor tympani, which is attached to the handle of the malleus, and the stapedius attached to the base of the stapes. The tensor is innervated by a motor branch of the 5th cranial nerve, and when it is stimulated it draws the handle of the malleus inwards and so increases the tension of the tympanic membrane. At the same time the plunger of the stapes is displaced into the oval window, thus putting compression on the contents of the internal ear. The contraction of the tensor has been supposed to have a protective function and has been compared to the sphincter pupillæ (Helmholtz). Others hold that it modifies the response to low and medium tones, but even here there is a divergence of opinion because, while some hold (probably correctly) that the tensor by its contraction decreases the natural period of the drum and thus enables it to respond to rapid changes of phase and high tones, others have held the opposite view. Observation shows that contraction occurs when sounds (particularly tones of high pitch) fall on the drum, and that the contraction is bilateral, even if the stimulus be only unilateral. The reflex therefore travels *viâ* the auditory nerve to the motor centre of the 5th nerve.

Since the tensor tympani is uncontracted when no sounds are falling on the ear, it allows the drum to go slack and therefore tends to prevent this membrane from becoming stretched through being continually in tension.

The stapedius muscle is innervated by a twig from the facial nerve. Its function is problematical. Some say it antagonises the tensor by decreasing the tension on the drum; others that it reduces the tension on the contents of the internal ear by diminishing the pressure of the stapes on the oval window. Hartridge's view is that the function of this muscle is to cause the body of the incus to engage with the spur of the malleus with sufficient force to prevent chattering and lost motion when the vibrations are being transmitted from one bone to the other.

The Eustachian Canal is a tube about 35 mm. long, which connects the middle ear with the pharynx. Normally it is kept closed and hence the respiratory rhythm does not affect the pressure in the tympanum, and the noise set up by the flow of air and by the voice is not heard. When the canal is shut, the middle ear becomes a closed chamber, which appears to increase the response to low tones. Since variations in barometric pressure would not be communicated to the middle ear if the canal were always closed, the air pressure on the two sides of the drum would vary. This is avoided by a periodic opening of the canal which accompanies the acts of swallowing and yawning. When the throat is infected, the inflammation often spreads to this canal, which then becomes blocked, either by mucus or by the swelling of its mucous lining. The air in the middle ear is then gradually absorbed and the difference in air pressure on the two sides of the drum decreases its response to sound, and the affected ear thus becomes partially deaf.

Temporary deafness also occurs if the barometric pressure is suddenly altered by a rapid change of level (as in an aeroplane) or by the application of external pressure (as in a caisson). The deafness is, however, immediately relieved by swallowing, because the altered pressure is communicated to the other side of the drum through the opening of the Eustachian canal.

Functions of Tympanum. The function of the tympanic apparatus (consisting of drum, bones and muscles) is to transform the energy of the aerial vibrations incident on the drum into a series of mechanical movements of the plunger of the stapes, by which the pressure within the internal ear is rapidly varied. The evidence may be summarised as follows. (1) If in man the external ear be made to form a gas chamber which is connected with a manometric flame, the flame shows vibrations when sound falls on the drum, which could only be caused if the drum were set into vibration. (2) If the drum be gilded, and a beam of light be made to fall on it, the excursions of the beam caused by vibrations of the drum can be recorded photographically, and are found to accompany the incidence of sound waves. (3) If to the chain of ossicles a light writing lever be attached, the point of which travels over a rotating smoked drum, when sounds fall on the drum the vibrations are recorded, showing that the ossicles are set into movement. (4) By opening the middle ear from above, and sprinkling with starch grains the ossicles lying within, the movements of the different parts can be readily followed under a low power microscope. When the drum is set into vibration by sound waves, it is readily seen that the whole chain of ossicles vibrates, so as to convey the vibrations to the plunger in the oval window. Many experimenters have noted the remarkable way in which the apparatus responds to vibrations varying very greatly in rate. Tones of low or of high pitch appear to be recorded with equal impartiality and fidelity. Experiment therefore confirms our sensations, which show that the ear responds to vibrations varying from 40 to 30,000 per second. It is stated that the natural period of the ossicles and drum, owing to their small size, is very much more rapid even than $\frac{1}{40,000}$ second, and it is because of this that the system is able faithfully to respond to the vibrations of longer period concerned in audition.

Direct observation thus shows that the ossicles form levers which together conduct the vibrations from the drum to the plunger of the oval window. It is necessary to consider the effect of this lever system on the amplitude and force of the vibration. Motion is applied to the manubrium of the malleus and is communicated to the long process of the incus. The former is one and one-half times the length of the latter and therefore the stapes moves with two-thirds the amplitude of the drum. If the levers moved without friction, this would be accompanied by an increase in the force of the vibrations of one and one-half times. But owing to the air which surrounds the levers and thus damps their vibration, and to the energy required to set them in vibration on account of their mass, it is probable that the force of the vibrations which reaches the oval window is not more than half that incident on the manubrium. The drum on the other hand, has an area which is about twenty times that of the oval window and the energy incident on the drum and communicated to the manubrium is as many times greater than it would be if the sound waves were incident on the oval window direct. But owing to the energy absorbed by the levers, the magnification is probably not greater than ten times, that is one-third of the calculated amount. Two other features of the chain of ossicles should be mentioned. In the first place it will be observed that the axis, about which the malleus and incus rotate, passes through the bones, so that the big mass formed by the articular surfaces is above, and the levers below, the axis of rotation, and the ossicles are approximately balanced. Secondly, the articulation between the malleus and incus is saddle-shaped, and there is a spur on the malleus which engages with the body of the incus so that, when the tensor tympani muscle relaxes and the malleus travels outwards, the spur disengages and the incus is therefore not forced to follow. When, on the other hand, the stapedius muscle is in tonic contraction, the spur is in engagement, and vibrations are therefore communicated from one bone to the other. If, however, the force applied is excessive, owing for example to a box on the ear, then the two bones separate slightly like the limbs of a compass, and the spur passes the body of the incus without communicating the blow to it. In this way rupture of the annular seal between the plunger of the stapes and the oval window is prevented.

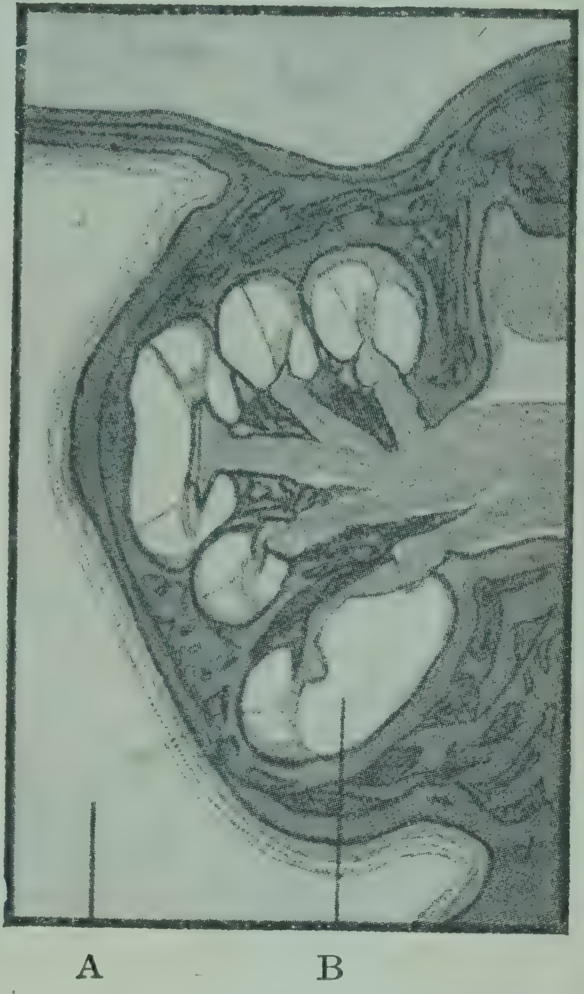

FIG. 309.
A = Middle Ear Cavity.
B = One section of Spiral duct of Cochlea.

Internal Ear. Within the petrous portion of the temporal bone are two mechanisms, anatomically in close relationship, but physiologically entirely separate. One of these mechanisms, which is called the cochlea, belongs to the auditory organ; the other, called the vestibule, consists of a series of organs which concern equilibration and have no connection with hearing.

The relation of the cochlea to the middle ear is shown in Fig. 309.

Of these structures, the cochlea alone is concerned with hearing, as the following evidence shows:

(1) Destruction of the utricle and canals causes disturbed equilibration, nystagmus and vomiting, but no deafness.

(2) Destruction of the cochlea causes deafness, but no disturbance of equilibration.

(3) Some fishes, in which no evidence of hearing can be found, possess utricle, saccule and canals, but no cochlea.

THE COCHLEA is a tube 20 to 30 mm. long, which is spirally wound round a cone of bone called the modiolus, along the axis of which runs the auditory nerve. From the modiolus a spiral lamina of bone extends about two-thirds of the way across the spiral bony canal, so as partially to divide it into two equal portions. From the outer edge of this lamina two membranes extend to the walls of the canal, so that the latter is divided throughout its length into three separate ducts. The duct nearest to the apex is called the scala vestibuli, the middle duct between the two membranes the scala media, and the duct nearest to the base the scala tympani (Fig. 309). The two membranes dividing off these ducts are quite different in structure; whereas the apical, called Reissner's membrane, is a thin layer of cells only, the basal is of complicated arrangement and is called the basilar membrane. To the latter is attached, in the organ of Corti, a series of sensitive hair cells connected with the fibres of the auditory nerve, which run through the osseous spiral lamina to the body of the modiolus. To the upper edge of the spiral lamina is attached a projecting membrane called the lamina or membrana tectoria; this is so mounted that it projects over the tips of the hair cells. Its function will be discussed later.

The way in which motion is imparted to the basilar membrane by movements of the ossicles may be described as follows. The osseous labyrinth communicates with the middle ear by means of two openings, the oval window and the circular window. The oval window connects with the upper of the three cochlear canals, *viâ* the vestibule. The upper canal is therefore called the scala vestibuli. The lower canal connects with the round window only, and since the round window is fitted with a membrane, the canal gets the name scala tympani (canal of the drum). Fitting into the oval window is the plunger of the stapes, and between the two is an annular membrane which permits motion of the plunger without allowing escape of the perilymph from the labyrinth. The circular window is also closed by its membrane, in order that leakage of perilymph may be prevented. When the plunger of the stapes is moved inwards under the influence of sound waves on the drum, the perilymph, being incompressible, is driven inwards into the vestibule. From the vestibule a corresponding volume of liquid is displaced into the scala vestibuli of the cochlea. This drives Reissner's membrane downwards, and thus increases the pressure on the endolymph in the scala media. The basilar membrane therefore moves downwards and the hair cells are drawn farther away from the membrana tectoria. But this movement of the basilar membrane presses on the fluid contents of the scala tympani which communicates with the round window,

and therefore causes bulging of the membrane closing that aperture.✓ Movement inwards of the plunger is therefore accompanied by movement downwards of the basilar membrane and movement outwards of the membrane of the round window and *vice versâ.* Vibrations of the ossicles are in this way communicated to the basilar membrane and to the hair cells, causing stimulation of the auditory nerve. The basilar membrane is composed partly of strong radial fibres and partly of weak longitudinal ones. It varies in width, being narrow at the base and wide at the apex.

THE ORGAN OF CORTI. The end organ of the auditory nerve is represented by the organ of Corti, which is attached to the basilar membrane (Fig. 311). It consists of a double row of stiff cells, the inner and outer rods of Corti, which run throughout the whole length of the scala media and are surrounded by sensory epithelium, the hair cells. On the inner side of the rods of Corti there is a single row, on the outer side three rows of hair cells. The fibres of the auditory nerve pass up through the column of the cochlea, through the bipolar ganglion cells which form the spiral ganglion, and then out along grooves in the spiral lamina to end in arborisations, partly in the inner hair cells and partly among the outer hair cells. Between the hair cells are the sustentacular cells, or cells of Deiters, the peripheral processes from which join together so as to form a reticulate membrane over the hair cells, the hairs themselves projecting through orifices in this membrane. Resting on the upper surface of the membrana reticularis is the membrana tectoria. To this membrane is often ascribed a damping effect on the vibrations of the structures below. Any movement of the basilar membrane would be transmitted to the rods of Corti, and by these to the overlying hair cells. With every vibration, these would oscillate in the line of their long axis, so that their hairs would move up and down and possibly strike against the under surface of the membrana tectoria.

O = Arch of Corti.

✓Other views have, however, been advanced as to the way in which the hair cells become stimulated. Thus Wrightson states that there is a to-and-fro movement between the hair cells and the membrana tectoria, so that the hairs are bent first to one side and then to the other. Keith suggests, on the other hand, that the hairs are embedded in the membrana tectoria and that the stimuli are set up by the pulling of the hairs which must occur when the basilar membrane is moved. Further research is required to elucidate this point.

The Cochlear Microphonic Action. Wever and Bray observed that the ear acts like a microphone, that is, that when sounds fall on it variations of potential occur which are closely related to the incident sounds. Thus when a tone of 250 vibrations per second falls on the ear variations of potential occur at this rate in it. The potential variations are small and need to be amplified by thermionic valves in cascade, as for nervous tissues. They can be produced by tones as low as 5 cycles per second and by tones as high as 16,000. They start immediately the tone starts and stop when it stops. If the phase of the tone is suddenly changed, the phase of the microphonic potential also changes at the same instant (Hallpike, Hartridge and Rawden Smith). When the tones falling on the ear are loud, then harmonics can be detected in the microphonic potential curve. They are produced by distortion during transmission by the drumskin and ossicles (p. 461).

The Cochlear Telephonic Action. Andrief, Gersuni and Volokhov showed that alternating currents of audible frequencies are able to cause the perception of sounds when they are suitably applied to the ear.

In one frequently used arrangement the head is held on one side and the upper external ear is filled with warm saline, and into this is inserted a silver wire electrode. The other electrode is placed in the mouth or is strapped to the forearm. The electrodes are connected to a suitable A.C. source such as a wireless set or a beat oscillator. Tests with pure tones show that it is difficult or even impossible to obtain an intense response at any part of the musical scale because of the painful stimulation of the skin caused by the alternating electric current. Both low tones and high tones are poorly reproduced, there being an apparent cut off at about 50 cycles per second. Ear generated harmonics are strongly present, so much so that a pure tone is frequently mistaken for the octave above it. Short interruptions in a tone, or a sudden change of phase in a tone are observed as clearly as they are in an air-borne sound (Hallpike, Hartridge and Rawden Smith).

The Cause of the Electro-Acoustic Effects. It seems reasonable on physical grounds to make the assumption that the microphonic and the telephonic effects of the cochlea originate in one and the same structure. Just as in the piezo-electric effect: When a suitable crystal is moved it generates an electric potential, or when a suitable potential is applied to it a movement is brought about, so in the ear, a structure or structures are present, movements of which generate electrical potentials, or when potentials are applied from without, movements are caused which bring about the sensations of sound. What the structure or structures are is not known at the present time, the hair cells of Corti's organ have been suggested, so also has Reissner's membrane.

2. THE THEORIES OF HEARING

THE RESONANCE THEORY (of Helmholtz) states that the organ of Corti and the basilar membrane together form a series of automatically recording resonators. In the same way that each of the strings of a piano can be set into vibration by the sounding of a note which corresponds with it in pitch, so also can the different fibres of the basilar membrane vibrate to a certain note, and so cause stimulation of the hair cells which are attached to it.

Four objections have been made to this theory. (1) That the fibres of the basilar membrane are so short that they could not respond to the low notes which the ear is able to hear. The answer to this criticism is that not only the length, but also the tension and weight of a cord determine its vibration rate. In the case of the basilar membrane the tensions in the fibres are probably minute, while the weights of the arches of Corti and the hair cells must make the period of vibration so much the longer.

(2) That the separate fibres of the basilar membrane are bound together so that vibration of the separate fibres would be impossible. This objection was met by the calculation, by Helmholtz, that a uniform membrane, in which the tension was greater from side to side than longitudinally, would be able to respond in the manner required.

(3) That the difference in length of the fibres is not sufficiently great for the short ones to vibrate to notes of 4,000 vibrations per second, while the long ones vibrate to 40 vibrations per second only. This objection also fails when we reflect that not only length, but also tension and weight determine the period of vibration of a stretched cord. However accurately we can determine length and weight by histological examination, the method tells us nothing concerning tension. This objection therefore does not prevail.

(4) That if the cochlea depends for its action on the resonance of the basilar fibres, we should expect a musical note to seem to go on sounding after the note

has actually ceased. Since, on the other hand, we know from our own experience that words such as "utter," in which there is an interval of silence between the two "ts," are quite different from "udder," in which there is no interval of silence, it follows that the fibres of the basilar membrane have not been in vibration for long after the sound ceased, and therefore probably resonance of the basilar membrane is slight. But if we suppose the fibres to be highly damped, so that they come to rest at once when the note ceases, how comes it that they can be set in motion so readily that in only three or four vibrations a note is distinctly heard ? The answer is probably obtained from the fact that the cochlea is filled with liquid. This liquid makes the basilar membrane "dead beat," because movements, when the liquid is still, set up eddies which, owing to the viscosity of the liquid, quickly check the motion. On the other hand, when a sound is entering the ear, and the fluid is therefore in motion, this movement is the more rapidly imparted to the basilar membrane because of its continuity, but even if it consisted of separate fibres it would still be set promptly into vibration owing to the viscosity of the liquid. In this way one can explain both the rapid response and the rapid damping of the cochlea.

In favour of Helmholtz' theory we have the following evidence :

(1) In boiler-makers' disease we have inability to hear high notes, and we find that it is the short fibres of the basilar membrane which have degenerated.

(2) In experiments in which the ears of animals have been stimulated for long periods by the same note, subsequent examination has shown the localisation of degeneration to one part of the organ of Corti. With a high note the short fibres are affected, with a low note the long.

(3) If one of the ears be fatigued by prolonged stimulation to a constant note, its response to the same note is found to be inhibited, but notes of slightly longer or slightly shorter pitch are found to be unaffected. This shows clearly that the response to a given rate of vibration must only affect a certain limited number of hair cells and nerve fibres, and is therefore strongly in favour of Helmholtz' theory.

(4) Animals whose calls have a small range of pitch (*e.g.* birds) have short basilar membranes which vary but little in width.

(5) Animals in which different parts of the cochlea have been destroyed, appear to give definite evidence for deafness to high notes when the short basilar fibres are damaged, and deafness to low notes when the long fibres have been removed.

(6) Patients are found in whom there are islands of deafness, that is, they are deaf to a limited part of the musical scale. The Helmholtz' theory readily explains these cases as being due to local disease of certain basilar fibres or their corresponding hair cells. Further, there are cases in which the two ears give different notes, a condition called double disharmonic hearing. This is easily explained by a change in the natural period of the fibres of the basilar membrane in the diseased ear, as the result either of stretching or of increased mass due to inflammation.

(7) If the input leads of a sensitive valve amplifier be connected to the cochlea of an anæsthetised animal, then, as Wever and Bray showed, the incidence of musical tones on the ear is accompanied by potential fluctuations in the cochlea at a frequency corresponding to that of the musical tone. Hallpike and Rawden Smith found, moreover, that with low-pitched tones the potential fluctuations were greater near the apex of the cochlea, whereas, with high-pitched tones they were greater near its base, as should be the case on the resonance hypothesis.

(8) When a musical tone, transmitted by a telephone (*i.e.* an aperiodic) circuit, is suddenly changed in phase by a half-cycle the potential fluctuations in the circuit continue almost without interruption.

When a musical tone, which is causing a tuned structure to perform resonant vibrations, is suddenly changed in phase by a half-cycle the vibrations of the tuned structure are first arrested and are then re-established. On performing a similar experiment with the human ear, Hartridge found that just after the change of phase the musical tone is heard to undergo a short interruption, *i.e.* the ear, unlike a telephone, behaves as if it contained resonators. This phase-change effect was heard whether the experiment was done in an ordinary room where there are echoes or in a room with sound-absorbing walls in which echoes were reduced to a minimum ; the effect cannot therefore be due to them.

(9) When a musical tone is interrupted for short periods of time similar interruptions can be identified in a telephone circuit which is excited by the sound. When a musical tone which is causing a tuned structure to perform resonant vibrations is interrupted for a short period of time the vibrations of the tuned circuit are found to continue with only a small diminution in amplitude. On performing a similar experiment with the ear it is found that short interruptions cannot be detected, *i.e.* the ear again behaves as if it contained resonators.

(10) When two musical tones differing considerably in frequency, for example, 200 v. per sec. and 250 v. per sec., are sounded simultaneously the voltage fluctuations in a telephone circuit are found to undergo periodic increases and decreases, which correspond to beats between the two musical tones. When the above two tones are caused to set up vibrations in a graduated series of resonators, two groups of resonators are found to be set into vibration, one by each tone. A careful examination of the groups shows that neither of them is exhibiting appreciable beats. On performing the experiments with the ear no beats are to be observed, *i.e.* the ear behaves as a series of resonators.

(11) When two musical tones having frequencies in the ratio of 1 to 3 are sounded simultaneously the voltage fluctuations in a telephone circuit excited by them are found to be greatly affected by the relative phases between the two tones. In one phase relationship a single sharp peak curve is produced. In another phase relationship a double hump curve is produced. When the above two tones are caused to set up vibrations in a graduated series of resonators two groups of resonators are found to be set into vibration, one group for each tone. The careful examination of the groups shows that neither their frequency nor amplitude is affected appreciably by changing the relative phases of the two tones. On performing the experiment with the ear it is found that changing the relative phases of the tones has no effect on the sounds which are produced, *i.e.* the ear behaves in accordance with the resonance theory and contrary to the telephone theory.

(12) It is well known that resonators exhibit the properties of selectivity (sharpness of resonance) and persistence, and that both these properties are related to the frictional losses to which the resonators are subject. In consequence of this, when different degrees of selectivity are multiplied by corresponding degrees of persistence a constant value is obtained, as is shown in the following table :—

S (selectivity)	P (persistence)	S × P
1·5	40	60
2·0	30	60
3·0	20	60
4·0	15	60
6·0	10	60

(Selectivity in the above table = percentage difference of frequency causing 1/10th the amplitude of that caused by the intune frequency at the same energy level.)

(Persistence in the above table = number of vibrations which correspond to the time required for the amplitude to be reduced to 1/10th its initial value.)

Now the selectivity of a graduated series of resonators can be ascertained experimentally by finding the smallest difference of frequency which causes beats owing to the overlap of the two vibrating groups of resonators. The persistence of a series of resonators can be ascertained experimentally by finding the duration of the longest interruption in the incoming sound energy which produces no observable decrease in amplitude. Both these methods of research are applicable to the ear, and the table below gives the values I obtained. The last column shows that their product gives a reasonably constant value, as should be the case if the ear resonators are of the kind familiar to the physicist.

Tone	S	P	S × P
128	12·7	1·78	22·6
256	10·0	2·06	20·6
326	9·45	2·19	20·7
384	9·07	2·18	19·75
512	8·45	2·37	20·0
640	8·15	2·54	20·65
760	7·82	2·68	20·95
1024	7·22	3·01	21·70

It would appear, therefore, that the evidence in favour of Helmholtz' theory is very convincing. Other hypotheses have been proposed, however, two of which will now receive brief consideration.

The Telephone Theory (of Rutherford) compares the cochlea with a telephone. In the same way as the diaphragm of the receiver is set into vibration by the sound waves, and starts corresponding variations in the strength of the current conducted to the transmitter, so the vibration of the basilar membrane as a whole causes impulses to be sent up the auditory nerve which correspond with the air vibrations received by the ear. Analysis does not take place in the cochlea at all, but in the brain. Wrightson, who has restated this theory and added much detail to it, states that the cerebral analysis is effected by differences between the time intervals of the points of zero pressure and of the maximum plus and minus pressures.

The following objections may be stated against the Rutherford-Wrightson hypothesis :

(1) It assumes that the auditory nerve can conduct complicated wave forms, intact as to pitch and amplitude, at rates up to 15,000 vibrations per second. Rutherford, in this connection, pointed to the motor nerves of the bee's wing, which are capable of responding to transmitted impulses at 460 per second. Between 15,000 and 460 is, however, a big gap which will certainly have to be bridged before this view as to the transmission of the vibrations intact to the brain can be accepted.

(2) We cannot picture a cerebral apparatus which can analyse these complicated nerve impulses even if they could reach it, and neither Rutherford nor Wrightson assist us to do so. The relegation of the powers of analysis to the cerebral cortex is, at the present at any rate, equivalent to giving up any attempt to explain the power of analysis possessed by the organ of hearing.

(3) It would seem that a very much simpler organ than that of the cochlea would be sufficient to convert sound waves into nerve impulses, if no analysis of the stimulus took place there.

(4) It would be very difficult to explain, on this hypothesis, the localisation of deafness to certain notes, which accompanies disease of part of the organ of Corti.

(5) This hypothesis does not explain why fatigue to one note leaves the response to all other notes apparently unaffected in intensity.

The objections to this hypothesis are therefore of a formidable character. Much additional evidence in its favour would be necessary to place it even on a par with the theory of Helmholtz.

The Sound Pattern Theory (of Waller and Ewald), stated that the basilar membrane vibrated in the form of pressure patterns, which are similar to those which may be seen on a vibrating plate. Ewald found by experiment that the patterns take the form of equidistant stationary nodes or ridges, the distance between which varies with the pitch of the note entering the mechanism. The distance between the nodes is measured by the hair cells, and corresponding impulses are sent to the auditory centre. The advantage of this hypothesis is that like that of Helmholtz, it places the analysis of the sound waves in the cochlea and therefore does not, like Rutherford's hypothesis, require the transmission by the auditory nerve of rapid impulses or the analysis of such impulses by the brain. It is clear, however, that so far as our present knowledge goes the evidence is all in favour of the Helmholtz view.

The Volley Theory has been devised to explain two different facts : (1) that the position in space of sources emitting tones below about 1,000 cycles is identified by the recognition of the time interval between the arrival of the sound at the two ears. When the source is straight in front of the observer the sound reaches the right and left ear simultaneously. If this source is moved round to the right the sound reaches the right ear first. If the brain is to appreciate this fact the nerve impulses reaching it must be discontinuous and must consist of volleys having time relationships corresponding to the vibrations set up in the ear by the sound waves. Thus a tone of 500 vibrations per second from a source of sound 45° right of the observer will cause 500 volleys of nerve impulses to travel to the brain along each auditory nerve. But the sound waves to the left ear have to travel about 4 inches farther than those to the right, and the velocity of sound in air being 13,200 inches per second, this distance will take $\frac{1}{3,300}$ of a second and the volleys up the right auditory nerve will be that time ahead of those up the left nerve. (2) That the responses in the auditory nerve are found to correspond in frequency to those of the tones falling on the ear up to about 2,200 cycles per second. But the separate fibres of the auditory nerve, like those of other nerves which have been experimentally investigated, cannot transmit more than about 1,000 impulses per second. The volley theory explains the faster rate of transmission by supposing that each fibre responds to every other sound wave, and possibly when the fastest rate of all is being transmitted (2,200 cycles per second), each fibre of the auditory nerve may respond to every third sound wave. When, however, tones of higher pitch are falling on the ear and each of the auditory nerve fibres should be transmitting every fourth, fifth, sixth, etc., up to possibly every tenth wave, the transmission of the nerve impulses has become too irregular for the precise conditions to be experimentally identified. If all the auditory nerve fibres had precisely the same refractory phase, and the same rate of conduction, then proof of the volley theory could probably be obtained for all musical tones including the highest. But this seems not to be the case. That the volley theory holds good for tones below about 2,400 cycles per second was shown by the experiments of Derbyshire and Davis. In Fig. 312 is shown the relationship between the frequency of the tone and the size of the electric response of the auditory nerve of a cat taken immediately after the brief transcent (the " on effect ") which always occurs at the beginning of a musical tone. It will be seen that the response is a maximum from 500 to 1,000 cycles per second. Experiment shows that this maximum extends right down the musical scale to low tones. Above 1,000 cycles per second, the graph shows a fall so that at 1,400 cycles per second the response has half the maximum value. At about 1,600 cycles the nerve response has flattened out and at 1,800 undergoes a second abrupt fall. The first fall at 1,100 cycles occurs at a point where, on the volley theory, a fall would be expected because some of the auditory nerve fibres are beginning to respond to every other wave. The second fall at about 1,800 cycles occurs at a point where on the volley theory a further fall would be expected, because some of the auditory nerve fibres are failing to be able to respond to every other wave and are beginning to respond to every third wave.

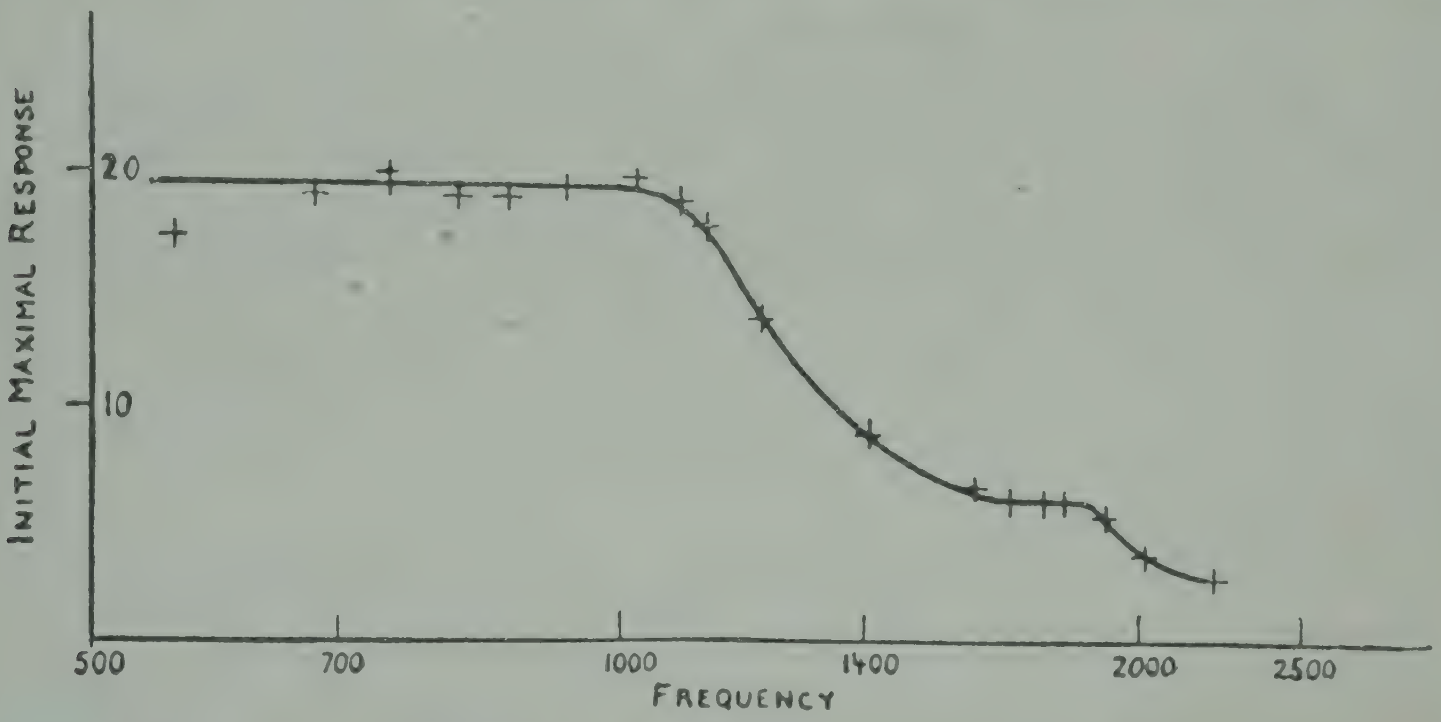

FIG. 312. Shows the relationship between the electrical response of the auditory nerve and frequency in cycles per second. (Derbyshire and Davis, *Amer. J. Phys.*) Between 500 and 1,000 cycles the curve is level because all the auditory nerve fibres respond to every vibration of the basilar membrane. The bend in the curve that occurs at 1,000 cycles is due to the fact that above this frequency, half the nerve fibres are responding to every other vibration in accordance with the volley theory. The bend in the curve that occurs at a frequency of 1,900 cycles is due to the fact that above this frequency, one-third of the nerve fibres are responding to every third vibration.

3. THE PHENOMENA OF HEARING

Limits of Pitch. The ear is unable to perceive a tone the pitch of which falls above or below certain fairly well-defined limits. If the number of vibrations is less than about twenty per second no musical tone is produced, the individual vibrations being perceived as a series of pulses in the surrounding air, and it is only when we increase the number to about thirty per second that we are able to appreciate a pitch in the note produced. As the number of vibrations per second is increased the note rises steadily without break till we arrive at about 15,000 vibrations per second. Above this number of vibrations, the human ear is incapable of perceiving any note at all, though it is probable that small animals can hear notes still higher in the scale. In music neither the lowest nor the highest tones are used. The lowest tone of large organs, 16 vibrations per second, is that produced by the sixty-four foot pipe, and one can hardly speak of its effect as that of a musical tone. The highest notes employed in music are *a*4 and *c*5 with 3,520 and 4,224 vibrations per second on the piano, and *d*5 with 4,752 vibrations on the piccolo flute. In music therefore we only employ between 25 and 4,800 vibrations per second, *i.e.* about seven and a half octaves.

Beats and Dissonance. If we sound two tuning forks, the vibrations of which differ only by one or two per second, the phenomenon known as " beats " is produced. This is due to the summation and interference of the waves from the two tuning forks. Let us suppose we have tuning forks vibrating, one at 100 and the other at 101 times a second, and that they begin vibrating together. At first the waves of compression started by each fork will coincide, so that the total compression of the air at each beat will be the compound effect of the compression produced by the two forks, which will reinforce one another. After the lapse of half a second the tuning forks will be at different phases of their excursion. The 101 fork will be moving in one direction while the 100 fork is moving in the other, so that the compression produced by one fork coincides with the expansion of the air produced by the moving backwards of the other fork. The sound produced by one fork is therefore diminished by the sound produced by the other fork, and the total sound is less than that of either of the two forks. At the end of one second, the phases of the two forks once more corresponding, we shall get the sound increased in loudness ; thus there is an alternate waxing and waning of the sound which recurs once a second and is spoken of as a " beat."

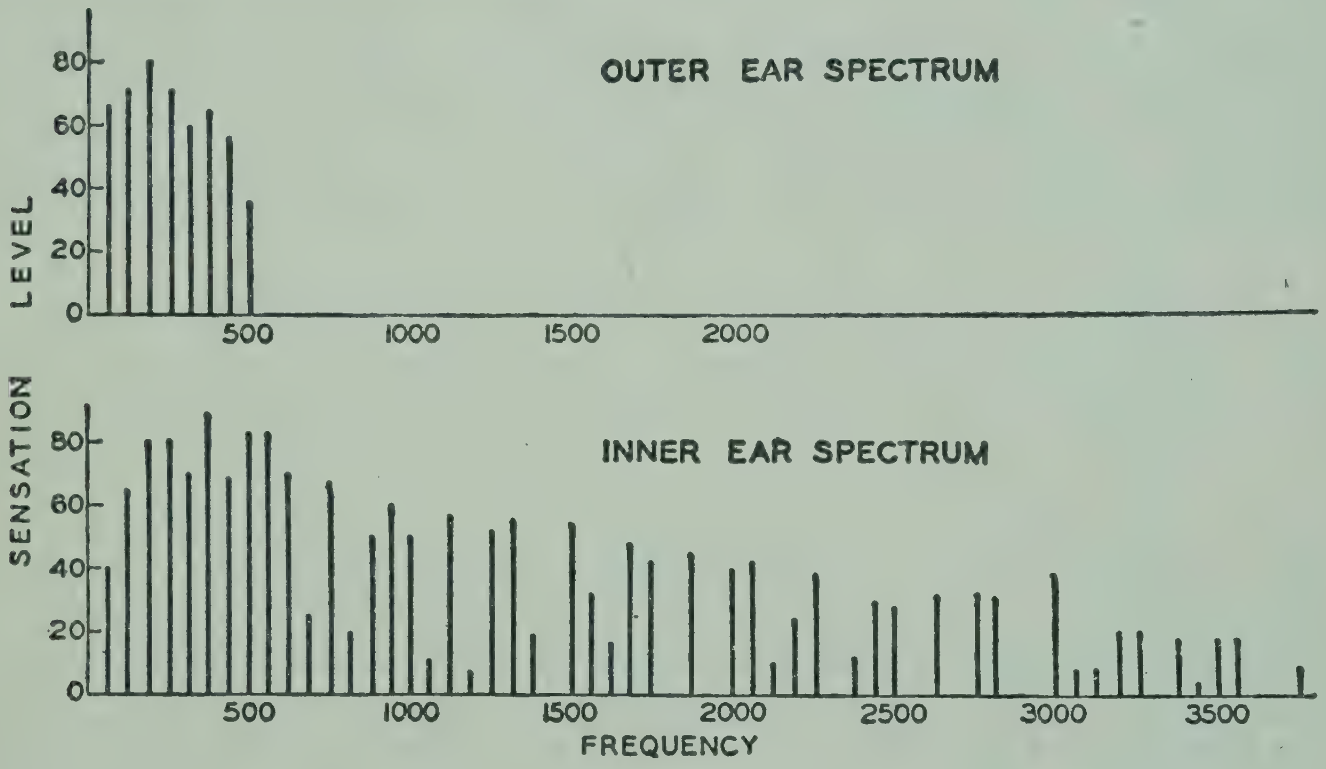

Fig. 313. Loudness spectrum : The top graph shows actual spectrum of a note of an organ pipe impressed upon the outer ear. The lower one gives estimated spectrum as impressed upon the nerve endings of the cochlea. The additional frequencies introduced owing to rectification effected by the drum are well known. (From Harvey Fletcher, " Speech and Hearing," Macmillan & Co., London, 1929.)

The number of beats per second may be used to determine the differences in the vibration frequencies of two forks. Thus, two forks vibrating, one at 100 and the other at 110, will give ten beats per second. As the number of beats increases, the effect produced on the ear becomes more and more disagreeable, just as the rapid alternation of illumination produced by a flickering light is disagreeable to the eye. This objectionable character of the sound is most marked when the beats recur at about thirty-three times per second; the individual beats are not then distinguished, but we speak of the sound as discordant or *dissonant.*

COMBINATION TONES. If two tuning forks, with an interval of one-fifth between them, are sounded together, we may hear a weak lower tone, the pitch of which is an octave below that of the lower fork. This is known as a "combination tone." The combination tones are divided into two classes: (1) "difference tones," in which the frequency is the difference of the frequencies of the generating tones; (2) "summation tones," which have a pitch corresponding to the sum of the vibrations of the tone of which they are composed. By means of appropriate resonators these tones can be reinforced, showing that they have an objective existence. They are, however, reinforced in the ear by the asymmetry of the drum skin and ossicles.

In consequence of these combination tones the sound spectrum of the motion conveyed to the cochlea is much richer in the higher frequencies than is the wave motion incident on the drum.

CONSONANCE. The opposite condition of *consonance* or harmony involves therefore, in the first place, an absence of beats, *i.e.* of rhythmic oscillations of amplitude of sound waves which reach the ear. The most complete consonance is attained when the two notes which are sounded together are identical in frequency. Almost as complete is the consonance obtained when a note is sounded together with its octave. The octave and other consonant intervals which are employed in music are as follows:—

1:2	Octave
2:3	Fifth
3:4	Fourth
4:5	Major third
5:6	Minor third
5:8	Minor sixth
3:5	Major sixth

It will be noticed that in all these consonant combinations, the vibration frequencies of the notes are in proportion to small whole numbers. If we put down not only the fundamental tones of these notes, but also their overtones, we shall see that there is considerable identity as regards the latter. In the case of the octave the two are almost identical, the only difference being the ground tone of the lower note; but the identity diminishes as we pass from the octave through the thirds to the sixths. The overtones which are identical are shown by black type:

Overtones

D = difference tone. S = summation tone.

It will be observed that in all cases, with the exception of the octave, the summation tone is discordant with the other partial tones.

In the second $\left(\frac{8}{9}\right)$ and the seventh, both of which are discordant, it is only the eighth and ninth overtones which are identical, while the fundamental tones will as a rule be so close together that beats of a number calculated to give dissonance will be produced. Since the phenomenon of beats depends on the absolute number of vibrations per second, they are more easily produced by two notes near together at the lower end of the scale than at the upper end. Thus the dissonance is quite perceptible in a major third at the lower end of the piano, but disappears at the upper part, since here the beats produced are so rapid that they become imperceptible.

The various notes used in music are obtained by employing the consonant intervals which we have given above. The major chord is composed of the fundamental tone, the major third and the fifth. If we take "*c*" as the fundamental tone, the notes of the chord are *c*, *e*, *g*, with vibration frequencies corresponding to 1, $\frac{4}{5}$, $\frac{3}{2}$, *i.e.* 4, 5, 6. The major chord from *g* is *g*, *b*, *d*, *i.e.* three notes with vibration frequencies corresponding to $\frac{3}{2}$, $\frac{15}{8}$, $\frac{9}{4}$, *i.e.* 4, 5, 6. The major chord from the fourth, *f*, is *f*, *a*, *c*, with the vibration frequencies $\frac{4}{3}$, $\frac{20}{12}$, $\frac{12}{6}$, *i.e.* 4, 5, 6. The C major scale is therefore as follows :

C	D	E	F	G	A	B	C	
1	$\frac{9}{8}$	$\frac{5}{4}$	$\frac{4}{3}$	$\frac{3}{2}$	$\frac{5}{3}$	$\frac{15}{8}$	2	Major scale
1	$\frac{9}{8}$	$\frac{6}{5}$	$\frac{4}{3}$	$\frac{3}{2}$	$\frac{8}{5}$	$\frac{15}{8}$	2	Minor scale

Different instruments are tuned to one normal note, *i.e.* to A with 440 vibrations per second (this note varies somewhat in different countries). Taking this as the normal, the vibration frequencies of the various notes used in music are given in the following Table :—

Notes.	Vibrations per second.						
C. . .	33	66	132	264	528	1056	2112
D. . .	37·125	74·25	148·5	297	594	1188	2376
E. . .	41·25	82·5	165	330	660	1320	2640
F. . .	44	88	176	352	704	1408	2816
G. . .	49·5	99	198	396	792	1584	3168
A. . .	55	110	220	440	880	1760	3520
B. . .	61·875	123·75	247·5	495	990	1980	3960

Sound Analysis. Not only can the ear appreciate differences between different musical instruments, dependent on the varying overtones present in the sound produced by each instrument but, when a number of these instruments are sounded simultaneously, the ear can pick out from the compound sound the notes due to an individual instrument ; and a person with a trained ear can with ease name notes composing any chord struck on an instrument such as the piano.

This power of analysis, which is possessed by the auditory apparatus, may be stated in the form of a law, known as Ohm's law :

" Every motion of the air which corresponds to a composite mass of musical tones is capable of being analysed into a sum of simple pendular vibrations, and to each single vibration corresponds a simple tone, sensible to the ear and having a pitch determined by the periodic time of the corresponding motion of the air."

Sound Localisation. Experiment shows that man and animals can appreciate with fair accuracy the direction from which a sound is coming. There has been considerable speculation as to how this information is obtained, and, although the subject has not been completely elucidated, it appears to have been established that the following factors are important :—

(1) The intensity of the sounds entering the two ears. When a sound is coming from one side, the ear on that side receives the more powerful stimulus.

The relative intensities of the components of high and low pitch vary with direction, because the notes of long wavelength (low pitch) will be diffracted the more readily round the head to the ear away from the sound than will those of short wavelength (high pitch).

(2) The sounds reaching the nearer ear will arrive earlier than those stimulating the other, because of the time taken to travel round the head. The nerve impulses from the two ears will therefore not arrive at the same instant, and by an appreciation of the difference in time, the approximate position of an external object can be gauged.

That this factor is of great importance can be shown by experiment in the following manner : A stethoscope with two earpieces is fitted in position, and to its mouthpiece is applied a loud tuning fork. The tube connecting the mouthpiece to one of the earpieces has an adjustable U-piece like a trombone, so that the distance travelled by the sound in reaching that ear can be varied. The other tube has a length which is equal to that of the others, with the U-piece in its mid position. When a note is sounded and the U-piece altered, the position of the sound appears to move from one side to the other according to which ear has the shorter tube.

In everyday life both the intensity and the time factors play their part. The intensity factor is more important for frequencies above 1,000 v. per sec., the time factor being more important for frequencies below this. Thus in the case of a musical tone of 400 v. per sec. rich in harmonics, the fundamental (400) and first harmonic (800) would involve the time factor while the higher harmonics would be bringing in the intensity factor.

(3) In animals, the ability to turn the ears in different directions and so find the direction of maximum intensity must be of the utmost possible value in sound localisation.

Note on the Decibel. The DECIBEL is a physical unit in terms of which DIFFERENCES IN SOUND INTENSITIES can be expressed. 10 DECIBELS = 1 BEL, called after Alexander Graham Bell, who invented the telephone. The decibel scale is logarithmic. INTENSITY DIFFERENCE BETWEEN TWO SOUNDS IN DECIBELS =

$$10 \times \log. \frac{\text{physical power of one sound}}{\text{physical power of other sound}}$$

e.g., sound 1 : 2 = 3 decibels.
1 : 5 = 7 ,,
1 : 100 = 20 ,,
1 : 1,000 = 30 ,,

A scale of loudness has been constructed as follows :—

The faintest audible sound	0
Rustle of leaves in gentle breeze	1 bel.
Whisper, 4 feet	2 bels.
Quiet suburban street, London	3 ,,
Centre of New York at quietest time of night	4 ,,
Conversational voice, 12 feet	5 ,,
Busy traffic, London	6 ,,
Loud peal of thunder	7 ,,
Very heavy street traffic, New York	8 ,,
Lion roaring, 18 feet	9 ,,
Riveter, 35 feet	10 ,,
Steel plate hammered by four men	11 ,,
	12 ,,
Limit of ear's endurance	13 ,,

4. SPEECH

The development of the analytical powers of the auditory apparatus is closely connected with that of the faculty of speech, which is best considered with the central nervous system. We may first consider the mechanism of production of *voice*, which man shares with many other animals, before discussing the physiology of the wholly human faculty of speech.

Voice is produced in the larynx, a modified portion of the wind-pipe, by the vibrations of two elastic bands, the vocal cords, which are set into action by an expiratory current of air from the lungs. In many respects the larynx resembles a reed instrument, in which a current of air is caused to vibrate by the vibrations of an elastic tongue. Whereas, however, the period of the vibrations in such an instrument, and therefore the note, is determined by the length of the tube which is attached to the reed and by the lengths of the reeds themselves, in the larynx the note produced by the blast of air is modified partly by alterations in the tension of the vocal cords, partly by altering the size of the aperture and partly by varying the strength of the blast of air.

ANATOMICAL MECHANISM OF THE LARYNX. The essential framework of the larynx is formed by four cartilages, viz. the cricoid, the thyroid, and the two arytenoid cartilages (Fig. 314). The cricoid cartilage, which lies immediately over the uppermost ring of the trachea, is shaped like a signet ring, the small narrow part being directed forwards and the broad plate backwards. The thyroid cartilage consists of two parts or alæ, joined together in front and forming the prominence known as Adam's apple; behind, it presents four processes or cornua, the superior of which are attached by ligaments to the hyoid bone, while the inferior cornua articulate with the postero-lateral portion of the cricoid cartilage. By means of this articulation very free movement is permitted between the two cartilages, the general direction of movement being one of rotation of the cricoid cartilage on the thyroid, round a horizontal axis directly through the two articular surfaces between the two cartilages, while movements of the thyroid upon the cricoid are also possible in the upward, downward, forward, and backward directions. The two arytenoid cartilages are pyramidal in shape. By their bases they articulate at some distance from the middle line with convex articular surfaces situated in the upper margin of the plate of the cricoid cartilage. The anterior angle of the base is the vocal process, while the external angle is the muscular process of the arytenoid. The crico-arytenoid joints permit of two kinds of movements of the arytenoid cartilages:

(1) Rotation on their base around their vertical long axis, so that the anterior process is rotated outwards and the muscular process backwards and inwards, or conversely.

(2) Sliding movements of the whole arytenoid cartilage either outwards or inwards, so that their inner margins may be drawn apart or approximated.

The larynx is covered internally by a mucous membrane continuous with that of the trachea. It is lined with ciliated epithelium, except over the vocal cords, where the epithelium is stratified. The two vocal cords, or thyro-arytenoid ligaments, consist of elastic fibres which run from the middle of the inner angle of the thyroid cartilage to be inserted into the anterior angle of the arytenoid cartilages. Their length in man is about 15 mm., in woman about 11 mm. The cleft between them is known as the glottis or *rim glottidis*.

Two ridges of mucous membrane above and parallel to the vocal cords are the false vocal cords. Between the true and the false vocal cords on each side is a recess known as the ventricle of Morgagni. This ventricle permits the free vibration of the vocal cords. The false cords take no part in phonation, but help to keep the true cords moistened by secretion of the numerous mucous glands with which they are provided. The false cords are also used in holding the breath. For this purpose they function in a similar manner to the mitral valve of the heart. It is found that animals, who need the thorax to be fixed in order that they may climb or strike, have well-developed false cords. The position and tension of the vocal cords are determined by the action of the intrinsic muscles of the larynx. The part taken by the various muscles in each movement cannot be directly ascertained. We can in most cases study only the direction of the fibres and judge, from this direction and consequent isolated action of the muscles, the part taken by any given muscle in the production of voice. The chief muscles (Fig. 314) are the following :—

(1) The *crico-thyroid* muscle is a short triangular muscle attached below to the cricoid cartilage and above to the inferior border of the thyroid cartilage: the fibres pass from below upwards and backwards. When this muscle contracts, the cricoid cartilage is drawn up under the anterior part of the thyroid cartilage, so that its broad expansion behind, with the arytenoid cartilages, is drawn downwards and backwards, thus putting the vocal cords on the stretch. This muscle is probably the most important in determining the tension of the vocal cord.

(2) The *posterior crico-arytenoid* muscle arises from a broad depression on the corresponding half of the posterior surface of the cricoid cartilage. It passes upwards and outwards, its fibres converging, to be inserted into the outer angle of the arytenoid cartilage. These muscles rotate the outer angle of the arytenoid cartilages backwards and inwards. They thus cause a movement outwards of the anterior angles, so that the glottis is widened. During every act of inspiration there is a widening of the glottis, which is probably effected by contraction of these muscles. If they are paralysed the vocal cords are approximated and tend to come together during inspiration, so that dyspnœa may be produced.

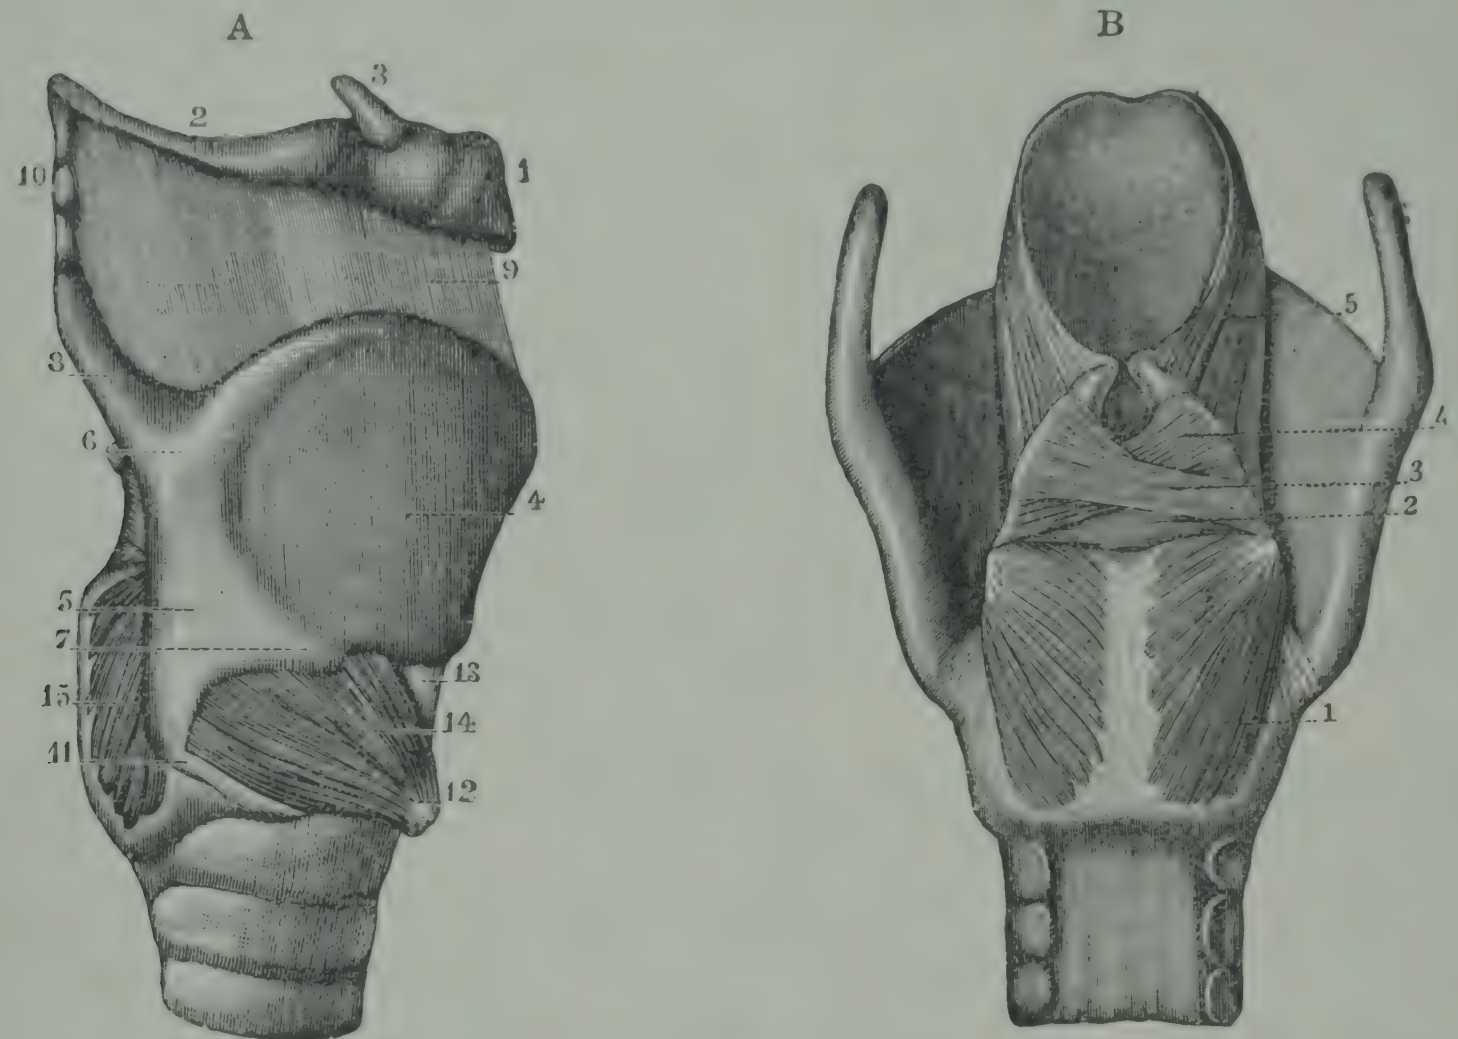

FIG. 314. Muscles of the Larynx. (SAPPEY.)

A, as shown in a view of the larynx from the right side.

1. Hyoid bone.
2, 3. Its cornua.
4. Right ala of thyroid cartilage.
5. Posterior part of the same separated by oblique line from anterior part.
6, 7. Superior and inferior tubercles at ends of oblique line.
8. Upper cornu of thyroid.
9. Thyro-hyoid ligament.
10. Cartilago triticea.
11. Lower cornu of thyroid, articulating with the cricoid.
12. Anterior part of cricoid.
13. Crico-thyroid membrane.
14. Crico-thyroid muscle.
15. Posterior crico-arytenoid muscle, partly hidden by thyroid cartilage.

B, as seen in a view of the larynx from behind.

1. Posterior crico-arytenoid.
2. Arytenoid muscle.
3, 4. Oblique fibres passing around the edge of the arytenoid cartilage to join the thyro-arytenoid, and to form the aryteno-epiglottic, 5.

(3) The *lateral crico-arytenoid* muscle arises from the upper border of the cricoid cartilage and passes backwards to be inserted into the muscular process of the arytenoid cartilage. These muscles when they contract pull the muscular process of the arytenoid cartilage forwards and downwards, thus approximating the vocal cords at their posterior ends and antagonising the action of the posterior crico-arytenoid muscles.

(4) The *arytenoid* muscles consist of transverse fibres, some of which decussate, uniting the posterior surface of the two arytenoid cartilages. When they contract they draw the arytenoid cartilages together.

(5) The *thyro-arytenoid* muscles consist of two portions. The outer fibres rise in front from the thyroid cartilage and pass backwards to be inserted into the lateral border and the muscular process of the arytenoid cartilage. Some of the fibres pass obliquely upwards

towards the aryteno-epiglottidean folds. These are often spoken of as a separate muscle, the *thyro-epiglottidean*. By their action they tend to draw the arytenoid cartilages forwards and to relax the vocal cords. The upper fibres may also assist in depressing the epiglottis. The inner fibres are called the *musculus vocalis*. They arise from the lower half of the angle of the thyroid cartilage, and, passing backwards in the vocal cords, are attached to the vocal processes and to the adjacent parts of the outer surfaces of the arytenoid cartilages. Many fibres do not run the whole distance, but end in an attachment to some part of the vocal cord. Although their action must be to draw the arytenoid cartilages forwards, yet, since they are contained in the vibrating portion of the vocal cords, they cannot by their contraction relax these cords. It is probable that they play a great part in determining the tension of the vocal cords after these have been put on the stretch by the action of the crico-thyroid muscles. They may possibly act as a sort of fine adjustment of the tension, the coarse adjustment being represented by the crico-thyroids.

The Production of Voice. In order to study the changes in the larynx which are associated with voice production, we must make use of the *laryngoscope*. The principle of this instrument is very simple. A large concave mirror with a central aperture is fixed before one eye of the observer, sitting in front of the patient or person to be observed. The latter is directed to throw his head slightly backwards and to open his mouth. In order to keep the tongue out of the way the patient is made to hold the end of it by means of a towel. The mirror is then so arranged as to reflect light from a lamp into the cavity

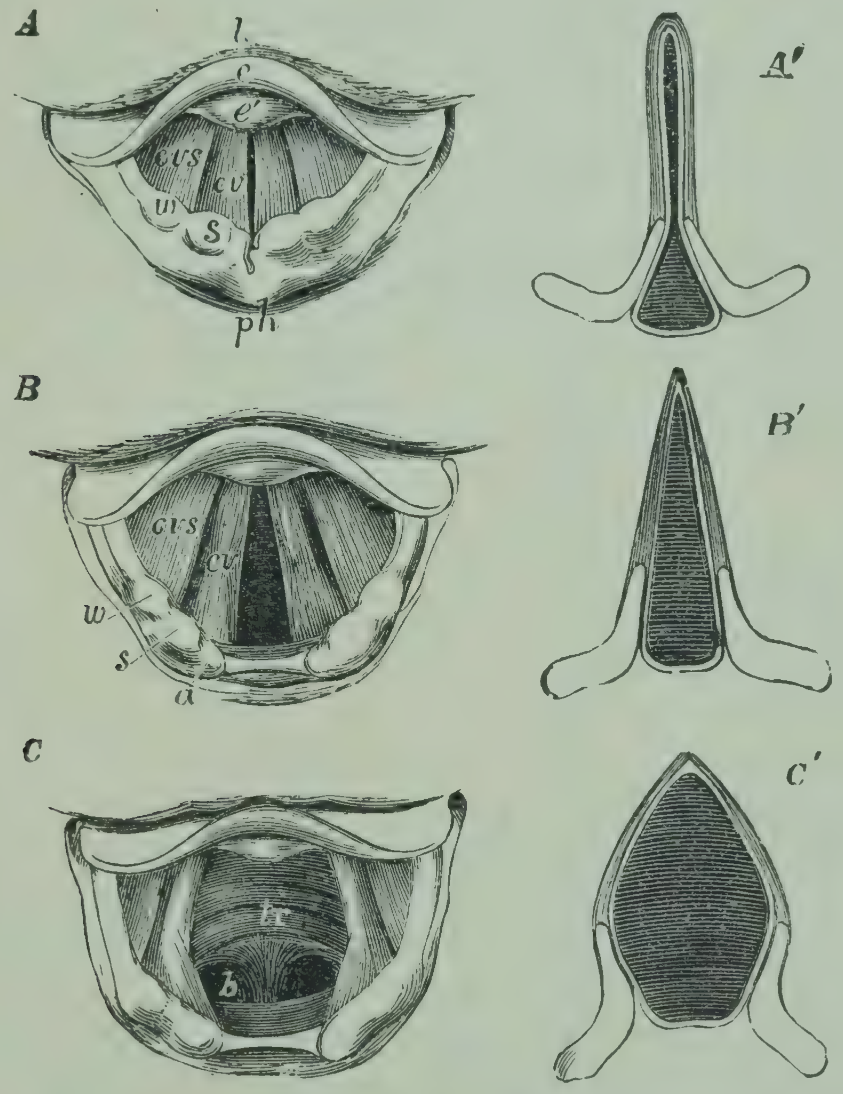

Fig. 315. Three Laryngoscopic Views of the Superior Aperture of the Larynx and surrounding parts on different states of the Glottis during life. (From Czermak.)

A, the glottis during the emission of a high note in singing.
B, in easy or quiet inhalation of air.
C, in the state of widest possible dilatation, as in inhaling a very deep breath.

A′, B′, C′ show in horizontal sections of the glottis the position of the vocal ligaments and arytenoid cartilages in the three states represented in the other Figures. Letters indicate as follows: *l*, base of tongue; *e*, upper free part of epiglottis; *e′*, tubercle of epiglottis; *ph*, part of anterior wall of pharynx behind the larynx; in the margin of the aryteno-epiglottidean fold *w*, the swelling caused by the cuneiform cartilage; *s*, that of the corniculum; *a*, tip of arytenoid cartilages; *cv*, true vocal cords; *cvs*, false vocal cords; between them the ventricle of the larynx.

In *C*, *tr* is placed on the anterior wall of the trachea, and *b* indicates the commencement of the two bronchi.

of the mouth. A small mirror fixed in a handle is then warmed, so as to prevent the condensation of the patient's breath, and passed to the back of the mouth until it rests upon and slightly raises the base of the uvula. By this mirror the light reflected into the mouth from the large mirror is again reflected down on to the larynx, and a reflection of the larynx and trachea is seen in the mirror.

By laryngoscopic examination we can see the base of the tongue, behind which is the outline of the epiglottis. Behind this again in the middle line are seen the two vocal cords, white and shining (Fig. 315, A). The cords appear to approximate posteriorly; between them is a narrow chink, the diameter of which varies with each respiration, being wider during inspiration. On each side of the true vocal cords are seen the pink false vocal cords. In some cases the rings of the trachea, and even the bifurcation of the trachea itself (Fig. 315, C) may be seen in the interval between the vocal cords.

In order that the vocal cords may be set into vibration, they must be put into a state of tension, and the aperture of the glottis narrowed so as to afford resistance to the current of air. In the dead larynx it is possible to produce sounds by forcing air from bellows through the trachea, after the vocal cords have been put on the stretch by pulling the arytenoid cartilages backwards. By experimenting on patients on whom tracheotomy has been performed, it has been found that the pressure of air in the trachea, necessary to cause production of voice, is, for a tone of ordinary loudness and pitch, between 140 and 240 mm. of water, and with loud shouting the pressure rises to as much as 945 mm. of water. This pressure is furnished by the contraction of the expiratory muscles, *i.e.* of the abdomen and of the thorax. Since the pitch of the note produced rises with increasing force of the blast, while the tension of the cords remains constant, it is evident that, in the act of "swelling" on a note, the increased pressure necessary for the crescendo must be associated with diminishing tension of the cords. It is the failure to secure this muscular relaxation that so often causes a vocalist to sing sharp when swelling on any given note.

The voice, like the sound produced on any musical instrument, may vary either in pitch, loudness, or in quality. The range of any individual voice is generally about two octaves. The pitch of the voice usually employed is determined chiefly by the length and mass of the vocal cords. Thus in children the voice is high-pitched. Before and at puberty there is a considerable development in the size of the larynx in both sexes. This is especially marked in the male, and accounts for the sudden drop in pitch ("breaking") of the voice. In the female the greater size of the larynx is chiefly perceptible in the increase in fulness and richness of the voice which occurs at this age. The ordinary human range, from deepest bass to highest soprano, is about four octaves. In singing, the voice may be produced in various ways, *i.e.*, in different registers. Thus we distinguish the chest register, the middle register and the head register. The deeper notes of any individual voice are always produced in the chest register. Observation of the vocal cord shows that when producing such notes the glottis forms an elongated slit, all the muscles which close the glottis and increase the tension of the cords being in action. The vocal cords are relatively thick and broad and can be seen to vibrate over their whole extent. When singing with the head voice, the vibrations of the cord are apparently confined to their inner margins; the aperture of the glottis is wider in front than behind, so that more air escapes during phonation by this method than in the production of the chest voice.✓

In order to change the pitch of the note the following means are probably employed in the larynx:

(1) Alteration in the tension of the vocal cords.

(2) Alteration in the length of the part of the vocal cords that is free to vibrate, which can be accomplished by the approximation of the arytenoid cartilage to one another, or by their approximation to the thyroid cartilage.

(3) The alteration in the shape of the vocal cords, which is determined by the activity of the different portions of the internal thyro-arytenoid muscles.

(4) The varying pressure of the blast of air passing through the glottis.

The loudness of the tone produced is practically proportional to the force of the blast of air employed. The quality or timbre of the voice depends not so much on the vocal cords as on the accessory resonating apparatus, represented by the trachea and chest and by the cavities of the mouth and nose. The greater part of the education involved in voice training is directed to the modification of the shape of the mouth cavity, so as to secure the greatest possible fulness, *i.e.* richness in overtones, of the tone produced in the larynx.

The Acoustics of Speech. The sounds employed in speech, viz. vowels and consonants, are produced by modifying the laryngeal tones by changes in the shape of the throat, mouth and nasal cavities. Vowel sounds are continuous, whereas the consonants are produced by interruptions, more or less complete, of the outflowing air in different situations. In whispering speech there is no phonation at all, but the sound is produced by the issue of a blast of air through a narrow opening between the lips, between the tongue and soft palate, or between the tongue and the teeth.

VOWELS. During phonation the expired air is forced under pressure between the tense vocal cords thus setting them into vibration. A series of fairly regular puffs of air thus pass up the throat to the mouth and nose. This series of puffs constitutes a musical tone which is very rich in harmonics. Certain of these harmonics may be emphasised by the resonant vibrations of the throat, mouth or nose. The various vowels are produced by the variations in the pitches of these accentuated harmonics. Thus on singing ū (as in tool) with a fundamental pitch of 100 v.p. sec. the third harmonic (400 v.p. sec.) and the seventh harmonic (800 v.p. sec.) are accentuated. If, on the other hand, the third and the twenty-first harmonic be accentuated the vowel becomes i, as in will.

The characteristic frequencies of components of the vowel sounds when the fundamental is 100 v.p. sec. are given in the table below.

Series.	Speech Sound.		Low Frequency.	High Frequency.
	ū	mule	**400**	800
	ō	mole	**500**	850
I.	au	maul	**600**	950
	ŏ	moll	**700**	1150
	ar	marle	**825**	1200
	ē	feat	375	**2400**
II.	i	fit	450	**2200**
	ā	fate	550	**2100**
	ă	fat	750	**1800**
III.	ō	foal	**500**	**800**
	ur or er	furl	**500**	**1500**
	ĕ	fell	**550**	**1900**
	ā	fail	**550**	**2100**

In the first series the low frequency resonance is loud and the high frequency one is quiet, and they rise in pitch together. In the second series the converse is found to be the case, for the low frequency resonance is quiet and the high frequency resonance is loud; moreover, as one rises, the other falls. In series III., which may be called the transitional series, since it connects series I and II., the low frequency resonance remains approximately constant in pitch, where the high frequency resonance changes greatly.

If these three series be plotted on a graph with the low frequencies as abscissæ and the high frequencies as ordinates a triangular figure is obtained.

There has been much controversy as to whether the pitch of these harmonic components changes at all with the pitch of the voice, or varies in different individuals. Some said that they did not change, others that their pitch kept in constant ratio with the pitch of the note sung; if the note doubled in pitch, so also did those of the vowel components. Several methods have been employed for investigating this point:

(1) By recording the vibrations emitted by the voice by means of the manometric flame.

(2) By analysis of the vibrations recorded by means of a gramophone.

(3) By measuring the intensity of vibration of series of resonators. All the above methods show that there must be some change, even if it is slight.

(4) By running a gramophone record of a bass voice at an increased speed so that the notes were those of a treble. If now the pitches of note and vowels were in constant ratio, the quality of the vowels should not change when the speed is thus increased. Experiment shows that the words are greatly altered, losing their O's and A's and taking E and I instead. This shows clearly that the change in pitch of the vowels is not nearly as great as that of the note sung with them. We must conclude therefore that neither those who say there is no change, nor those who say there is constant ratio, are right, but that the truth lies between the two extremes. Diphthongs are produced by changing the form of the mouth cavity from that of one vowel sound to another, thus AI (the English I) = ah-ee run together and abbreviated.

CONSONANTS. These are sounds produced by a sudden check being placed in course of the expiratory blast of air by closure of some part of the pharynx or mouth. They are classified into labials, dentals, or gutturals, according as the check takes place at the lips, between teeth and tongue, or between back of tongue and soft palate. Each of these again can be divided into soft and hard consonants as they are accompanied or not by phonation. Thus when we pronounce D the production of the laryngeal sounds goes on during the check of the sound produced at the teeth, whereas with T there is an absolute interruption of phonation during the pronunciation of the consonant. It is thus practically impossible to make any marked difference between hard and soft consonants when whispering.

In the production of nasal sounds, such as NG, the mechanism is the same as for the production of B, D, G, except that the posterior opening of the nares is not kept shut by the soft palate, so that part of the sound comes continually through the nasal passages, when it acquires a peculiar resonance. These sounds are on this account often spoken of as "resonants." The aspirates are produced by the passage of a simple blast of air through a narrow opening which may be at the throat as in H, between tongue and teeth as in TH, or between lips and teeth as in PH or F.

The vibratives, such as R, are formed by placing the tip of the tongue, or the uvula, or the lips, in the path of the blast of air so that they are set into vibration by the blast. The vibrative R employed in English is entirely due to the tongue.

The sibilants, which may be voiceless, as in S, or accompanied with phonation, as in Z, consist of continuous noises produced by a narrowing of the path of the air between the tongue and the hard palate. They are therefore similar in production to the aspirates. In the production of the sound L, the tongue is applied by its edge to the alveolar process of the upper jaw, so that the air or voice escapes by two small apertures in the region of the first molar and between the inner side of the cheek and the teeth. The acoustic characters of these various consonants are still but imperfectly studied.

Much work has recently been done, notably at the Bell and H.M.V. laboratories, to determine the conditions necessary for speech to be intelligible. In the first place the sounds must have adequate intensity. In the second place an adequate band of frequencies must be present. Thus on cutting out low frequency tones from 16 to 400, no loss of intelligibility results. On cutting off from 16 to 500 a 2 per cent. loss results. On cutting out from 16 to 600 a 10 per cent. loss results. With regard to high frequencies, on removing those above 4,000 to 5,000, little or no loss is found. On cutting off those above 3,000, there is a 10 per cent. loss in intelligibility. Thus for good speech, frequencies of 500 to 4,000 should be transmitted to the ears. For adequate speech, probably 600 to 3,000 would be sufficient. In the third place, " hang-over " or reverberation must not exceed about half a second. When a sound is generated in an empty, undraped hall, it continues for some time to reflect to and fro with gradually decreasing intensity. This phenomenon is called reverberation. Knudson carried out investigations in a room the reverberation of which could be altered by lining it with various thicknesses of felt. He found a decrease of intelligibility of speech of 7 per cent. for each second of reverberation time. A room with a reverberation time of half a second should cause a 3½ per cent. decrease of intelligibility, which is a hardly noticeable amount.

The Neurology of Speech. The intricate act of speech involves the employment of three different mechanisms : (*a*) The lungs, (*b*) the larynx, and (*c*) the cavities of the pharynx, mouth and nose. The lungs develop the necessary air pressure. The vocal cords of the larynx set the air into vibration with the required pitch. The cavities above, *e.g.* the mouth, modify the intensity of the tone and the relative intensities of its overtones so as to produce words.

THE LUNGS. For purposes of respiration the lungs are alternately filled and emptied by the synchronous action of the muscles of the chest wall and of the diaphragm. In addition, the muscles of the abdomen and arms and neck may be called into play when occasion demands more thorough ventilation. These muscles are innervated by nerve fibres which originate in the cells of the anterior horn of grey matter in the spinal cord. These same muscles are synchronously brought into play for purposes of phonation by voluntary impulses which, for a time, replace the normal respiratory rhythm. In general, inspiration is quickened, the vocal cords are separated, and air pours into the lungs. The vocal cords are now brought together and put under tension. Expiration now begins, and air commences to pass between the cords ; these vibrate, producing sounds which are modified into speech. Expiration is prolonged until we have completed the sentence. The expiratory pressure even in quiet speech is above that during ordinary respiration, while in shouting not only the ordinary expiratory muscles are forcefully contracted, but the accessory muscles of expiration (*e.g.* the abdominal) are freely made use of as well. Considerable muscular effort is required for loud speech or song. So great may it be that the individual becomes breathless as he does when performing other kinds of severe muscular effort.

THE MUSCLES OF THE MOUTH, Etc. There are six points at least at which modification in diameter of the air cavities above the vocal cords may be produced : (*a*) The false cords, innervated by the recurrent laryngeal branch of the vagus nerve ; (*b*) the pharynx at the level of the root of the tongue, by the pharyngeal branch of the vagus ; (*c*) the buccal cavity near its posterior part, by the elevation or depression of the soft palate, supplied by the spinal accessory nerve ; (*d*) the buccal cavity near its middle, by the elevation or depression of the dorsum of the tongue, innervated by the hypoglossal nerve ; (*e*) the buccal cavity near its front, by the approach of the tip of the tongue to the upper teeth ; (*f*) the buccal cavity at its anterior outlet, by the approximation of the lips (facial nerve).

In addition, the mouth cavity may be varied in size by the change in angle of upper and lower jaw (trigeminal nerve), and the nasal cavity may be allowed to communicate with the pharynx at its posterior outlet (spinal accessory nerve).

We may summarise these nervous controls by saying that the seventh, tenth and twelfth cranial nerves play the principal part in controlling this mechanism of speech.

THE CORTICAL CENTRES OF SPEECH. At one time it was thought that there was a circumscribed motor area for speech. It was called Broca's area after its discoverer, and occupies the posterior part of the inferior frontal gyrus. In right-handed people it is found on the left side of the brain only, and *vice versâ*. Destruction of this area undoubtedly causes dumbness, but histological evidence shows that it is an association area only. After destruction of this area the lungs can still be voluntarily ventilated. The cords can still be approximated and set into vibration, the false cords, pharynx, tongue, and lips can all be separately moved, but the complex correlation of all these separate motor functions is no longer possible. We may say, then, that, as the result of external stimuli, impulses reach Broca's association area, and by it they are distributed in suitable combination to the motor cortex of lips, tongue, cords, diaphragm, etc. The impulses travel down the axons of the Betz cells thus innervated, through the corona radiata, internal capsule, mid-brain, and pons, to reach either directly or through intermediate connections the motor nuclei of the seventh, tenth, and twelfth cranial nerves and the anterior horn cells of the spinal segments involved in the act.

Broca's area is by no means the only important cortical association area involved in speech ; others are found near both the auditory and visual cortex. ✓

APHASIA. It has been usual to divide the disorders of speech, known as aphasia, into the following groups : (1) motor aphasia of Broca ; (2) sensory aphasia of Wernicke ; (3) alexia ; (4) anarthria. A more fundamental idea of the processes involved will, however, be obtained if it is remembered that there are two ways in which the necessary ingoing impressions are received, namely, by reading written or printed words and by hearing spoken words. There are, correspondingly, two different mechanisms by which language may be conveyed, namely, by writing and by speaking. Consideration of these facts would suggest that there may be eight different possible defects: (1) vision may be perfect and yet there may be complete inability in understanding written or printed words (alexia); (2) hearing may be perfect and yet the man may be incapable of understanding what is said to him (this is called sensory aphasia of Wernicke); (3) he may be able to use his hands and to draw with a pencil and yet be unable to write (agraphia); (4) he may be able to use his lips and to make noises with his throat and yet be unable to speak (anarthria or motor aphasia of Broca). Each of the above defects concerns one particular mechanism alone. Other possible defects may concern two mechanisms, one ingoing and one outgoing. Thus (5) there may be ability to read with inability to copy what is read, or (6) ability to read but inability to read aloud, or (7) ability to understand what is spoken but inability to write it down to dictation, or (8) ability to understand what is spoken and yet inability to repeat it.

The neurological basis of language must be regarded as co-extensive with the sensory centres, and with the whole region of lower association. We might speak of auditory and visual word-centres as located in the visuopsychic and auditory psychic centres. There is probably, however, no word, still less a collection of words, expressing an idea which does not involve the activity of practically all parts of the cerebral cortex. As Bolton points out, "a word, such as 'mouse,' at once sets in effect processes of association which pass to every projection sphere with the solitary exception of the gustatory, and even this may be aroused in a person who has eaten a fried mouse in the hope of thereby recovering from an attack of whooping-cough." The amount of impairment of intelligence will vary in different cases according to the extent of the lesion. Thus, softening affecting the occipital lobe may, with hemianopia, cause "word-blindness" or "alexia," a loss of power of appreciating the meaning of written words. In most individuals, and certainly in the uneducated, this power may be cut out altogether without interfering considerably with the mental powers. On the other hand, from babyhood upwards we have learnt the meaning of words and their grouping by auditory impressions. If the whole of the auditory associations be destroyed by an extensive lesion in the first and second temporal convolutions, the resulting loss of word appreciation, sensory aphasia, will be attended with great diminution of mental powers. It must be remembered that the area of Wernicke is not a sensory centre, but a centre of association between the various sense impressions, especially those of hearing and sight. It may therefore be spoken of as an intellectual centre. Pure motor aphasia, if it exists, is always anarthria and is due to a lesion in the lenticulate zone, *i.e.* in the lenticular nucleus and its neighbourhood, in the anterior part and the genu of the internal capsule and possibly in the external capsule.

THE FUNCTION OF EXPRESSION. Although, since it is extremely exact, we rightly give precedence to speech as a means of conveying our ideas to one another, other modes of expression are of considerable interest since they probably once played a more prominent part than they do at the present day. No attempt will be made here to analyse them in detail. They may be divided anatomically into facial, manual, corporal, and pedal. The first comprises all those movements of expression of the superficial muscles of the face, the lips, the jaw, tongue, etc., which are called into play. Thus, corrugation of the superficial muscles of the forehead indicates surprise or worry; if the eyebrows are raised at the same time it indicates surprise; if they are lowered it indicates anger. The orbicularis muscles of the eyes when relaxed show astonishment or interest, and when contracted indicate boredom. Tremor of the lids expresses extreme mental agitation. The lips may be pursed up to show doubt, spread out in a smile, or separated in a grin.

Manual expressions are not so easily analysed as the above, but may be divided arbitrarily under a time, space, and intensity distribution. For example, the placing of the first finger on the lips to give the order for silence;

patting the hands quietly together to signify approval; the slow raising and lowering of the right hand, palm downwards, to signify go slowly or stop. They are largely matters of convention, and some races use them much more than others. The conductor of an orchestra will show many examples of the expressions which come under this category.

As examples of corporal expressions, we have the leaning forward in a chair when interested, or leaning back when bored, or crouching as if to spring when in disagreement with what is being said, or when angered with the speaker, and as instances of pedal expressions, the shuffling of the feet when the mind is anxious, or the stamping of the foot when angry.

All the above are under the control of the will. In addition, there are the emotional symptoms controlled by the sympathetic system which are not under voluntary control—namely, the erection of the hair (the hair " stands on end "), the dilatation of the pupil, the activity of the sweat glands, stimulation of the lachrymal glands expressing sorrow, and the cessation of the secretion of the buccal glands when the mouth becomes dry accompanying an anxious state of mind.

CHAPTER XXVII

CUTANEOUS SENSATIONS

The skin, being the outermost layer of the body, represents the tissue or organ by which the organism is brought into relationship with its environment. In the widest sense of the term the skin is protective. This function it discharges by virtue not only of its physical properties, but also of its rich endowment with sense organs, by means of which the intracorporeal events can be correlated with those occurring outside and immediately affecting the organism.

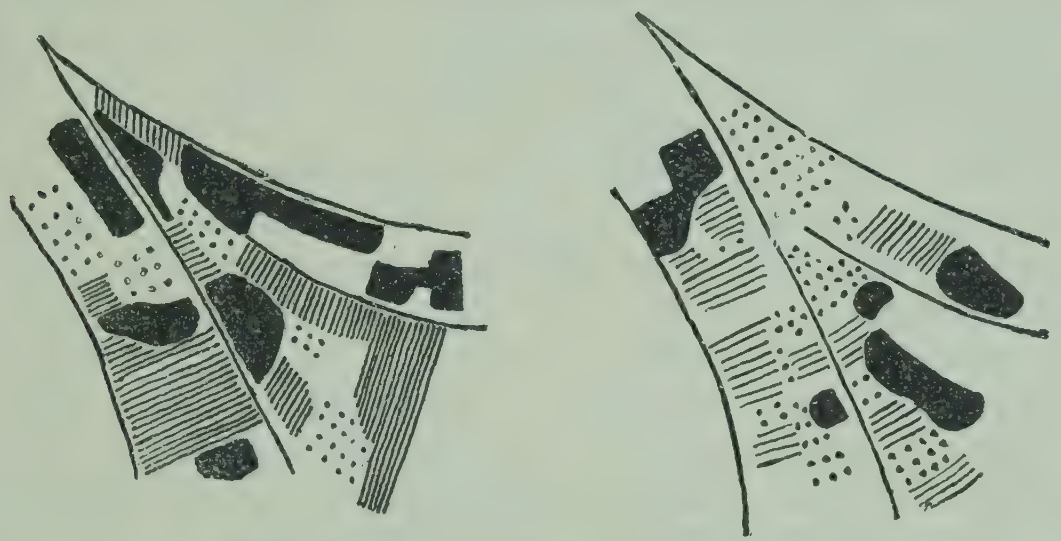
We are accustomed to distinguish several qualities of sensation among those having their origin in the skin, the chief of which are the sense of touch, including that of discrimination, the sense of pain and the sense of temperature. The very different qualities of sensation included under these three classes suggest that there may be a special mechanism, or class of mechanism, for each sense, and a careful investigation of the sensory qualities of the skin surface bears out this idea. Isolated stimulation of minute areas on the skin does not excite all the sensations together, but only a sense of touch or of pain, or a sense of cold or warmth. We are therefore justified in dealing with each of these sensations separately.

THE TEMPERATURE SENSE

By means of the skin we can appreciate when a body coming in contact with it is either cold or warm. If the body is at the same temperature as the skin, as a rule no sensation of temperature is excited. It was formerly thought that the sensations both of heat and cold were determined by the excitation of one and the same end organ. The warming of this end organ would produce a sensation of warmth, while a diminution of its temperature would produce the sensation of cold. Careful investigations of the distribution of the temperature sense by Blix and Donaldson has shown that this opinion cannot be maintained. If a small object warmed to a few degrees above the temperature of the skin be moved over any part of the surface of the body, *e.g.* the back of the hand, it is found that the warmth of the instrument is not equally appreciable at all parts of the surface of the skin. At some points the sensation of warmth will be very pronounced, but between these points the sensation of warmth may be entirely wanting and the instrument may be judged to be of the same temperature as the hand itself. In this way a series of " warm points " may be mapped out. On now cooling the instrument a few degrees below the temperature of the surface of the body and then moving it over the surface in the same way, it will be found again that the coolness of the instrument is appreciated only at certain points ; these can be regarded as " cold points " and as containing the nerve endings by the excitation of which the sensation of cold is produced. If the warm points be pricked out in red ink and the cold points in blue ink, it will be seen that they do not in any way correspond.

A convenient instrument for this purpose is the one invented by Miescher, consisting of two tubes cemented together and communicating at a small flattened extremity, which is applied to the surface of the skin ; water can be led through the tubes at any desired temperature, which is read off by a thermometer placed within the tube. Having mapped out the warm spots, it may be shown that they are excitable by means of mechanical or electrical stimuli and that the sensation produced is the same as if they had been excited by their adequate stimulus, viz. a rise of temperature.

Exact Location of the spots is rendered difficult by the irradiation of the sensation produced, so that it is difficult to refer the sensation of warmth or cold definitely to the point stimulated. An investigation of the topography of these warm and cold spots shows that the apparatus for the appreciation of cold is much more extensively distributed over the body than that for the appreciation of warmth, as is evidenced from the diagram (Fig. 316) giving the topographic distribution of the cold and warm sense organs on the palm of the hand. Waterston (1923) claims that in the case of both heat and cold, the topographic distribution of the spots alters continually. In skin suffering from a mild erythema, all parts respond to warmth, that is, all signs of a punctate arrangement have gone. He concludes that all parts of the skin can respond to both heat and cold, the punctate arrangements found at a single examination being due to some parts being more active than others. The skin capillaries are stated to show a similar change from time to time in the quantity of blood which they transmit. The temperature sense is best marked in the following regions of the body : the nipples, chest, nose, the anterior surface of the upper arm and the anterior surface of the fore-arm, and the surface of the abdomen. It is much less marked on the exposed parts of the body, such as the face and hands, and is but slight in the mucous membranes. Thus it is possible to drink hot fluid, such as tea, at a temperature which would be painful to the hand, and still more to other parts of the body. The scalp is also very insensitive to changes of temperature. The acuteness of the temperature sense varies considerably with the condition of the skin and with the previous stimulation of the sense organs. The sense is most acute at about ordinary skin temperature, *i.e.* between 27° and 32° C. At this temperature the skin can appreciate a difference of $\frac{1}{8}$° C. When the skin is very cold or very hot, the temperature sense is not nearly so delicate. This sense presents the phenomenon of adaptation in a marked degree. It is a familiar experience that, on coming from the external air on a cold day into a warm room, a sensation of warmth is experienced all over the body. In a few minutes this sensation wears off. On now leaving the room to go outside again, the sensation of cold is at once appreciated, to disappear in its turn after a few minutes. The effect of adaptation is still better shown by the experiment of taking three basins of water, *a*, *b*, and *c* ; *a* contains cold water, *b* tepid water, *c* hot water. The left hand is immersed in the cold water and the right hand in the hot water for a few minutes. On now placing both hands into the basin of tepid water, it feels hot to the left hand and cold to the right hand. Such experiences as this led Weber to the conclusion that the essential stimulus for the temperature sense was not the actual temperature to which the sense organs were subjected, but the fact of a change of temperature. He imagined that, while the temperature sense organs were being warmed, a sensation of warmth was produced, and when their temperature was being lowered, a sensation of cold. Such a theory,



Cold spots. Heat spots.

Fig. 316. Heat and Cold Spots on part of Palm of right Hand.

The sensitive spots are shaded, the black being more sensitive than the lined, and these than the dotted parts. The unshaded areas correspond to those parts where no special sensation was evoked. (Goldscheider.)

however, would not account for the fact that, above a certain temperature, water may feel warm and the feeling may continue so long as the skin continues to be stimulated. On a cold day the air may feel cold to the face and the feeling may last the whole time that the face is exposed. Moreover we have in the temperature sense, conditions which remind one of the after images which occur in the eye. If a cold object be pressed on the forehead and then removed, the sensation of cold lasts some little time after the object has been removed. In this case a sensation of cold is produced although the end organs are being gradually warmed up after the removal of the cool object. In order to account for these facts Hering, at a time when the differentiation of hot and cold spots had not yet been effected, suggested that the temperature sense organs could be regarded as having a zero point at which no sensation was produced. If their temperature was raised above this point, a sensation of warmth was produced, and *vice versâ*. The zero point, however, was not a fixed one, but could move upwards to a certain extent on prolonged exposure to high temperature, or downwards on prolonged exposure to a low temperature. In the light of the researches of Blix and Goldscheider, we should have to apply Hering's theory of a zero point to each of the temperature end organs separately.

A cold pencil passed over a warm spot evokes no sensation whatsoever. If, however, a pencil considerably warmer than the skin be passed over a cold spot, this may be excited so that the paradoxical result is produced of a sensation of cold as the result of stimulation by a warm body. It is a familiar fact that the immediate effect of entering a hot bath is very much the same as that of entering a cold bath, viz. a rise of blood pressure and contraction of the unstriated muscles of the skin and hair follicles with the production of "goose skin." It has been suggested that the distinctive quality of a sensation of *hot* as compared with that of *warm* is due to the simultaneous stimulation of cold spots. With regard to the identity of the sense organs for warmth and cold, J. P. Nafe's theory must be referred to, namely that the sensation of warmth is brought about by dilatation of the skin vessels, and that to some extent the sensation of cold is brought about by their contraction. He supports his theory by evidence among which we may notice (1) the sensation of flashes of warmth and cold when the arteries of the skin are punctured * ; (2) the striking proximity of blood vessels to cold points ; (3) the absence of blood vessels and the absence of cold and warmth sensations from the cornea ; (4) the similarity of the reaction times for the appreciation of warmth and cold, and the contraction and dilatation of the skin blood vessels.†

THE SENSE OF TOUCH

By means of the sense of touch we arrive at a conclusion as to the qualities, such as shape, texture, hardness, etc., of the bodies with which the skin is in contact. In this judgment, however, very many other sensations are involved besides those which can be regarded as strictly tactile. Thus, the hardness of an object signifies its resistance to deformation, besides its power of deforming the skin surface with which it is in contact ; the former quality, *i.e.* of resistance, is one which involves the muscular sense, since we judge of it by the extent to which we can move our muscles without causing any alteration of the surface of the object.

The tactile sensibility of the skin as a whole, like its temperature sensibility, was thought to have a punctate distribution. Recent work on the subject, by Waterston (1923), throws very great doubt on the validity of this idea.

RESPONSE TO DIFFERENT STIMULI. The adequate stimulus for the tactile nerve endings is not so much pressure, as deformation of surface. It appears to matter little whether the surface be deformed by pulling it or by pushing an instrument into it. The ineffectiveness of mere pressure is shown by dipping the finger into a vessel of mercury. The sensation of pressure is noted only at the point where the finger passes through the surface of the mercury, and this is the only part where there is an actual deformation of the skin, due to the sudden passage from the pressure of the mercury to the negligible pressure of the outside air. The tactile apparatus is smarter in its response than any other of the sense organs. On this account stimuli are still perceived as discrete, when they are repeated at a rhythm which would result in complete fusion in the case of any of the other sense organs. Thus if a bristle be attached to a tuning fork and allowed to press on the skin, the vibrations of the fork are perceived by the ear as a continuous sound and by the skin as a series of discontinuous taps. Faradic currents when applied to the skin can be perceived as separate when repeated at the rate of 130 per second. The sensations evoked by placing the finger against the edge of a cog-wheel do not become continuous until the wheel is revolving at such a rate that the stimulation on the skin by the serrations occurs at a greater rate than 500 or 600 per second. The tactile apparatus resembles all the other skin sense organs in showing adaptation. A stimulus after continuing for some time may become ineffective. We are usually entirely unaware of the stimulation of our skin by the pressure of the clothes, and even an unwonted stimulation, such as that of the mucous membrane of the mouth by a plate carrying artificial teeth, though almost unbearable during the first day, rapidly becomes less, and in a few days it is not perceived at all.

† See p. 1057, "Handbook of General Expt. Psychology." (Clark Univ. Press, 1934.)

In order to test the sensitiveness of touch we may use the method introduced by Hensen, viz. the bending of a glass-wool fibre. We can determine the pressure at which any given fibre will bend, and if we find by trial the fibre which just evokes sensation when pressed on the skin, we know exactly the force which we are applying to the skin. Von Frey employed hairs of different thickness for the same purpose (Fig. 317). The following represents the minimal excitability of the surface of different parts of the body when tested in this way:

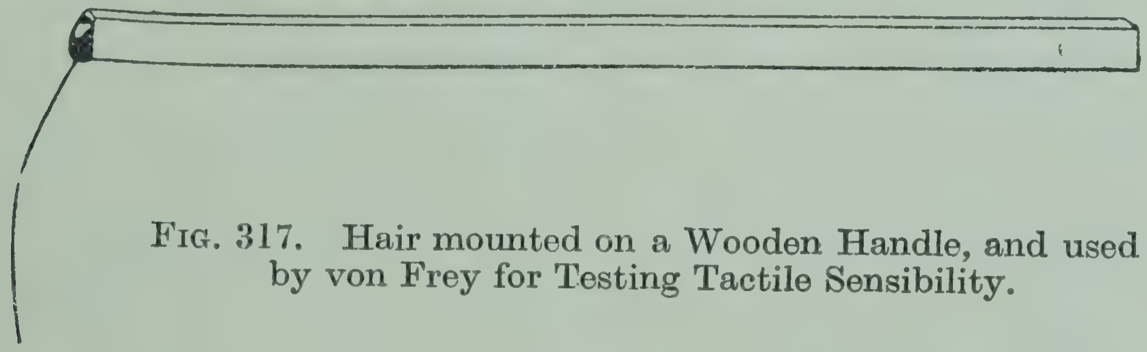

FIG. 317. Hair mounted on a Wooden Handle, and used by von Frey for Testing Tactile Sensibility.

	Grm. per sq. mm.
Tongue and nose	2
Lips	2·5
Finger-tip and forehead	3
Back of finger	5
Palm, arm, thigh	7
Fore-arm	8
Back of hand	12
Calf, shoulder	16
Abdomen	26
Outside of thigh	26
Shin and sole	28
Back of fore-arm	33
Loins	48

The sensitiveness of the sense organs in the skin is probably much greater than that of the nerve trunks themselves. Thus Tigerstedt found that the minimal mechanical stimulus necessary to excite the exposed nerve amounted to 0·2 grm. moving at 140 mm. per second. For the touch spots, von Frey found that 0·2 grm. moving at 0·17 mm. a second is an adequate stimulus.

In testing the sensibility of any surface, it is important to remember that the hairs themselves form very effective tactile organs. The touch spots are distributed in greatest profusion around hair follicles, and there is a rich plexus of nerve fibres round the root of each hair. A slight touch applied to the hair acts on these as on the long end of a lever, the hair being pivoted at the surface of the skin, so that pressure on the hair, increased five or more times in force, is transmitted to the hair follicle and the surrounding nerve endings. The actual sensibility of any part is therefore much diminished by removal of the hairs. On 9 sq. mm. of the skin, from which the hairs had been shaved, the minimal stimulus necessary to evoke a tactile sensation was found to be 36 mg., whereas on the same surface before it was shaved 2 mg. was effective.

WEBER'S LAW. The smallest increment or decrement of stimulus which determines a perceptible difference of sensation must, according to Weber's law, always bear the same ratio to the whole stimulus. In measuring such differences it is best to apply the stimulus successively to the same surface of the skin, rather than simultaneously to adjoining areas. The time interval between two successive stimuli should not be more than five seconds and the duration of the stimuli should be equal. Weber found that in the terminal phalanx of the finger the minimal perceptible difference was about one-thirtieth, but the ratio was not the same for all regions of the skin nor for all individuals. The following represents the liminal difference in various skin regions :—

Forehead, lips and cheeks	1/30th to 1/40th
Back of fore-arm, of leg and of thigh ; back of hand, and first and second phalanx of finger, etc.	1/10th to 1/20th
All parts of the foot, leg and thigh	more than 1/10th

THE SPATIAL QUALITY OF TOUCH. DISCRIMINATION. If any part of the skin be stimulated, the subject of the experiment can tell at once the exact situation of the excited spot. If two points be stimulated simultaneously, excitation is perceived as double, *i.e.* as proceeding from two points, provided the distance between the points exceeds a certain amount, varying in different parts of the body. The power of discrimination, *i.e.* of judging whether a stimulus is single or double, can be tested by arming the points of a pair of compasses with small pieces of cork and then seeing how far apart these must be when pressed on the skin in order that the stimulus may be perceived as double. The following Table represents this distance for various regions of the body :—

DISTANCE IN MM.

Skin region.	mm.
Tip of tongue	1·1
Volar surface of finger tip	2·3
Dorsum of third phalanx	6·8
Palm of hand	11·3
Back of hand	31·6
Back of neck	54·0
Middle of back, upper arm, and thigh	67·1

When touch spots are sought out for stimulation with the points of a compass, the distance at which the excitation is perceived as double is much diminished, as is shown by the following Table of distances for the touch spots in millimetres :

Skin region.	Distance of touch spots.
Volar side of finger tips	0·1
Palm of hand	0·1
Fore-arm (flexor side)	0·5
Upper arm	0·6
Back	0·4

The compass points are perceived to lie apart with a special distinctness when they are applied to touch spots lying on different lines which radiate from the hair follicles. The figures given in the first Table have no relation to touch spots, but show the average distance at which no excitation can be perceived as double.

The delicacy of discrimination of any part is largely associated with its mobility. Thus, in the arm the delicacy increases continuously from the shoulder to the finger tip. If the localising power for touch on the shoulder be taken as 100, that of the finger tips will be represented by 2,582. In the same way there is a continuous decrease of the distance of discrimination as we pass along the cheek from the ear to the lip, *i.e.* from the nonmobile to the mobile part. The power of discrimination is increased to a certain extent by practice and largely diminished by fatigue. Any factor which diminishes the tactile sensibility of the part, such as cold, will also diminish the power of discrimination.

Localisation of Touch. The fact that we can localise the point of stimulation shows that every tactile sensation derived from the surface of the body, besides the qualities of intensity and extensity, has also associated with it a characteristic quality dependent on its position. This localised quality of a tactile sensation was called by Lotze "local sign." Among psychologists there has been much discussion as to how far this local sign is an inborn attribute of the sensation of every point on the body surface, or how far it is acquired by experience and based on memory of movements and muscular impressions. In the retina we have a sense organ which, like the skin, possesses local sign but in far higher degree, the power of discrimination of the retina being three thousand times as great as that of the most sensitive part of the skin. Cases of congenital cataract occur in which the subjects have been blind from birth. By extraction of the cataract we can give such persons the power of sight. It is found that at first there is no power of localising visual impressions. The local sign is developed only in response to experience, by comparing simultaneous visual, tactile and motor sensations. By analogy we might ascribe the local sign of cutaneous sensations to a similar causation. Our study of the spinal animal has indeed given us a physical or histological conception of local sign. We know that stimulation of any part of the body evokes an appropriate reaction, the nature of which is determined by the central connections of the entering nerve fibres. A fibre entering at one segment must therefore come into relation with a different set of motor cells from those which are set into action by a fibre entering one segment lower down. Every nerve fibre from the skin will therefore have an appropriate complex of motor paths in functional connection with its central endings ; and when the activity of these reflex paths comes to be represented in consciousness, it is evident that the sensation derived from any one point must differ from that derived from any other point of the skin, by virtue of the differing motor events actually or potentially excited from the two points. In ascribing local sign to coincident muscular sensations and to the memory and experience of past movements, we are therefore giving but an imperfect explanation ; since the difference between the sensations from different parts, which is at the bottom of our powers of localisation, has its origin in the structure of the central nervous system itself and is present from the very beginning of the evolution of a reactive nervous system.

Projection of Touch. Since the alterations in the surface of the skin which give rise to tactile sensations are habitually caused by contact with external objects, we come to regard the sensations themselves, not as changes in the skin, but as qualities of the object which touch the skin, *i.e.* we project the sensation. The projection is, however, not so great as in the case of visual sensations. Cutaneous sensations we always consider as qualities of an object immediately affecting and altering the condition of ourselves, whereas the visual sensations are referred at once to objects lying right away from ourselves, so that we are not aware that any change has taken place in our bodies as a result of the entering of rays of light into the eye.

It is remarkable to what extent projection of touch sensation may occur.

Thus a surgeon actually lengthens his fingers by using a probe. When he is probing for dead bone he feels the grating of the bone, not at his finger tips, but he projects the sensation to the end of the probe. In the same way tactile sensations evoked by the contact of bodies with the insentient endings of hairs are referred to the ends of the hairs rather than to the hair follicles where the nerve impulses actually come into being.

The dependence of local sign on habitual experience is shown by the various tactile illusions, such as the well-known experiment of Aristotle. If with the eyes shut we cross the first and middle fingers and bring them in this position in contact with a pea, we should at once say that two peas lay under the fingers. This is especially marked if the pea be rolled between the fingers. The two sides of the fingers which come in contact with the pea usually touch two different objects, and these parts of the skin would have to be re-educated, *i.e.* their local sign would have to be changed in accordance with the changed conditions, before the pea would be perceived in its true state as single.

THE PAIN SENSE

When the pressure of a hard object on the skin is increased beyond that necessary to evoke a tactile sensation, at a certain pressure the quality of sensation changes and it becomes painful. For the evolution of the race as well as for the preservation of the individual this pain sense is all-important; it is the expression in consciousness of the reflexes of self-preservation which can be evoked in the spinal animal by stimuli which are nocuous, *i.e.* calculated to do actual damage to the tissues of the body. Thus when a sharp point is pressed on the skin, the sensation becomes painful just before the pressure is sufficient to cause penetration. The so-called trophic lesions, which occur in parts devoid of sensation, are determined for the most part by the lack of the pain sense and the consequent failure of the preservative reflexes of the part. It is remarkable that pain may result from changes in organs which are devoid of ordinary sensibility. Thus the intestine may be cut, sewn or handled without arousing any sensation whatsoever. A strong contraction of the muscular wall or increased distension of the gut will, however, evoke a griping pain. In the same way the ureters, which are normally devoid of sensation, can give rise to excruciating agony when they are contracted firmly on a retained calculus.

We are accustomed to distinguish many different qualities of pain, but on analysis it will be found that these qualities depend on the nature of the sense organ which is simultaneously stimulated. Thus a burning pain denotes simultaneous stimulation of the pain sense and of the nerve endings to the warm spots. A throbbing pain results when the vessels of the part are dilated and the part is tense with effused lymph, so that each pulse of the vessels causes an exacerbation of the painful stimulation and perhaps also stimulation of the tactile end organs.

The sense of pain has often been ascribed to over-maximal stimulation of any form of sensory nerve. Although it is true that over-stimulation of the auditory or optic nerve by a loud sound or a bright light may be extremely unpleasant, the sensations evoked do not partake of the characters of painful sensations such as would be produced by pricking or burning the skin. Moreover a careful investigation of the sensory points on the skin brings out the fact that there are, besides the tactile and temperature spots, other spots from which only painful sensations can be evoked. We have seen already that over-stimulation of a touch spot does not, as a matter of fact, cause pain. The pain spots which are distributed among the touch and temperature spots are insensitive to a low grade of stimulus. As the strength of the stimulus is increased, a point is suddenly reached at which the sensation evoked is painful. Moreover, in parts of the body, tactile and temperature sense are entirely wanting, though painful impressions can be easily evoked. The best example of this is seen in the cornea, minimal stimulation of which evokes pain, but nothing which can be regarded as a tactile sensation. The specific quality of pain sensation is shown moreover by the fact that in many cases of disease the sense of pain may be abolished without the sense of touch. Such a patient is said to suffer from analgesia, but not from anæsthesia. When an analgesic part is pricked the patient can say that he is pricked, but has no objection to any amount of repetition of the stimulus, since the sensation is entirely devoid of painful character. In the case of the skin, pain is found to differ somewhat from the other skin sensations in being much more uniformly distributed, more difficult to locate accurately, and more hardy. Thus while most sense organs are rendered less sensitive by cutting off blood supply, pain at first reacts more violently.

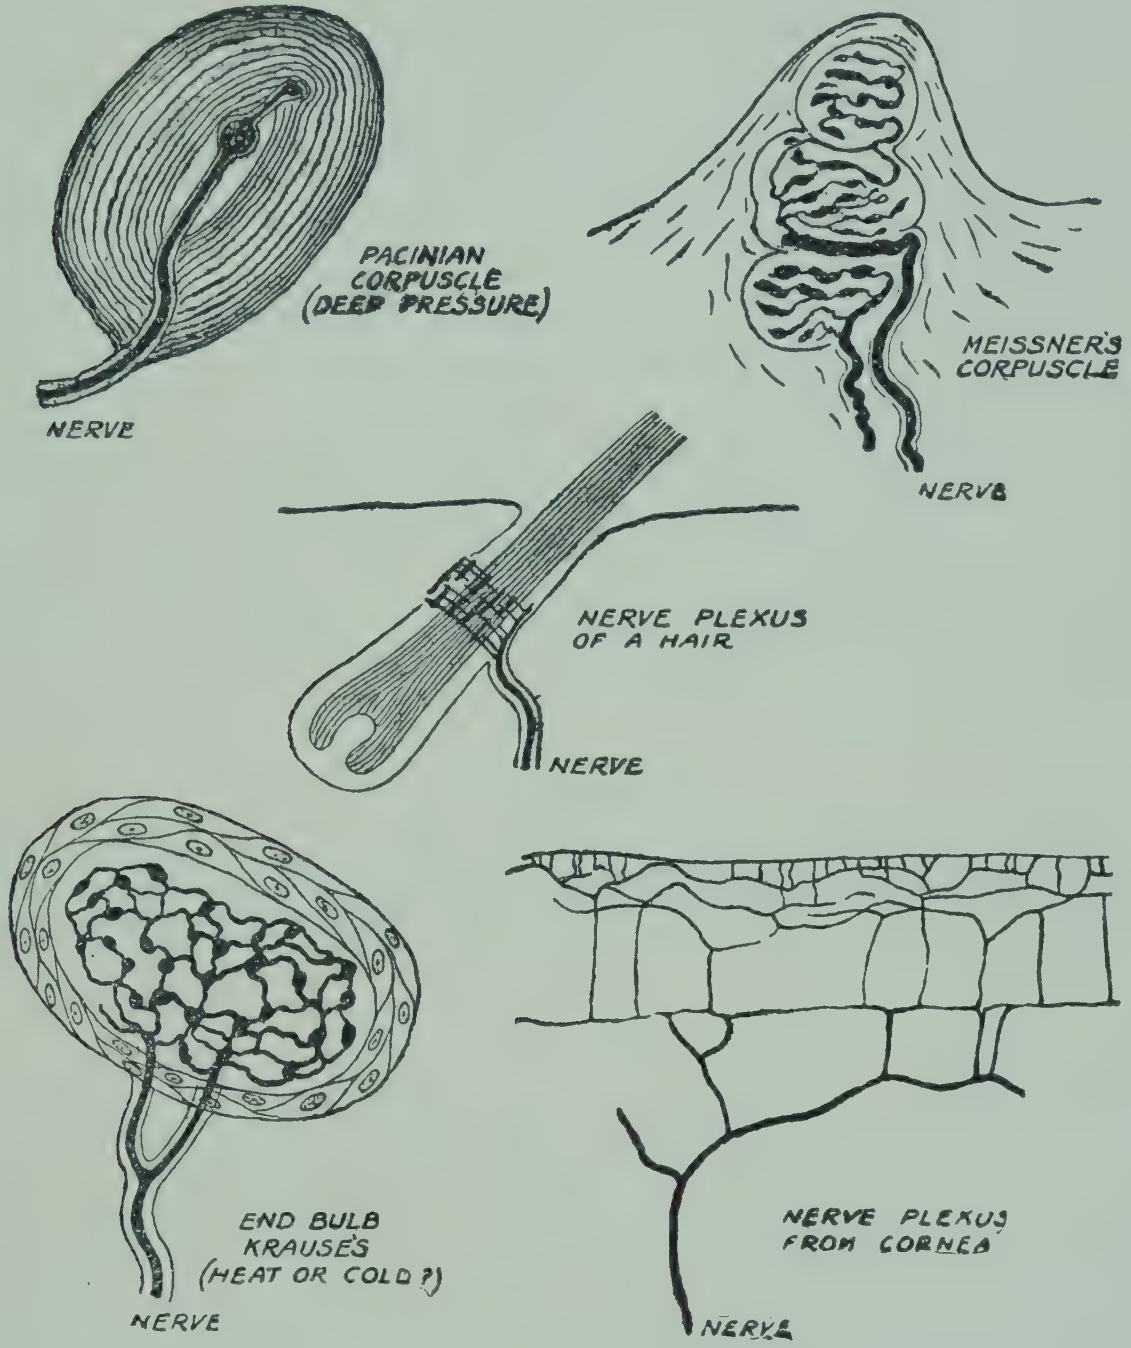

FIG. 318. Skin End Organs and the Sensations which they arouse. It has been supposed that corpuscles of the type of Meissner's corpuscle are for touch, and that nerve plexuses, such as that illustrated for the cornea, subserve pain sense.

Protopathic and Epicritic Sensations. As the result of experiments by Head and Rivers, in which a sensory nerve (the radial) in the arm was cut, and the returning sensibility followed during regeneration, it was thought that the sensations could be divided into three groups—epicritic, protopathic and deep. Deep sensations remained after the nerve had been cut, and consisted of pressure sense and pressure pain. Protopathic sensibility was the first to return and consisted of a vague pain sense and a sensation to hot objects above 38° C. and cold ones below 24° C. Epicritic sensation, the last to return, gave critical discrimination and localisation and differentiation of temperatures between 25° C. and 37° C.

But recent workers, Trotter and Davies (1909), and Boring (1915), who have repeated Head's and Rivers' experiment, and Carr (1916), who subjected Head's and River's own data to analysis, agree in the conclusion that the distinction into protopathic and epicritic is purely artificial and must be finally abandoned.

The Histological Character of the Elements Involved in Cutaneous Sensations

A very large number of different forms of sensory nerve endings have been described in relation to the skin. Their exact allocation among the different cutaneous senses presents considerable difficulties.

As regards touch, two kinds of elements are probably involved. In the first place, the most sensitive tactile apparatus are the follicles of the short hairs. Around these follicles we find a sheaf of nerve fibres, some of which end in the hair papillæ and others form a ring near the level of the openings of the sebaceous glands. The other tactile end organ is, according to Waterston (1932), the nerve plexus which terminates in the epithelial cells of the more superficial layers of the epidermis. The evidence he advances for this view is that on cutting away the superficial layers with a razor the sensation of touch is impaired or removed, leaving the sensation of pain unaffected. Other end organs, which are supposed to be stimulated by changes of pressure and therefore to be tactile, are the organs of Ruffini which occur in the papillæ of the palm and fingers, and, lying more deeply, the elastic tissue spindles as well as the Golgi corpuscles and the Pacinian corpuscles in the subcutaneous tissue.

As regards pain, we know that in the cornea, which possesses only the pain sense. the sensory nerve endings are in the form of branches of axis cylinders among the epithelial cells. Since by a section of the skin parallel with the surface the touch spots can be removed, leaving the pain spots, Waterston concludes that the sensory end organs for pain are more deeply placed than those for touch, and he identifies pain with Meissner corpuscles. It would be possible, however, to explain Waterston's experiment on the basis of the usual assumptions (*i.e.* that pain originates in free nerve terminals and touch in Meissner corpuscles), by supposing that the sensation of pain which remains is due to irritation of the cut ends of the sensory nerves and not to stimulation of the Meissner corpuscles. Further experiments are required to clear up these points. We have at present no evidence as to the histological character of the organs by which the sensations of heat and cold are aroused. They are believed to be Krause's end-bulbs.

CHAPTER XXVIII

SENSATIONS OF SMELL AND TASTE

EVERY living organism shows a susceptibility, *i.e.* a power of reaction, to chemical stimuli. These movements of attraction and repulsion are spoken of as positive and negative chemiotaxis respectively. The aggregation of leucocytes round microbes or other foreign particles in the tissues is also determined by their chemiotactic sensibility. *Chemiotaxis*, then, represents the faculty by means of which these minute organisms are able to adapt themselves to chemical changes in their environment and to react to chemical substances diffusing towards them from a distance.

On the other hand, a chemical sensibility of the body surface, or part of it, furnishes the criterion by which particles are accepted and ingested as food or rejected as useless or harmful. Consciousness in this case would be of something in contact with and affecting some part of the organism itself. The sensation would not be projected farther than the periphery of the body.

These two kinds of chemical sense—the projected and the surface sense—are found throughout almost all classes of the animal kingdom, and in the higher animals at least are known as the senses of smell and taste. The former sense in many animals attains a high degree of complexity and is prepotent in determining the behaviour of an animal in response to the changes in its surroundings. In the elasmobranch fishes the olfactory lobes form the greater part of the higher brain, and extirpation of them produces a loss of spontaneity and of delayed reactions similar to that which can be brought about in higher types by extirpation of the whole of the cerebral hemispheres.

The sense of taste, on the other hand, is used only for sampling the nature of substances taken into the mouth and determining their ingestion or rejection. It is therefore much simpler in its extent and more susceptible of analysis.

THE SENSE OF TASTE

The end organs which subserve the function of taste are represented by the *taste buds*. These are oval bodies (Fig. 319) embedded in the stratified epithelium, which occur scattered over the tongue, a few being also found on the hard palate, the anterior pillars of the fauces, the tonsils, the back of the pharynx, the larynx, and the inner surface of the cheek. On the tongue they are found chiefly in the grooves around the circumvallate papillæ of man, and in the grooves of the papillæ foliatæ of rabbits. A few are also present in between the fungiform papillæ. They consist of medullary and cortical parts, the latter being composed of columnar or sustentacular cells, the former of thin fusiform cells, the taste cells proper. The nerve fibres concerned with taste end in arborisations among these taste cells. The peripheral end of the fusiform cell projects as a delicate process through the orifice of the taste bud, so that it can come in contact with the fluids contained in the cavity of the mouth. A sapid substance, to stimulate these organs, must be in solution ; hence quinine in powder is almost tasteless, owing to its slight solubility.

DIFFERENTIATION OF TASTE. The number of classes of tastes is very limited. We distinguish four primitive taste sensations, viz. sweet, sour, bitter and salt, some authors adding to these an alkaline taste and a metallic taste. Many substances owe their distinctive character when taken into the mouth to the fact that they stimulate not only the taste nerves but also the nerve endings of tactile sensation. Thus acids, when in weak solution, have an astringent character besides their sour taste, and if strong produce a burning sensation. The primitive taste sensations can affect one another if excited simultaneously. With weak stimulation one taste may practically annul another. Thus a dilute solution of sugar is rendered almost tasteless by the addition to it of a few grains of common salt. If the primitive taste sensations are more strongly excited we get a mixed sensation, in which the components can still be distinguished. Thus, adding sugar to lemon juice not only diminishes its acidity but produces a mixed sensation, the quality of which is pleasant and in which the components, sour and sweet, can be easily distinguished. We get no such fusing of sensations as in the eye, where a sensation of white light may result from stimulation of the retina by two complementary colours. Stimulation of one kind of taste organ heightens the sensibility of the other taste organs. Thus, after the application of salt, distilled water may taste sweet. The sense of taste may be investigated in three ways: (1) By ascertaining the greatest dilution of a substance that will cause a definite taste; (2) by ascertaining how long a solution of a substance must be applied for a taste to be aroused; (3) by ascertaining the least difference between the strengths of two solutions of the same substance which taste different to the experimenter.

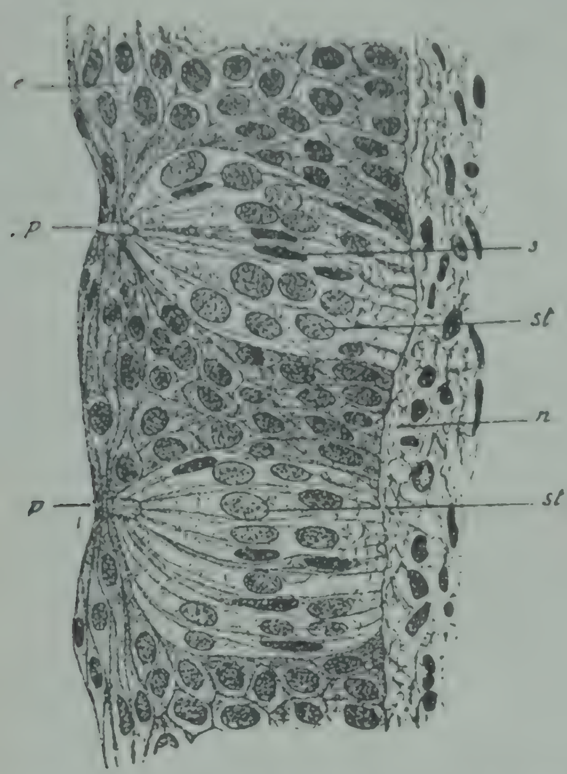

FIG. 319. Two Taste Buds from the Tongue. (KÖLLIKER.)

e. Stratified epithelium.
p. Opening or pore of taste bud.
n. Sub-epithelial tissue.
s. Gustatory cells.
st. Sustentacular cells.

By these methods we find:—

(*a*) The tongue is not equally sensitive at all points to all four tastes. Thus the back of the tongue is more sensitive to bitter, while the tip and sides of the tongue react more easily to sweet and sour substances. A difference may even be detected between the circumvallate papillæ themselves; a mixture of quinine and sugar applied to one papilla may excite chiefly a bitter taste, while with an adjacent papilla a sweet taste may predominate.

(*b*) By certain drugs we can depress the sensibility of the taste organs, and we then find that the various tastes are affected to different degrees. Thus on painting the tongue with cocaine the first effect is a diminution of tactile and pain sensibility, so that the application of acid evokes a very sour taste without any of the astringent or stinging sensations normally aroused by the contact with the acid. After this point the taste sensations are also mostly abolished. The bitter sensation disappears first, then the sweet and then the sour, while the taste of salt appears to remain unaffected. On the other hand, if the leaves of *Gymnema sylvestre* be chewed, the sensations of bitter and sweet are abolished, leaving intact the acid and salt tastes, and also the general sensibility of the mucous membrane.

TASTE AND CHEMICAL CONSTITUTION. There is no doubt that the stimulating effect of any chemical substance on the taste nerves has relation to its chemical constitution. Thus a sour taste is determined by the presence of H ions; the alkaline taste by that of OH ions. The fact that certain acids, *e.g.* acetic, have a stronger sour taste than would correspond to their dissociation, *i.e.* to the number of H ions present, is due to the fact that these acids penetrate more easily into the gustatory cells than the mineral acids with a larger dissociation co-efficient. All the α-amino-acids have a sweet taste. On the other hand, the polypeptides produced by the combination of these amino-acids, as well as the peptones derived from the hydrolysis of proteins, have a bitter taste. Most of the alcohols and sugars have a sweet taste, while the metallic derivatives of these substances are bitter. We do not yet understand the law which determines whether any given substance shall have a taste at all, and what its taste should be.

The nerves of taste are the glossopharyngeal, which supplies the back part of the tongue, and the lingual branch of the fifth nerve and the chorda tympani which supply the front part. All these fibres are probably connected with a continuous column of grey matter in the brain stem, which represents the splanchnic afferent nucleus of the fifth nerve, the nervus intermedius and the glossopharyngeal. Some authors have stated that all the taste fibres of the fifth nerve are derived from the glossopharyngeal by the communication through the tympanic plexus and the chorda tympani nerve, while Gowers has recorded a case of complete unilateral loss of taste in which there was a lesion destroying the fifth nerve, the glossopharyngeal being intact. It seems possible that the actual region of the taste nerve may vary, the fibres running to the splanchnic column of grey matter being contained sometimes in the fifth, sometimes in the glossopharyngeal, and sometimes in both.

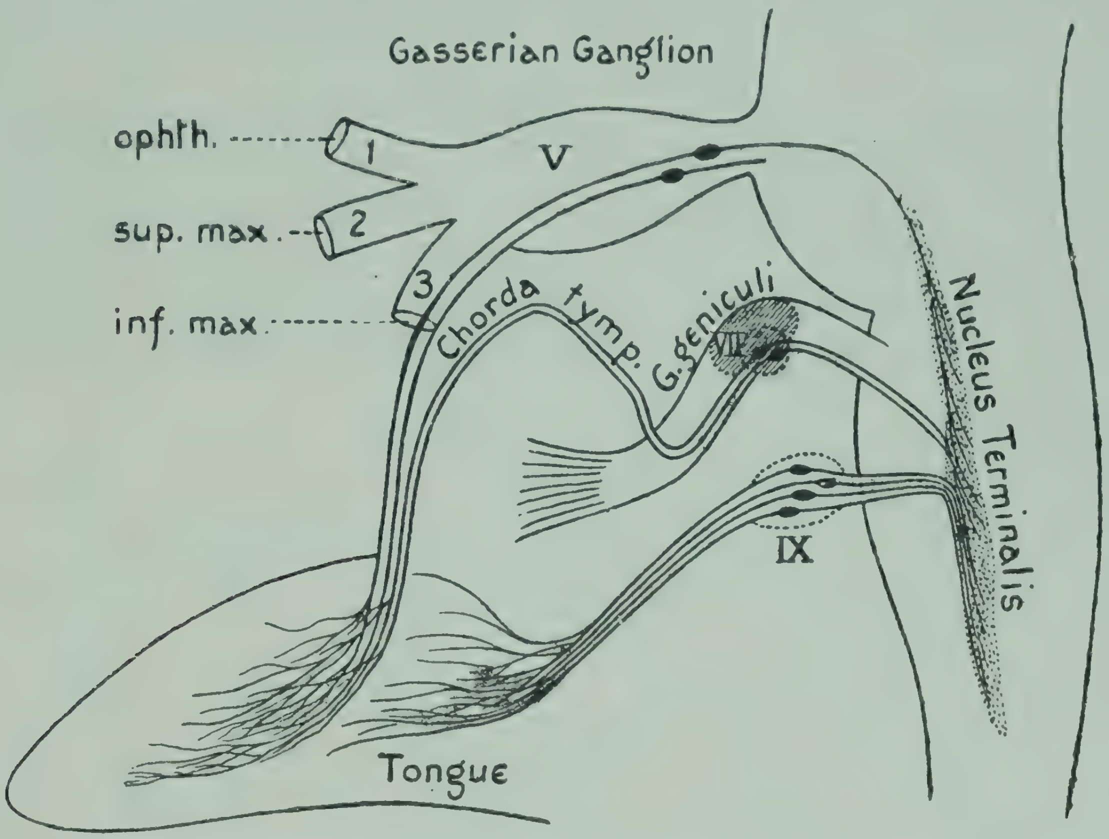

FIG. 320. Diagram showing Origin and Course of the Nerve Fibres of Taste.

Most of our so-called tastes should rather be designated flavours and are dependent not on the gustatory nerves but on the sense of smell. When the olfactory sense is destroyed, very little difference is to be perceived between an onion and an apple. The epicure with a fine palate has really educated his sense of smell and would be but little satisfied with the simple sensations derived from his tongue.

THE SENSE OF SMELL

The analysis of olfactory sensations is rendered difficult by the fact that this sense in man plays but a small part in his usual adaptations. We have thus to deal with a sense which is in many respects vestigial. We see traces of great complexity in its possibilities of performance, but are baffled in our endeavours to reduce the whole of the phenomena to the simpler factors of which they are composed. Moreover, like all vestigial functions, the extent to which the sense is developed varies from one individual to another. Many, for instance, are unable to appreciate the smell of vanilla, of hydrocyanic acid or of violets. On the other hand, in animals such as the dog, the olfactory sense seems to play a great part in determining behaviour, and the nervous associations, which are the physiological basis of ideas, must in these animals be largely connected with olfactory impressions. Another factor which diminishes the importance of olfactory sensations in man is the ease with which the sense organ becomes fatigued. It often happens that the inmates of a room are perfectly comfortable and may perceive no fault in the ventilation, although a newcomer from the outside at once remarks that the air is foul.

THE ORGAN OF SMELL is situated at the upper part of the nasal cavities. Here the mucous membrane covering the superior and middle turbinate bones and the corresponding part of the septum is different from that covering the rest of the nasal passages. Over the lower parts of the nasal cavities the mucous membrane is of the ordinary respiratory type, and is composed of ciliated columnar epithelium containing a number of goblet cells. In the olfactory part the epithelium is much thicker, of a yellow colour, and apparently composed of a layer of columnar cells resting on several layers of nuclei. These nuclei belong to the olfactory cells proper, true spindle-shaped nerve cells with one process extending towards the mucus covering the free surface, while the other is continued along channels in the bone, and through the cribriform plate as one of the non-medullated olfactory nerve fibres. These nerve fibres enter the olfactory lobes, where they terminate by a much-branched arborisation or end basket in the so-called olfactory glomeruli, in close connection with a similarly branched dendrite of the large *mitral* cells of the olfactory lobe. The axons from these latter carry the olfactory impulse towards the rest of the brain. In the connective tissue basis (dermis) of the mucous membrane are a number of small serous glands (Bowman's glands) whose office it is to keep the surface of the membrane constantly moist.

In ordinary respiration the stream of air never passes higher than the anterior inferior border of the superior turbinate bone, so that it does not come in contact with the olfactory mucous membrane. The sensations of smell which are aroused during ordinary respiration depend on diffusion from the respiratory air into the still air of the upper olfactory portion of the nasal cavity. The direction of olfactory attention is achieved by sniffing; in this act the nostrils are dilated and the direction of the anterior part of the nasal respiratory chamber altered, so that the stream of entering air is directed towards the upper olfactory portion of the cavity.

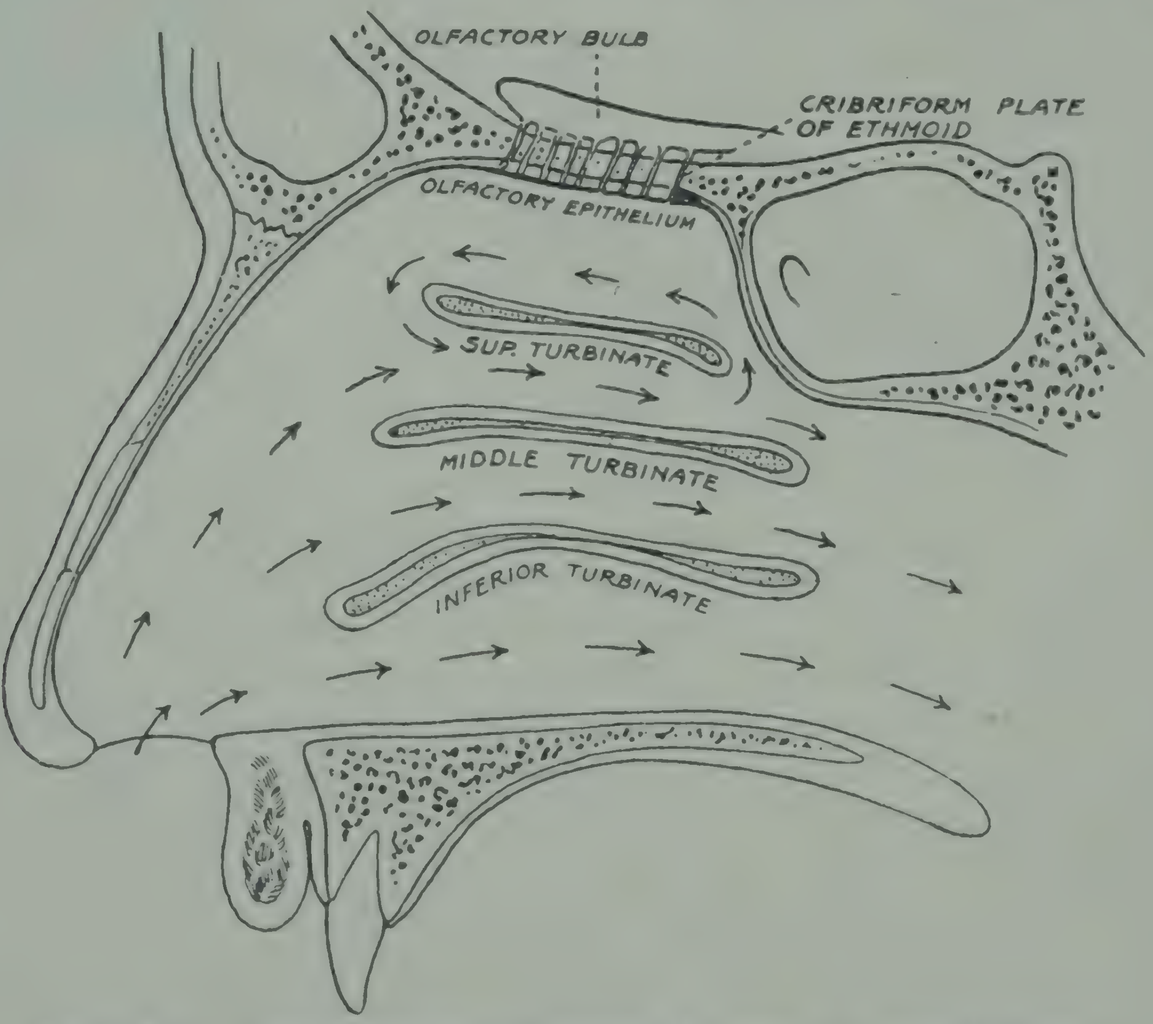

FIG. 321. Antero-posterior Section through the Nasal Fossæ.
The arrows show the direction of the air currents during inspiration.

The fact that the air, which enters the nasal cavity during respiration, does not come into direct relationship with the olfactory epithelium has the following advantages :—

(1) The cold inspired air does not come into contact with and cause damage to the sensory surface.

(2) Foreign particles carried by the air (including bacteria) do not get deposited there. The position of the epithelium at the very top of the nasal cavity is an additional safeguard.

(3) The olfactory epithelium is not dried by the rush of dry air across it.

(4) Noxious vapours only reach it indirectly and therefore do not cause permanent damage as they otherwise might.

The amount of substance necessary to excite sensation is extremely minute. Thus 0·01 mg. of mercaptan diffused in 230 cubic metres of air is still distinctly perceptible. In this case a litre of air would contain only ·00000004 mg. of the substance, and the amount actually in contact with the olfactory epithelium would be still smaller. It is possible, however, to show the presence of these odorous substances in air by physical means. Tyndall pointed out that air containing a small proportion of odorous substances absorbed radiant heat to a much greater degree than did pure air. Thus in one experiment, air containing patchouli absorbed radiant heat thirty-two times as strongly as the pure air. Most odorous substances possess large molecules and have therefore high vapour densities. On this account the smell tends to hang about objects, the rate of diffusion of the vapour being only small.

MODE OF ACTION OF ODOURS. Since the endings of the olfactory cells are bathed in fluid, it is evident that the odorous substances must be dissolved by this fluid before they can excite the olfactory nerve fibres, and in the case of aquatic animals we know that the projected chemical sense, which we call smell, can be aroused only by substances in solution. It is difficult to show in man that the nerve endings can be excited by solutions. Most of the experiments have been made with solutions which had an injurious effect upon the olfactory epithelium. According to Aronsohn it is possible to excite sensations of smell if the nasal cavity be filled with normal saline fluid containing a very small proportion of the odorous substance.

Many olfactory stimuli owe their peculiar character to the simultaneous stimulation of other kinds of nerve endings. Thus a pungent smell, as that of ammonia, chlorine, etc., besides stimulation of the olfactory nerve, involves stimulation of the nerve endings of tactile sensibility, supplied by the fifth nerve.

OLFACTOMETRY. Elsburg, Levy and Brewer have recently devised a satisfactory method of measuring the acuity of smell in different people. A bottle containing the odorous substance can be filled with air at a slightly raised pressure so that on releasing a valve a known volume of air containing the odour is injected into the nasal cavities. For different odorous substances, different volumes of air must be used to reach the threshold, as the following table shows :—

Benzene	5·26 c.c.
Xylene	10·0 ,,
Camphor	15·0 ,,
Clove oil	17·22 ,,
Cedar wood oil	32·65 ,,

They have found that in women just prior to menstruation the acuity of the sense of smell is increased. A cold in the head depresses it often for several days. Smelling a substance depresses for a time the acuity for that substance.

THE CLASSIFICATION OF SMELLS. No satisfactory classification of smells has yet been made. The following facts tend to show that there are a number of primitive sensations of smell, as of other sensations :

(*a*) Certain individuals, whose olfactory sense is in other respects normal, have no power of distinguishing some odours.

(*b*) The olfactory sense is easily fatigued. If it be fatigued so as to be absolutely insensitive for one kind of smell, it is still normally excitable for other smells.

(*c*) It is possible by mixing odoriferous substances in certain proportions to annul their effect on the olfactory organ. Thus 4 grm. of iodoform in 200 grm. of Peruvian balsam is almost odourless, and the same neutralisation of odours is obtained if the odour of each substance be allowed to act separately on each side by tubes inserted into each nostril.

BOOK V

SYSTEMS FOR DISTRIBUTION OF MATERIALS

BLOOD, CIRCULATION AND RESPIRATION

HISTORICAL NOTE

Blood. Although the more conspicuous properties of the blood must have been familiar from the earliest times, it was regarded as a homogeneous fluid until late in the 17th century, when the red cells were first accurately described by Leeuwenhoek (1674). Their enumeration was first effected by Vierordt in 1852, by counting the cells in a film made with a minute known volume of blood: the counting chamber was invented by Cramer in 1855, and the first hæmocytometer somewhat on present lines was that of Gowers (1877) and the now familiar dilution pipette was devised by Potain in 1873.

The arresting phenomena of blood coagulation were prematurely studied by Galen; a speculation by Borelli that it was due to the throwing down of a solid from the plasma was confirmed by Hewson in 1772, and by Buchanan (1845), who showed that fibrin was formed by the action of a rennet-like substance on a soluble precursor. This precursor, fibrinogen, was isolated by Denis in 1856, and a "fibrin ferment" recognised by Schmidt in 1872; Hammarsten, in 1876, showed that fibrinogen was the sole precursor of fibrin, the thromboplastic substance making no contribution. The necessity of calcium salts for clotting was recognised by Arthus and Pagès in 1890, and the existence of prothrombin and its conversion to thrombin by Ca salts by Pekelharing in 1891. The part played by the thromboplastic substance emerged from the work of Wooldridge (1891) and of Morawitz (1903): the latter called it thrombokinase, and put forward a theory of coagulation which is still current. The inhibitory influence of the endothelial lining of the blood vessels was observed by Brücke (1857), the liver regarded as the site of formation of an anti-coagulative substance by Hédon and Delezenne in 1892, and heparin discovered in 1928 by Howell.

Attempts to ascertain the volume of blood in the body have been made since the times of Harvey and of Hales, but Allen Moulin in 1654 and Floyer in 1710 got somewhere near the truth, with figures of one-twentieth and one-fourteenth of the body weight respectively. Experiments on man began, in 1855, with Bischoff's application, to executed criminals, of Welker's rinsing-out method. In 1838, Valentin conceived the principle of adding a given amount of a recognisable substance to the circulating blood, and then estimating its amount there: the first suitable substance to be found, however, was carbon monoxide, used by Gréhant and Quinquaud in 1882.

Blood transfusion, now so popular, was speculated upon by the ancients, and often essayed in the past, *e.g.* by Lower, 1666, but was generally discredited as being inapplicable to man until after the principle of compatibility was revealed by Landsteiner's discovery of the blood groups in 1901.

Haller (1754) mentions that the insoluble part of blood ash contains some particles which are attracted by the lodestone, but the significance of this fact was not realised for a long time. Hæmoglobin was first properly described by Hoppe-Seyler between 1866 and 1871, crystals of hæmoglobin were prepared quite early, notably by Preyer in 1871, and the spectra of the important blood pigments were further studied by Stokes (1864) and Hüfner (1879). Claude Bernard had shown as early as 1854 that CO was poisonous because it was fixed by, and drove out oxygen from, the blood, and Donders in 1872 showed that the combination was a reversible one due to the formation of carboxyhæmoglobin.

Lymph. The lacteal vessels were discovered by Aselli in 1662, and considered by him to play a part in absorption, taking the absorbed material, in accordance with the Galenical doctrine, to the liver. Accordingly, it was not until after the discovery of the thoracic duct by Pecquet in 1651, and of the general lymphatic system by Bartholin (1653) that the system was considered as a whole. Most of our modern views on lymph formation, and on its relation to the circulatory system, originated in Starling's work about 1894.

Circulation. For five centuries from the time of ERASISTRATUS of Alexandria (3rd century B.C.), the arteries were believed to be filled with air, and only the veins with blood. In the 2nd century A.D., GALEN showed by experiment that the arteries were quite filled with blood: from his further researches was formulated his doctrine of *pneuma*, or spirits, which was accepted with little modification during the next 14 centuries, and which was briefly as follows: food first becomes "chyle" in the alimentary canal, is absorbed into the blood, and, being carried at once to the liver, is there converted into blood and provided with "natural spirits"—a nutritive principle. The blood, thus endowed, and mixed with blood of the vena cava, is distributed all over the body by way of the veins, in an ebb-and-flow motion, and also reaches and recedes from the right ventricle. A part of it, however, passes from the right ventricle by invisible pores into the left side, and another part passes to and fro along the pulmonary artery or "arterial vein," and, reaching the lungs, which it nourishes, at the same time gives out into the expired air all its noxious ("fuliginous") vapours. That part of the blood from the right side which seeped through into the left side is next mixed with air, which, drawn into the lungs in inspiration, and passing along the pulmonary vein, or "venal artery," reaches the left side of the heart, where heat is created, and the "vital spirits" engendered, giving to the blood its bright colour. The vital spirits were necessary for life and movement, and the vitalised blood ebbed and flowed along the arteries with their pulsations, expansion (diastole) of the heart and arteries occurring together at one phase, and collapse (systole) at another. When the blood reached the brain, the "animal spirits" were generated: thus pneuma, rid of air and blood, could pass down the nerves to cause movement and sensation.

One of the chief points in the Galenical doctrine concerned the route by which the blood of the right side of the heart reached the left side. Doubt was first thrown on the permeability of the interventricular septum by VESALIUS in 1543, and was confirmed by REALDUS COLUMBUS in 1559. Next, the disposition and action of the valves of the veins were described by FABRICIUS at Padua in 1574: the logical inference from his discovery was, however, only pointed out later by his pupil, WILLIAM HARVEY.

The fact that blood can pass from the right to the left ventricles by way of the lungs—the pulmonary circulation—was first advanced by IBN NAFIS, an Arabian physician, in the 12th century,* and again independently by MICHAEL SERVETUS in 1553,† and by COLUMBUS and three others in the 16th century. SERVETUS, however, only believed that part of the blood passed through the lungs.‡

The discovery that the blood travels round in a circuit, returning again and again to the same point, was made by WILLIAM HARVEY, physician to Charles I., and was given to the world in a book of seventy-two pages, printed at Frankfurt in 1628.§

This, the greatest discovery in the whole of medical science, of which indeed it laid the foundation, was the result of prolonged experiment and patient observation; in his masterly though modest treatise Harvey shows that the circulation is a logical necessity to which we must be led by the contemplation of certain elementary facts, *e.g.*:—

(i) The arrangement of the valves in the heart and veins is such as to allow of one-way movement only.

(ii) "If the heart is grasped in the hand, it may be felt to become harder during its action." When this happens, the ventricles become smaller and the arteries *expand*; if an artery is severed, blood spurts from its central end at each heart contraction.

(iii) Since, at each contraction of the heart, blood is forced into the arteries and cannot return, it follows that, even if only a small quantity were so expelled, there would not be enough blood in the heart, or even in the whole body, for the process to continue, nor could all this blood remain in the arteries. The heart must, therefore, receive blood continuously from the veins and pass it out continuously into the arteries. If a vein is compressed or tied by a ligature, it swells up on the side furthest from the heart, and collapses on the side nearest the heart. With an artery it is the reverse. Hence the blood must be passing continuously from the arteries, through the tissues into the veins. Similarly, the blood in the right ventricle must pass by way of the pulmonary artery and lungs to the pulmonary veins and so reach the left side of the heart.

Harvey could not be certain how the blood passed through the tissues from arteries to veins, but with the use of the microscope, the capillaries were discovered by Malpighi in 1661, and the missing link in the argument was thus provided.

Once the fact of the circulation was established, further aspects soon pressed for attention. LOWER (1669) made important observations on the structure and action of the heart, and BORELLI (1680) considered the circulation from the hydraulic standpoint: but the next important experimental study was made by the Rev. STEPHEN HALES (1733). By inserting vertical tubes into the arteries or veins in horses and dogs, he showed the relative pressures in those vessels, distinguished end-on from lateral pressures, and, in confirmation of FLOYER (1710), explained the loss of pulse in the veins. Hales also tried to assess the cardiac output, carried out perfusions, estimated the velocity of the blood, and made studies on œdema production Attempts to understand the significance of the heart sounds began with LAËNNEC, who invented the stethoscope, in 1819. That the apex of the heart moved but little during the beat was a forgotten observation of LEONARDO DA VINCI in the 15th century, rediscovered independently by HAYCRAFT in 1891 by an almost identical method.

D'ARCY POWER (1897). "William Harvey." (London, Unwin.)

SINGER (1922). "The Discovery of the Circulation of the Blood." (London, Bell.)

The volume of the cardiac output was for centuries a matter for speculation : a method for its determination was outlined by FICK in 1870, but was not much used until 1912 when KROGH and LINDHARD introduced the nitrous oxide method.

The frog's heart, which was used by Harvey, and again in 1797 by v. HUMBOLDT, has played a large part in the investigation of the properties of heart muscle. The myogenic view of the origin of the heart beat, which had been held by HALLER (1736) was challenged by LEGALLOIS (1812), who revived the idea of a neurogenic explanation : in apparent support of this, various local ganglia were discovered by REMAK (1844), LUDWIG (1848) and BIDDER (1852), and these came, through Bidder and ECKHARD (1858) to be regarded as local motor centres : the experiments of STANNIUS (1852), though now differently interpreted, are still well known. A fierce and prolonged controversy raged, but was finally settled in favour of the myogenic theory, largely by the work of GASKELL (1882–7). The all-or-none property was discovered by BOWDITCH in 1871, and the refractory phase by KRONECKER and STIRLING in 1874 ; the influence of ions by RINGER in 1880, the nature of the conducting system (A–V bundle) by KENT (1892) and the AV node by KEITH and FLACK in 1906. The electrical changes in the human heart were first recorded by A. D. WALLER in 1887, with the capillary electrometer. The string galvanometer, invented in 1901, was used for recording the electrocardiogram by EINTHOVEN in 1903.

Although LEGALLOIS (1812) and PHILIP (1826) showed that stimulation of the spinal cord accelerated, and of the medulla slowed, the heart rate, the pathways were unknown till 1845, when the WEBER brothers showed the inhibitory nature of the vagus : the effect of the sympathetic was shown by v. BEZOLD in 1862, and the action of the depressor nerve by CYON and LUDWIG in 1866. The importance of the carotid sinus was not revealed until 1925 (KOCH).

A method for the study of the mammalian heart doing normal and controllable amounts of work, while fed with blood, yet freed from the complications of the variable factors introduced by the systemic circulation, was long sought and often attempted, but for long with only partial success. The practical problem was solved by the work of KNOWLTON and STARLING in 1912, in which the heart-lung preparation was introduced ; this has proved of value for a variety of investigations.

The mercurial manometer was introduced by POISEUILLE (1825) and the float for recording by LUDWIG in 1847, and thereafter studies on arterial pressure quickly developed. LUDWIG also introduced the kymograph, the stromuhr (1867) and other experimental devices. The study of intracardiac pressures by CHAUVEAU and MAREY in 1861 led to a more accurate analysis of the events in the cardiac cycle, while FRANK's work, about 1906, on the physical properties and defects of recording apparatus marked a new epoch in the technique of graphic registration. The apparatus for measuring human arterial pressure was introduced by RIVA-ROCCI in 1896. The dynamics of the flow of blood began to be studied by POISEUILLE in 1840, and between 1825 and 1875 a good deal of attention was devoted to the study of the form and velocity of the arterial pulse by the WEBER brothers, DONDERS, and MAREY, the first sphygmograph being produced by the last-named in 1860. The venous pulse was known from ancient times, but was not adequately investigated until MACKENZIE's studies in 1902.

The variability of the peripheral resistance through contraction of the small arteries was not properly appreciated until the 19th century, but was firmly established when the hitherto hypothetical vasomotor nerves were found in 1851 by CLAUDE BERNARD and others. That the capillaries were also independently contractile was claimed by ROUGET in 1879, but was not recognised generally until the work of KROGH in 1916, and the subsequent work on human skin by LEWIS.

Respiration. Aristotle, circa 300 B.C., thought that respiration cooled the blood, and ERASISTRATUS, who postulated two pneumata, thought that one of these, the vital spirit, was a form of air which filled the arteries, and was derived from air entering the left heart from the lungs. GALEN, about A.D. 170, showed that arteries were, in fact, entirely filled with blood, and was the first to suggest that breathing not only added something to the blood (vital spirits), but also removed something (" fuliginous vapours ") from it at expiration. He recognised the chief respiratory muscles, and knew the functions of the phrenic and recurrent laryngeal nerves. LEONARDO DA VINCI, about A.D. 1500, recognised the similarity between flame and living things, in that both consumed and altered the air.

It is evident that, even after the discovery of the circulation of the blood, in 1628, the function of breathing could not in any case have been appreciated until the discovery of oxygen, of carbon dioxide, and of the fundamental nature of combustion. In fact, the meandering trail of discovery took over 160 further years to pass those milestones.

It is true, however, that on the way a few exceptional observers had a misty pre-view of things to come, though this was overlooked. So, BOYLE, in 1670, by the use of the air-pump, demonstrated the indispensability of air for life, as for flame ; he extracted gases from the blood, and claimed that a part of the air was essential for life and combustion. So, also, **Mayow**, in 1668, probably under the influence of Boyle, not only actually discovered what we now know as oxygen (his " nitro-aerial spirit "), but came within an ace of explaining, once and for all, the true nature of combustion, of respiration and of the source of animal heat. The dominance, in chemistry, of the phlogiston theory of Stahl from about 1680 to 1794, however, was an obstacle to the acceptance of such views.

One of Mayow's accepted discoveries (1668) was that of the manner in which the expansion of the chest draws air into the lungs. Opening of the chest was long known to cause death, but **Vesalius**, about 1543, showed that death could be warded off if the lungs were rhythmically inflated by bellows. The regular inflation and deflation of the lungs was afterwards supposed in some way to be essential, until **Hooke**, in 1667, showed that, provided the air was renewed, as by a continuous blast which escaped by holes made in the lungs, the actual movements of the lungs could be dispensed with

That the change from venous to arterial blood took place in the lungs, and was connected with the renewal of the air in them, was discovered by **Lower** in 1669 : he showed that the colour change of the blood could be observed in animals with opened chests, that it took place in passing through the lungs, but ceased soon after artificial respiration was stopped.

The definitive discovery of carbon dioxide was made by **Black** in 1754 (though it was confused with nitrogen until 1772), and oxygen was discovered independently by **Priestley** and by **Scheele** in 1771. Many facts regarding combustion, respiration, and the formation of oxygen by plants were discovered by Priestley, but owing to his adherence to the phlogiston theory, he missed the correct interpretation of them. It was **Lavoisier** who supplied this, in 1775, and between then and 1794, when he was guillotined, he unveiled the true nature of combustion and respiration (the composition of water having been discovered by **Cavendish** in 1781, and of air in 1784), outlined the changes which took place in the air as a result of breathing, determined the oxygen usage of men at rest and doing work, propounded the true cause of animal heat, and, in general, laid the foundations for the study of oxidative metabolism. He thought, however, that the lungs were the actual site of the combustion process.

Edwards (1824), following the work of **Spallanzani** at the close of the 17th century, showed that animals, or their tissues, when deprived of oxygen, continue to give up carbon dioxide, and he formulated a theory of respiratory exchanges much akin to our present-day views. The fuller explanation had to await the further study of the blood gases. These had been extracted *in vacuo* by Boyle, but the first thorough investigation was that of **Magnus** in 1837. Using a mercurial pump, he extracted the gases from blood, demonstrated the difference between arterial and venous blood, and thus established the true relations of the blood, air, and general tissues of the body. The laborious method of extraction *in vacuo* was thereafter employed for the estimation of the blood gases up till about 1900, when the ferricyanide method was introduced by J. S. **Haldane**.

The study of the tensions of the blood gases began with **Lothar Meyer**'s discovery, in 1857, that oxygen was not released from blood in proportion to any given reduction of pressure, but much more slowly, and was, therefore, not in simple solution. **Hoppe-Seyler**, five years later, showed that it was held in combination with hæmoglobin, and in 1885 **Bohr** expressed the relationship between oxygen content and oxygen partial pressure in the form of the oxygen-dissociation curve. The means by which CO_2 was carried, adumbrated by **Zuntz** in 1867, was not explained till **Hamburger**'s work in 1892. The remarkable interrelations between various blood components, which found its final expression in the nomographic work of **Lawrence Henderson** about 1928, began with the observations, by **Bohr**, **Hasselbalch** and **Krogh** in 1904, that carbon dioxide tended to expel oxygen from the blood, and by **Christiansen**, **Douglas** and **Haldane** in 1914, that oxygen reciprocally tended to expel CO_2.

Long controversy centred around the ultimate cause of the respiratory exchange in the lungs, and began with **Müller**'s declaration, in 1870, that the interchange was a secretory process, a position taken up and held consistently by **Haldane** from 1896 to 1922. The invention of the aerotonometer by **Pflüger** in 1869 enabled the matter to be tested by various investigators, and finally, in 1908, by **Krogh**, with his microtonometer, which seemed to decide the issue in favour of a physical explanation. **Haldane** being still recalcitrant, however, J. **Barcroft** entered the lists, and after the contending parties had, in turn, scaled higher and higher peaks in their study of the effects of altitude, and exposed themselves and their colleagues to progressively reduced pressures or lowered oxygen atmospheres in chambers, it came to be almost universally agreed that the oxygen intake is, in fact, effected as a result of a difference in partial pressures, and not as an act of secretion of oxygen from air to blood.

That the movements of respiration are dependent upon a centre in the medulla was first shown by **Legallois** in 1811, and further definition and studies of the respiratory centre, and of the effects of vagus section, were due to **Flourens** (1842), **Gad** (1892), and **Rosenthal** (1864), while **Hering** and **Breuer**, in 1868, demonstrated the effects of inflation and collapse of the lung, and of the influence of vagal section thereon.

The influence of the chemical composition of the blood on the action of the respiratory centre was noticed by **Rosenthal** in 1862, in studies on hyperventilation apnœa : this he attributed to over-oxygenation of the blood, but **Traube**, in 1867, showed that over-ventilation with nitrogen would also cause apnœa, and **Pflüger**, in 1868, showed that increase of CO_2, as well as deficit of oxygen, could excite the centre. The classical work of J. S. Haldane did much to clarify the means by which breathing is regulated, and particularly to show that carbon dioxide was the principal chemical regulator of respiration (Haldane and Priestley, 1905), while response to alteration of oxygen partial pressures was much less delicate. The effects of altered atmospheric pressure, studied by Paul Bert in 1878, also provided much valuable information. The discovery that the pressure and composition of the blood flowing through the carotid sinus region exerts an important effect on the respiratory centre was made by Heymans and his colleagues in 1927–30.

CHAPTER XXIX

THE BLOOD

THE function of the blood is to convey food materials and oxygen to the tissues. From these it receives in exchange their waste products, and carries them to the excretory organs, such as the lungs and kidneys, by which they are eliminated. The composition of the blood must vary from time to time and place to place according to the activity and function of the organ which it is traversing, but the organs are adjusted to respond to very minute changes in the composition of the circulating fluid, and add to or subtract from its constituents according as these are present in deficiency or excess. The changes are therefore kept within narrow limits and we may regard the blood as a fluid of approximately constant composition.

Blood obtained from a mammal is an opaque fluid varying in tint according to the vessel from which it is derived, being scarlet when taken from an artery, purplish in colour when taken from a vein, the difference being determined by the degree of oxygenation of the blood. On shaking venous blood with air, it takes up oxygen and acquires the scarlet colour characteristic of arterial blood. If examined in a thin layer under the microscope, its opacity is seen to be due to the fact that it is not homogeneous, but consists of a number of *corpuscles* of different kinds, suspended in about their own bulk of a light yellow transparent fluid, the *plasma*. It is seen to contain three main classes of corpuscles. Much the most numerous and conspicuous are the *red corpuscles*. Next most conspicuous are the *white corpuscles;* the third type of formed elements are very small and are called the *blood platelets*. The average numbers of these formed elements per cubic millimetre of normal human blood are as follows :

Red corpuscles	5,400,000
White corpuscles	9,000
Platelets	300,000 (variable).

In the whole body there are about 32 billion red corpuscles and about 50,000 million white corpuscles. The total red cell volume of the body is about 2 l., or 30 c.c./kg. body weight.

Normally, the process of clotting ensues shortly after the blood has left the vessels. If blood be received into a beaker it is at first perfectly fluid. After three to eight minutes it begins to be viscous, and if poured out of the beaker leaves an adherent layer on the sides of the vessel. A minute later the whole mass of the blood becomes solid and the beaker can be inverted without spilling its contents. If a section be made of this blood clot, it is found to owe its solidity to a network of fine threads of a protein substance named *fibrin*, which have formed throughout the plasma and enclosed the corpuscles in their meshes (Fig. 322). On leaving the clot for some hours, drops of yellow fluid appear on its surface and run together. The whole clot contracts, and finally there is a dark red clot, floating in a transparent yellowish fluid known as *serum*. If the blood on leaving the vessels be whipped with a bunch of twigs, or stirred with a glass rod, the filaments of fibrin as they are formed are deposited on the stirrer. After three or four minutes the twigs can be withdrawn and the spongy fibrin collected. The blood which is left consists only of the corpuscles *plus* serum, and it will not clot since its fibrin has been removed. It is known as *defibrinated*

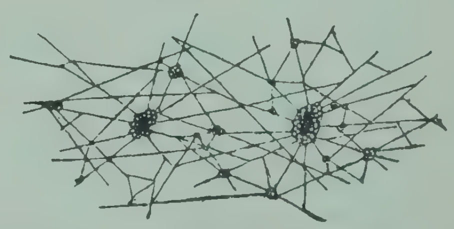

FIG. 322. Network of Fibrin, after washing away the corpuscles from a film of blood that has been allowed to clot; many of the filaments radiate from little clumps of blood platelets. (SCHAFER.)

blood. Since clotting occurs in blood plasma entirely separated from corpuscles, we must look upon the process of coagulation as determined by changes in the blood plasma.

THE QUANTITY AND COMPOSITION OF THE BLOOD IN MAN

The Total Blood Volume. The amount of blood in the body can be estimated by Welker's method, in which the animal is bled and the vessels washed out with salt solution. The depth of colour of blood *plus* washings is then determined and compared with that of the undiluted blood. In this way it was found by Bischoff that in man and the dog the blood equals about 7·7 per cent. of the body weight.

Modern methods, applicable also to man, involve the addition to the circulating blood of a known amount of some substance which does not quickly leave the blood stream, and the subsequent estimation of the substance in the blood after mixing has occurred. Suitable substances are carbon monoxide, an appropriate dye, or a radioactive component of the red cells. The first and third give the volume of the whole blood, the second that of the plasma, from which the volume of blood can be deduced if the hæmatocrit value is known.

The carbon monoxide method,* not now much used, depends on the fact that when carbon monoxide gas is inhaled it combines with hæmoglobin. It therefore depends on the determination of available hæmoglobin which is accessible to the circulation. It probably does not include that present in corpuscles stored in the spleen, though sometimes there may be some increase from this source.† The estimation probably gives too high a result, because some of the CO would be fixed by the myoglobin of the muscles. The error is probably not greater than 10 per cent.

The dye method ‡ consists in injecting a known amount of a non-toxic, non-diffusible dye substance into the blood stream and estimating its dilution with plasma by colorimetric comparison. Many dyes easily diffuse out of the circulation, while colloidal ones are liable to be taken up by the cells of the reticulo-endothelial system. In either case the estimated blood volume would be too high. The dye now used is Evans Blue (T 1824).§ In performing the test a few c.c. of blood are removed from an elbow vein into a syringe containing one-fourth of its volume of isotonic (1·6 per cent.) sodium oxalate to prevent clotting. About 0·2 c.c. per kg. body weight of a 1 per cent. solution of the dye in distilled water is then slowly injected by the same needle. Four minutes later a second specimen of blood is withdrawn into a quarter of its volume of oxalate solution. A part of this sample is drawn into a hæmatocrit tube and centrifuged for twenty minutes at a high speed in order to determine the relative volume of corpuscles and plasma (+ oxalate). From this is calculated the ratio of plasma : plasma + oxalate, since $\frac{1}{5}$th of the whole mixture is oxalate. The percentage by volume of corpuscles and plasma is also calculated. The rest of both samples of blood are centrifuged in order to obtain the plasma. These samples of plasma are then compared by preparing the following mixtures :—

Standard	2 c.c. of a standard dye solution ($\frac{1}{267}$ per cent.).‖ 2 c.c. of the plasma before dye injection. 2 c.c. 0·9 per cent. NaCl solution.
Test	2 c.c. of plasma after dye injection. 4 c.c. 0·9 per cent. NaCl solution.

§ DAWSON, EVANS and WHIPPLE. *Amer. J. Physiol.*, 1920, **51**, 232 ; GIBSON and EVANS, *J. Clin. Investig.*, 1937, **16**, 301. CROOKE and MORRIS. *J. Physiol.*, 1942, **101**, 217.

‖ There is no esoteric significance in the curious fraction $\frac{1}{267}$: it merely happens to be a *convenient* strength, obtained by diluting 0·75 c.c. to 200 c.c., as originally recommended.

The two solutions are compared in a colorimeter (preferably photoelectric *) and the strength of the test solution read off as a percentage of the standard. Let x be this percentage, and let V be the c.c. of 1 per cent. dye injected, and C the ratio, c.c. plasma/c.c., plasma + oxalate.

We actually compare the concentration of dye in the plasma (diluted with oxalate), with that of the known dilution of 267 times. For the test to be x per cent. of the standard, the V c.c. of dye must have been diluted, first to the fraction C, and then $\frac{267 \times 100}{x}$ times. Hence the volume of plasma in the circulation must be $\frac{26{,}700\,\mathrm{VC}}{x}$.

The blood volume is calculated from the hæmatocrit reading.

$$\text{Total blood volume} = \frac{100 \times \text{c.c. plasma}}{\text{percentage plasma in blood}}.$$

By reversing the process and injecting undyed plasma into the dyed circulation, errors due to dye losses are claimed to be reduced. This method gives plasma volumes only 85 per cent. of those by dye-distribution. Further, the total cell volume is claimed to be only 85 per cent. of that derived from the hæmatocrit of arterial blood, partly because distribution of cells is not uniform throughout the circulation.†

Radioactive elements also have been used for measurement of blood volume. Some blood is mixed with sodium phosphate containing radioactive P, which the corpuscles absorb. These are well washed and their radioactivity measured : a known amount is injected and the radioactivity of the circulating blood determined after a suitable mixing interval.‡

Estimates of blood volume vary from $\frac{1}{10}$th to $\frac{1}{20}$th of the body weight. The CO method gives 5 to 7 per cent. of body weight, the dye method in most laboratory mammals gives about 7 per cent. of body weight, but no constant relationship to body surface.§ As a round figure we may take 5·0 l. as the blood volume of a 70 kg. adult. In children it is also in linear relation to body weight.||

The total blood volume certainly varies slightly with alterations in the condition of the animal, *e.g.* in thirst. It is influenced by posture, there being a loss of up to 15 per cent. of the total plasma in the erect position as compared with the horizontal.¶ It is also affected by the height of the blood pressure as well as by the oxygen tension in the air breathed, and therefore alters with the altitude. Some of these variations we shall have to consider more fully in a later section. Any lowering of blood pressure causes an absorption of fluid from the tissues into the blood, so that the latter becomes more dilute. The blood during the last stages of slow bleeding may contain many fewer corpuscles than were present in the first samples, pointing to a corresponding dilution of the blood during the bleeding by means of tissue fluid. By this means, *i.e.* the absorption of fluid from tissues, the volume of circulating blood after a limited hæmorrhage is brought up to normal, though in conscious humans the hæmodilution may take as long as 90 hrs. to complete.**

Determination of the Relative Volumes of Corpuscles and Plasma. The relative volumes of corpuscles and plasma in any sample of blood may be approximately determined by means of the *hæmatocrit* (Fig. 323).* This is a graduated capillary tube of uniform bore in which the specimen of blood, treated with a suitable anti-coagulant, is centrifuged at a high speed until the sedimented corpuscular layer shows no further shrinkage, and appears translucent. The depth of the layer of corpuscles is then read off, multiplied by 0·95 to allow for trapped plasma,† and expressed as a percentage of the whole length of the column of blood. Other methods (*e.g.* by adding the blue dye T.1824 in known amount and then finding its concentration in the plasma ; or by diluting the plasma and finding the change in its protein content) give a cell volume about 8·5 per cent. lower than that given by the hæmatocrit.‡ It is usually found, by the hæmatocrit, that in normal human blood the corpuscles occupy about 40 to 50 per cent. of the volume of the blood.

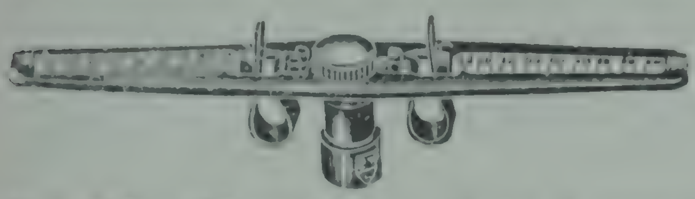

FIG. 323. Hæmatocrit. (From HARRIS' "Experimental Physiology.")

The number of red cells in unit volume of the circulating blood is variable in two ways, viz. by alterations in the quantity of plasma in circulation, as mentioned above, and by variation in the total number of red cells in circulation. The latter may alter abruptly in consequence of the storage in, or liberation of red cells from, the spleen. The significance of the spleen in this respect in man is not known.§

Cell Count and Hæmoglobin Content. In order to enumerate the red corpuscles, a known volume of the blood is diluted with a known amount of an isotonic fluid and the number in a measured volume of the mixture is counted with a hæmocytometer. The average number (*v.* Fig. 324) of red corpuscles is about 5,400,000 per cubic millimetre in healthy adult men, and rather fewer and more variable, in adult women. The enumeration of corpuscles is subject to considerable errors, rarely less than 5 per cent. Moreover, different conditions of the circulation may cause variations in the relative distribution of plasma and corpuscles in different parts of the circulation, so that the blood-count of a specimen from the capillaries of the finger or lobe of the ear may differ considerably from a count in blood obtained directly from a vein or artery.

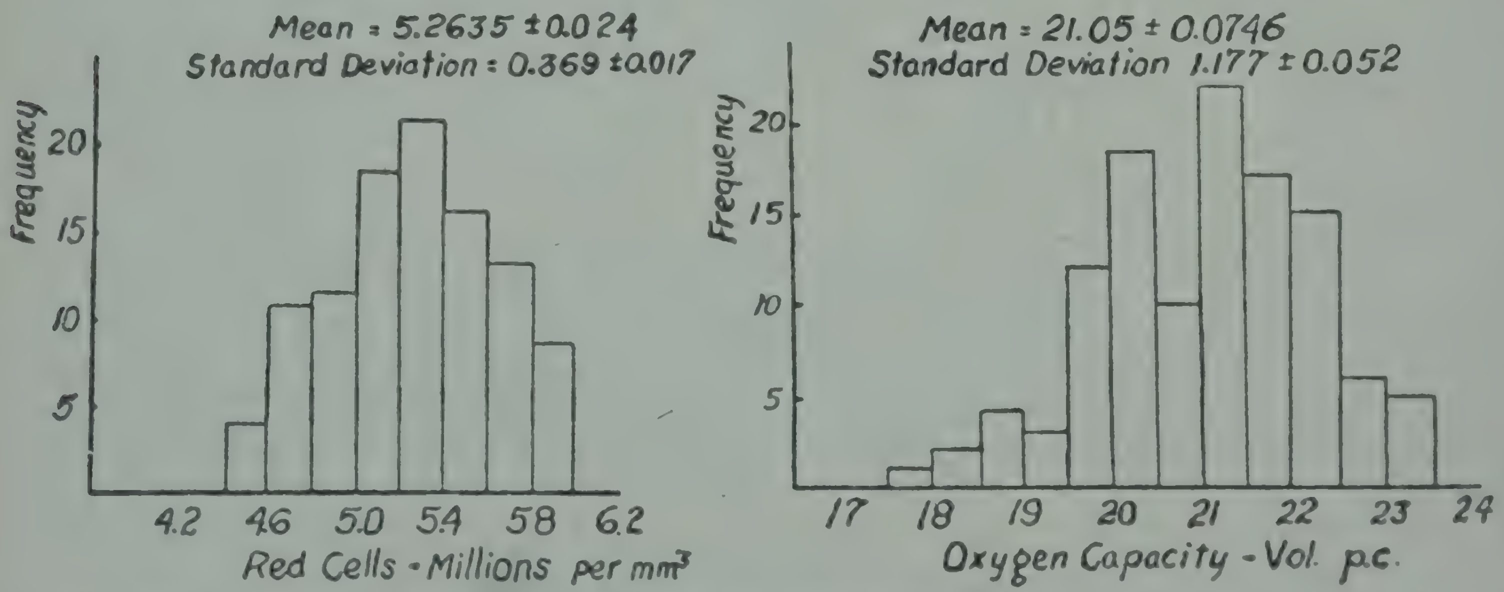

FIG. 324. Showing statistical grouping of red cell count and oxygen capacity in American male students, age 18–30. (FOSTER and RAYMOND JOHNSON.)

More important, perhaps, is the determination of the hæmoglobin. For this purpose, a measured quantity of the blood, say, 20 c.mm., is mixed with a given volume of water. The red fluid thus obtained is compared (often photoelectrically) in a colorimeter, or a specially designed "hæmoglobinometer," with a standard. Usually the hæmoglobin is converted into a more deeply coloured and more stable derivative, *e.g.* cyanhæmoglobin, or acid hæmatin.[*] Haldane's method [†] depends upon the conversion of the hæmoglobin into CO-hæmoglobin, and its comparison with a standard specimen of CO-hæmoglobin, which is stable in solution. Haldane's standard for hæmoglobin in human blood is one with an oxygen capacity now accepted at 19·8 volumes per cent., or 14·8 g. Hb or 49·5 mg. Fe per 100 ml.[‡] This is called 100 per cent. on the Haldane hæmoglobinometer as defined by British Standards Institution. This standard is largely used in clinical work in Great Britain. Normal adult males usually have about 102 to 114 per cent., and females about 88 to 103 on the Haldane scale. The practice of stating the hæmoglobin in terms of g. Hb per 100 c.c. blood, or of oxygen capacity, is increasing.

§ BARCROFT *et al.* *J. Physiol.*, 1925, **60,** 443.

Another method is to determine the iron content of the blood,[§] since hæmoglobin contains 0·335 per cent. Fe, and it has been shown that in blood the ratio of oxygen capacity : iron content is 393 ml./g. Fe.

An important clinical determination is that of the *Colour Index* of the blood. For this a red cell count and a hæmoglobin determination are needed. Then, calling 5 million red cells 100 per cent., the colour index $= \dfrac{\text{per cent. Hb}}{\text{per cent. cells}}$ This index, which normally is 1·0, shows the relative hæmoglobin content of the average corpuscle.

The Oxygen Capacity of the Blood. Instead of determining the hæmoglobin, we may measure directly the oxygen capacity of the blood, since the oxygen-binding power of this fluid is entirely dependent on the amount of hæmoglobin it contains. For this purpose we may make use of the fact discovered by Haldane, that the combined oxygen in oxyhæmoglobin is liberated rapidly and completely on addition of a solution of potassium ferricyanide to alkaline laked blood, and may thus be easily measured.

For this purpose the blood-gas apparatus of Haldane is convenient (Fig. 325).

Into the flask B is placed 1·5 ml. of borate buffer of *p*H 10·0.[||] The blood (1 ml.), rendered incoagulable with oxalate, is run into it, and well mixed, laked, and oxygenated by rotating in the flask for a few minutes. Then 0·25 ml. of 6 per cent. ferricyanide solution and a pinch of saponin is put into the small tube C, and the cork inserted, the control flask A, containing 2·5 ml. of water, being similarly corked, and both flasks placed under water in the bath D, the three-way taps J and K being open to the air with the ⊤ bore thus : ⊤. After allowing a few minutes to attain temperature equilibrium, the levelling tubes H and I (filled with water containing a little saponin or bile-salts) are adjusted so as to bring the water in F and G to the marks, and the taps J and K are then turned with the bore thus : ⊣. The burette E is then read, the flask B is tilted so that the ferricyanide runs into the blood solution, and the flask is shaken in the bath until no more gas is evolved. After allowing a few minutes to equalise any differences of temperature, the water level is again adjusted in F and G, and the volume of gas evolved read off on the burette E, and reduced to dry volume at N.T.P. When the *p*H 10 buffer is used the results agree with those obtained by the Van Slyke method.

For most work on blood gases the Van Slyke apparatus [¶] or its modern manometric form [**] is valuable.

The manometric Van Slyke apparatus depends on the principle of measuring the *pressure* of gases evolved or absorbed in a chamber of a *given volume*. From these pressures, or pressure differences, the volumes, or volume differences at N.T.P., can be calculated in accordance with Boyle's law. The *principle* of the apparatus is illustrated by Fig. 326, from which the actual apparatus differs only in some unessential details. The tube A, graduated in mm. is a barometer filled with dry mercury, and connected by a U-shaped bend with the extraction chamber E, junction being effected by a thick-walled rubber tube D. The extraction chamber is graduated at three marks, from the tap, viz. 0·5 ml., 2 ml., and 50 ml., and can be filled or emptied of mercury by raising or lowering the bulb B. If it is filled with mercury, and the tap G closed, lowering of the bulb to a low enough level will produce a vacuum in the chamber. By manipulating the level of the mercury bulb and the tap C, the vacuum can be made of any volume desired, *e.g.*, the mercury can be brought exactly to the 2 ml. mark. If the mercury in the chamber were dry, the levels in the chamber and in the barometer would now be equal; if it was wetted with water this would exert a vapour pressure dependent on the temperature, and the barometer would be higher by that amount, *e.g.* by 17·5 mm. at 20° C. Suppose that we were now to introduce into the chamber (at 0° C.) 0·5 ml. of a gas consisting of, say, 10 per cent. CO_2, 20 per cent. O_2 and 70 per cent. N_2, and by admitting mercury adjust the volume of this again to 2 ml. Then the mercury would rise by $\frac{760 \times 0{\cdot}5}{2{\cdot}0}$ mm. = 190 mm. in the barometer. Suppose that now we admit by the tap G a small amount of a NaOH solution to absorb the CO_2, and again bring the volume to 2 ml. We should find the pressure had fallen to 171 mm. above the "wet level." Similarly, after absorbing the oxygen by hydrosulphite solution the pressure would fall to 133 mm. above the vacuous wet level.

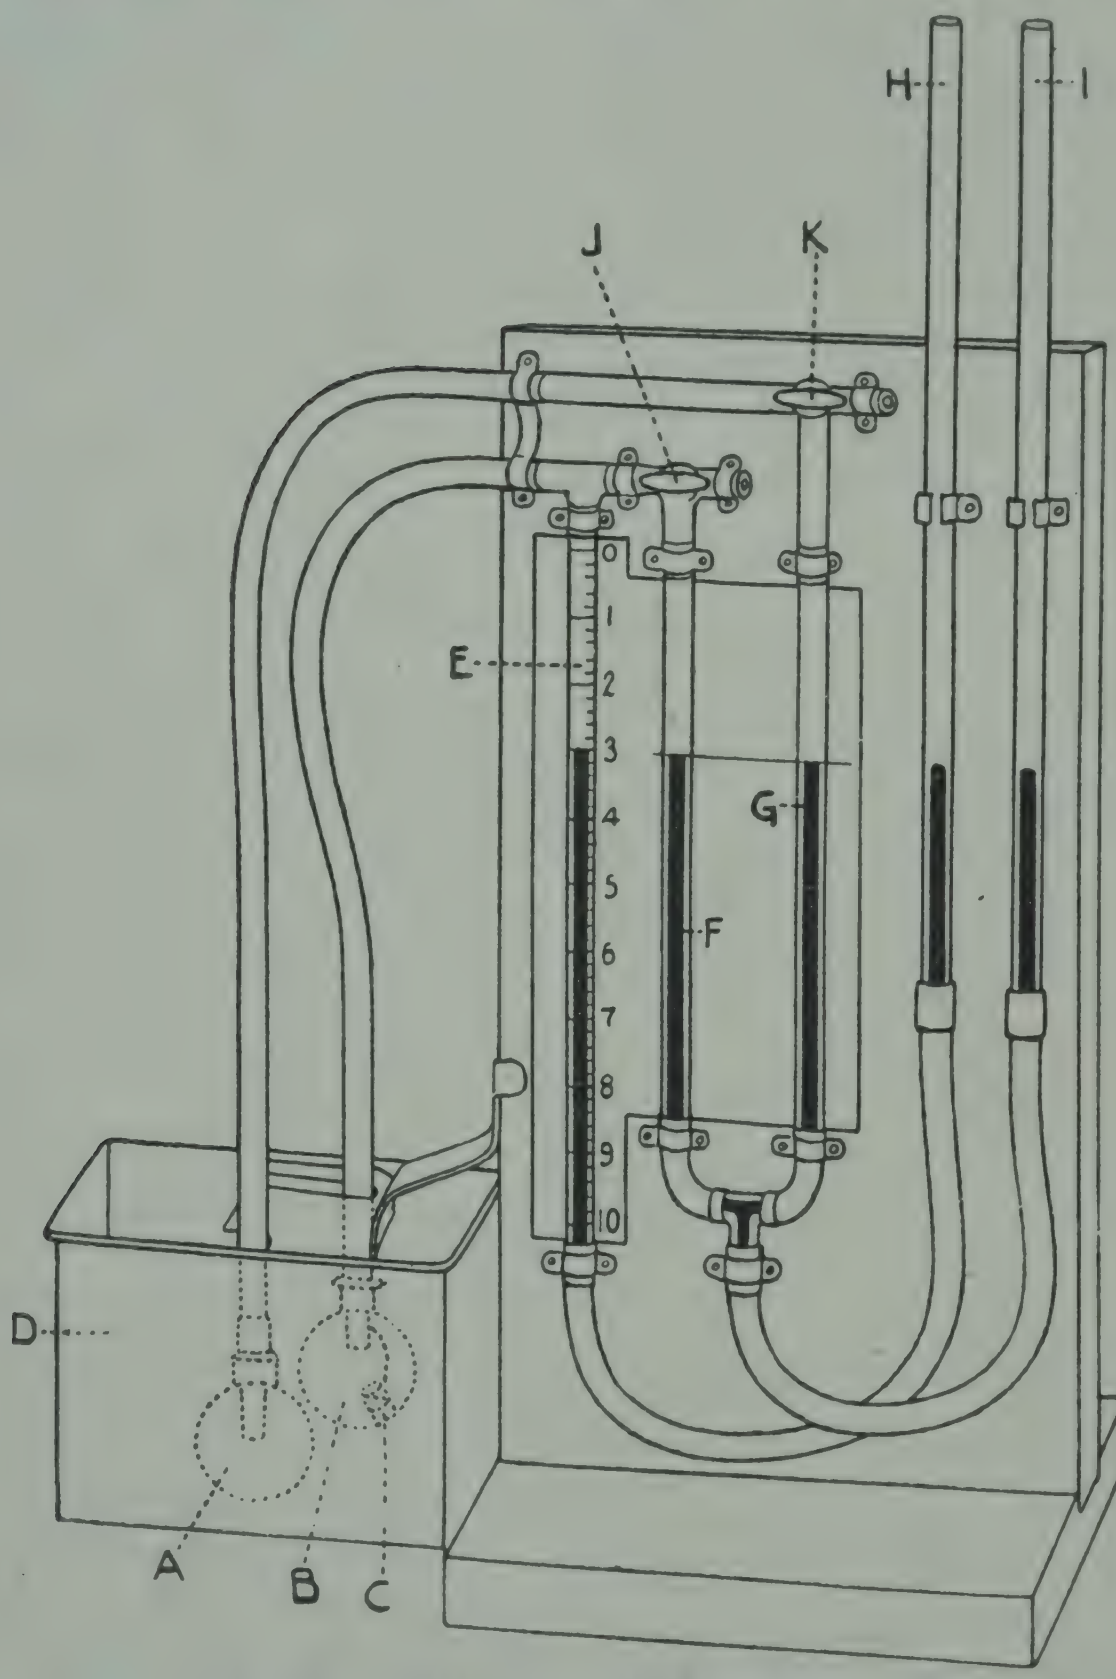

FIG. 325. Haldane's Blood-gas Apparatus.

Evidently the composition of the gas could have been deduced from these readings, and also the amounts at N.T.P. Thus the pressure of oxygen would be 171 − 133 = 38 mm., and its volume would be $\frac{2 \times 38}{760} = 0{\cdot}1$ ml., which we know to be correct.

In using the apparatus for the estimation of the gases in blood, an acidified ferricyanide solution is first introduced into the chamber, which is then evacuated and shaken by the motor attachment, to extract all dissolved air. A measured volume of blood (1 ml.) is then introduced through tap G, the chamber again evacuated and shaken, and thus all gas expelled from the blood, the CO_2 by the acid, the oxygen by the ferricyanide, and the nitrogen by the evacuation. The volume of gas is then brought to 2 ml., and the pressure p_1 is read. Then 1 ml. of N·NaOH is admitted to absorb CO_2, the volume again brought to 2 ml., and pressure p_2 is read. From p_1-p_2 with certain corrections, the volume of CO_2 is found. Next 1 c.c. of an alkaline hydrosulphite is introduced, volume brought to 2 ml. and p_3 read. Oxygen is calculated from p_2-p_3. For very small volumes of blood the gases may be read at 0·5 ml., so that pressures four times as great are given throughout. In practice various precautions have to be taken, but the calculations are greatly simplified by the use of appropriate tables.*

* PETERS and VAN SLYKE. Quantitative Clinical Chemistry, 1932. (Baillière, Tindall and Cox).

OXYGEN CONTENT AND PER CENT. SATURATION. It is often necessary to know the actual *content* of oxygen in the blood under given conditions, and also the degree of full saturation which that content represents. This is called the *percentage saturation* *i.e.*, $\frac{\text{content}}{\text{capacity}} \times 100$. Thus if a blood of 20 volumes per cent. oxygen capacity contains under given conditions 15 volumes per cent., then its degree of saturation is 75 per cent., its *deficit* of saturation being 25 per cent.

It is easy, on any given sample of blood, to determine at one time the oxygen content, percentage saturation and capacity, by the use of Haldane's apparatus. For this purpose, 1·5 ml. of borate buffer at *p*H 10·0 is placed in flask B; then 1 ml. of blood is run beneath the surface of the alkali, and the flask corked and immersed in the water bath D until its temperature is constant. The flask A contains 2·5 ml. of water, and is similarly corked, and the T-taps J and K left open to the air. The levelling tube I is adjusted to bring the water in F and G to the marks, and H to bring that in E to a suitable level, and then taps J and K are turned so that the T-bores lie thus : ⊣ The burette E is now read, and the flask B agitated for a few minutes so that the layer of blood is mixed with the alkali, laked, and fully saturated with oxygen. After again equalising temperatures, the levels in F and G are adjusted by the levelling tubes H and I. The blood has now absorbed the amount of oxygen necessary to saturate it ; this volume (" the deficit ") is read off on the burette E and corrected for temperature and pressure ; call it D c.c. Flask B is now opened, and 0·25 ml. of 6 per cent. ferricyanide, with a pinch of saponin, added to the tube C, the flask closed, and the oxygen capacity of the now fully saturated blood determined by adding the ferricyanide. Call it S ml. After making certain minor corrections * we can then calculate the original oxygen content C :

$$C = S - D$$

and the percentage saturation, P

$$P = \frac{S - D}{S} \times 100.$$

For instance, suppose that the oxygen capacity was 17·4 ml. per 100 ml. of blood and the deficit was 0·92 ml. per 100 ml. blood, then the blood as taken contained 17·4 — 0·92 = 16·48 ml. oxygen per 100 ml., while the percentage saturation would be $\frac{16\cdot48}{17\cdot40} \times 100 = 94\cdot7$.

The degree of oxygen saturation of the blood can also be approximately estimated by the use of a photoelectric method, and continuous records of the oxygen saturation of the circulating blood can thus be made.†

Average Red Cell Data for Human Blood. The data accepted in Britain for average human red cell count and hæmoglobin content at the beginning of the present century appear now to be too low.

Price-Jones ‡ found as follows for 100 healthy men and women in London :

	Men (average age 27)	Women (average age 24)
Red cells, p.c. mm.	5·428 million	5·012 million
Hæmoglobin, p.c. (Haldane) . . .	105·42	98·26
Colour Index $\left[= \frac{\text{Hb\%} \times 5}{\text{Millions of cells per c.mm} \times 100} \right]$	0·97	0·98

In the U.S.A., still higher Hb average values have been reported for young adult males. The following data, averaged from 115 healthy American male students, aged 18 to 30, are given by Foster and Raymond Johnson (1931) § (*v.* Fig. 324).

(1) Red cells = 5·26 million, p.c. mm.
(2) Hæmoglobin = 15·63 grams per cent.
(3) Oxygen capacity = 21·05 vols. per cent. (= 114 per cent. on Haldane Scale and Colour Index = 1·08).
(4) Hæmatocrit volume : 46·7 per cent. (Heparinised.)
(5) Average volume of corpuscle = $88\cdot8\mu^3$ per corpuscle $\left(= \frac{(4)}{100 \times (1)}\right)$.
(6) Average corpuscular Hb = $30\cdot03 \times 10^{-12}$ grams $\left(= \frac{(2)}{(1) \times 10^5}\right)$.
(7) Relative corpuscular Hb = 34·77 per cent. $\left(= \frac{(6)}{(5)}\right)$.

THE SPECIFIC GRAVITY OF THE BLOOD. The specific gravity of the blood may be determined by discharging drops of it into a liquid of known specific gravity, with which it will not mix. The simplest technique is to use a series of solutions of copper sulphate of different strengths and of densities covering the required range. The solution in which the drops remain suspended is that of the specific gravity of the blood.* From the specific gravity of blood and of plasma the Hb content, plasma protein, and hæmatocrit volume can be roughly inferred by reference to nomograms. The specific gravity varies between 1,055 and 1,066, being lowest in women. It is increased by loss of water, as after profuse perspiration, or by passive congestion of the part from which the sample is taken. It is also increased as a result of any operation upon a serous cavity in consequence of exudation of plasma in the inflamed or irritated part. It is diminished as the result of bleeding. The specific gravity of serum is 1,028 to 1,032, of corpuscles about 1,090. It is interesting to note that the specific gravity of the blood is highest in the fœtus at full term, when it amounts to 1,066, contrasting with that of the mother at the same time, the specific gravity of whose blood is only 1,050. The specific gravity rapidly falls after birth.

VISCOSITY OF THE BLOOD. Blood is more viscous than water, but since it is not a homogeneous liquid its apparent viscosity varies according to the method used for the measurement. Thus when viscosity is determined by the rate of flow along a capillary tube, the apparent viscosity is increased by increase in the relative number of corpuscles, by diminution in the bore of the capillary and by reduction in the driving pressure. A figure commonly given is five times that of water.

THE SUSPENSION STABILITY OF THE BLOOD. From the size of the red cells and the difference in specific gravity between them and the plasma, it can be calculated that when blood is allowed to stand the corpuscles should sink at a speed of about 0·2 mm. per hour ; yet the experience of centuries has shown that the speed with which sedimentation occurs is far more rapid and shows enormous variations, being greatly increased in some disorders.

In the days when blood-letting was almost universal in the treatment of disease, it was a frequent observation that on allowing the blood to stand there was formed at the surface of the clot a pale layer, known as the *buffy coat.* This was due to the fact that the corpuscles settled so rapidly that the clot was formed in part in the supernatant plasma, and was, therefore, pale in colour.

Fåhræus studied the sedimentation of citrated blood by allowing samples to stand undisturbed in long narrow tubes, and measuring the length of clear plasma after one hour. The following average results were obtained :—

New-born children	0·5 mm. per hour.
Normal men	3·3 ,, ,,
Non-pregnant women	7·4 ,, ,,
Pregnant women at term.	44·9 ,, ,,

The rapid rate of sedimentation is due to the phenomenon known as *agglutination,* which consists in the corpuscles aggregating together into clumps. In blood with a sedimentation value of 1 mm., each clump consists of about eleven corpuscles, while one with a value of 75 consists of clumps each composed of about 58,000 corpuscles. If the corpuscles and plasmata be separated off from two bloods with very different suspension stabilities, *e.g.* normal male and gravid female bloods, and then exchanged, it is found that the speed of settling is determined by some constituent of the plasma and not of the corpuscles. The logarithm of the maximal sedimentation velocity is proportional to the concentration in the plasma of the specific substances causing agglutination. This constituent is usually associated with the globulin fraction.

Blood Groups. The phenomenon of agglutination is often shown in an exaggerated form when the blood of one individual or species is added to the blood, or to the plasma or serum, of another. If, for instance, a drop of human blood be mixed, on a slide or white plate, with some horse serum, the agglutination is at once evident to the unaided eye. It is found that human beings fall into four main groups, when agglutination tests are performed.

Agglutination is due to the interaction between substances in the corpuscles, called *agglutinogens,* and substances called *agglutinins* in the plasma. The agglutinable substances, or agglutinogens, occur on the corpuscles in an insoluble form, and sometimes in tissue fluids in soluble form, and in various forms of mucin, and appear themselves to be mucoids.*

---

* PHILLIP, VAN SLYKE *et al. Bull. U.S. Med. Dept.*, Dec., 1943, **71,** p. 66.

The agglutinins are naturally occurring anti-bodies. Two main agglutinogens, called A and B, may exist in human red cells, and these can react with two agglutinins, called α and β, found in human plasma or serum. Thus α agglutinates A corpuscles and β agglutinates B. The cells of an individual may contain one or both agglutinogens, or none at all, and similarly for the agglutinins of the serum. Subjects thus fall into four groups, according as the cells are A, B, AB (*i.e.* with both) or O (*i.e.* with neither). A blood with A cells cannot have a plasma with α agglutinins, nor can one with B cells have β plasma, *i.e.* the agglutinogens have no antigenic properties. The blood with A cells contains the β plasma, that with B contains α, that with AB contains neither agglutinin, and that with the O group of cells contains both α and β agglutinins in the plasma. Hence when the sera of one group are mixed with cells of other groups the results are as shown in the table (+ indicates agglutination).†

Corpuscle Group	Serum contains	Effect of adding Serum of Blood Group			
		A (serum = β)	B (Serum = α)	AB (Serum = o)	O (Serum = αβ)
A	β	−	+	−	+
B	α	+	−	−	+
AB	o	+	+	−	+
O	αβ	−	−	−	−

The corpuscles of Group O are not agglutinated by the plasma of any group, and Group O are accordingly called "Universal Donors," since their blood is safe for transfusion into any person. In Group AB the plasma is *o*, and does not agglutinate any corpuscles, so that people belonging to this group could receive blood from any healthy person. The other groups are as shown. Thus Group B could act as a donor to Groups AB or B only. For transfusion work, account need only be taken of the action of the agglutinins of the recipient on the cells of the donor ; the serum of the donor will be so diluted that its effect on the recipient's corpuscles is relatively slight.

It is usual to carry out grouping tests by the use of tested sera belonging to Groups A and B. Drops of the diluted citrated blood of the person to be tested are mixed on a white plate with a drop of each of these, and, as in the table :

Blood of Group AB is agglutinated by serum of A and B (containing β and α respectively).
,, Group A ,, ,, B (containing α).
,, Group B ,, ,, A (containing β).
,, Group O ,, ,, neither.

Among English people, about 2 per cent. belong to Group AB, 40 to Group A, 15 to Group B, and 43 to Group O. With other races the distribution is different.‡ The agglutinogens are passed on by inheritance, A and B being Mendelian dominants, the agglutinins and therefore Group O, being recessives —a fact of medico-legal importance in cases of disputed paternity,§ *e.g.* if the mother is, say, B, and her child A, the father must have been A or AB.

The classification of blood groups is made still more precise, especially in examination of medico-legal cases, by the discovery that, quite independently of the AB system mentioned above, another classification can be made, based on different agglutinogens called

§ HARLEY and ROCHE LYNCH. *B.M.J.*, 1937 (i), 163 ; THOMAS. *Ibid.* (ii), 315.

M and N. These are identified by special immune rabbit sera, and provide three independent types, M, N and MN. As these occur independently of the AB groups, the combination yields twelve possible blood types, and in fact, yet other subsidiary groups are known.

An important factor, called the Rh factor was discovered in 1940. It is an antigen of the Rhesus monkey, is present in the red cells of 85 per cent. of white people, and may be transmitted from father to child. To take the simplest case, if the mother is Rh negative, and the fœtus Rh positive because the father is positive, she forms anti-bodies to it ; these pass by the placenta to the fœtus and cause extensive blood destruction (erythroblastosis fœtalis) in the new-born child, which is shown by extra medullary blood formation and persistence of erythroblasts in the blood. This state of affairs is probably the commonest cause of fœtal death. A further difficulty is that the woman who has become sensitive will always remain so, and will herself be thenceforth unable to support a transfusion with a Rh positive blood. The inheritance of the Rh factor is too complex to discuss here, since it can be subdivided into several (probably at least six) genetic sub-groups.

Blood Transfusion. The facts of blood grouping acquire great practical importance, because agglutination is the precursor of hæmolysis, and because the plasma of one human being frequently causes agglutination of the corpuscles of another. Transfusions of incompatible blood may lead to severe symptoms and may be fatal. The incompatible corpuscles are hæmolysed in the body, hæmoglobin is excreted in the urine, or the kidneys may even cease to function, and a state of shock and collapse ensue. In carrying out the urgent operation of blood transfusion, it is therefore a matter of great importance to ensure that the corpuscles of the donor will not be agglutinated by the plasma of the recipient, *i.e.*, that the recipient's plasma does not contain agglutinins that react with the donor's corpuscles. To make quite sure of this, it is necessary, if circumstances allow, to test out the blood of the donor directly against the serum of the recipient, in addition to the grouping test, because some corpuscles may in spite of identity of main groups, belong to subsidiary groups and prove to be incompatible with a given serum. The M and N factors do not complicate the test because there are no natural agglutinins in man corresponding to them, but occasional anti-Rh antibodies may occur. Further essential precautions include the avoidance of clotting, and of infection, and the introduction of blood at the proper temperature, and at the proper rate, into the veins of the recipient. Coagulation is usually prevented by the addition of sodium citrate, 3·2 per cent. solution, to five times its volume of blood. The citrated blood can be preserved at 5° C. for periods up to ten days, or longer, if an equal volume of 5·4 per cent. glucose should be added to the mixture. Collections of stored blood (blood banks), duly grouped are often kept at large hospitals. When hæmolysis begins to set in rapidly the stored blood must be rejected.

The blood donor usually gives 420 c.c. of blood at each bleeding : this results in a loss of about 2·3 g. of Hb per 100 c.c. blood, and it takes about 50 days for complete restoration, though if iron is taken by mouth the time for return to normal is reduced considerably.* Men regenerate Hb at about 0·05 g./100 c.c./day, and women at about 0·04 g./100 c.c./day.

The Reaction of the Blood. The blood is slightly alkaline to litmus, and can be titrated with an acid. Such a procedure, however, gives a measure, not of the degree of alkalinity, but of the alkaline reserve—*i.e.* of the total amount of base in combination with weak acids which can be replaced by a stronger acid. This *alkaline reserve* consists almost exclusively of sodium bicarbonate.

In Van Slyke's method the alkaline reserve of the plasma is determined by finding out how much CO_2 is evolved from 1 c.c. of the oxalated plasma, when this is treated with 0·5 c.c. of 5 per cent. sulphuric acid. Since the amount of carbon dioxide taken up depends on the partial pressure of the CO_2 in the atmosphere to which the plasma is exposed, the plasma is first shaken up with alveolar air provided by the experimenter himself, which always contains about 5·5 per cent. of CO_2.

Normal human blood plasma treated in this way yields between 60 and 70 c.c. of CO_2 per 100 c.c., which corresponds to about 0·2 per cent. of sodium bicarbonate.

The *hydrogen ion concentration* of the blood can be determined by the electrometric method, or by the use of indicators, as described on p. 65.

---

* Fowler and Barer. *J. Amer. Med. Assoc.*, 1942, **118**, 421.

By these methods the hydrogen ion concentration of the blood, *i.e.* of the plasma, at 38° is found to be $0{\cdot}4 \times 10^{-7}$, or pH 7·4. It might be thought that with such a feeble alkalinity the merest trace of acid added to the blood would suffice to make it acid. It is found, however, that a relatively large proportion of an acid must be added to the blood in order to produce a considerable change in its reaction. This is due to the fact that the sodium bicarbonate acts as a "buffer"—*i.e.* a substance which can take up acid or alkali with a minimal change of reaction. As in other buffer systems (*v.* p. 64) the hydrogen ion concentration depends on the ratio of the weak acid to its salt, *i.e.* to $\frac{H_2CO_3}{NaHCO_3}$. This in blood is usually $\frac{1}{20}$ when the molar concentrations are taken, and the *p*H of the blood can be determined by finding the concentrations of free and fixed CO_2, and the use of the *Henderson-Hasselbalch equation :*

$$pH = pK_1 + \log \frac{[NaHCO_3]}{[H_2CO_3]}$$

where pK_1 has the value of 6·1 (*i.e.* $pH = 6{\cdot}1 + \log 20 = 7{\cdot}4$ approx.) The property of the blood of retaining a nearly constant reaction, even though fixed acids are added to it, is of immense importance, since all cellular functions are acutely sensitive to changes in reaction, and as we shall see later, the activity of the respiratory centre is largely dependent on the hydrogen ion concentration of the blood with which it is bathed.

The alkaline reserve of the blood is significant, since pronounced diminution indicates in all probability the production of fixed acids in the tissues, and a progressive reduction will precede the point at which the "buffer" action of the sodium bicarbonate is lost, and the blood then responds to any addition of acid by a considerable change in reaction. It is only when the alkaline reserve has been greatly reduced that a true condition of *acidæmia*, or increased H-ion concentration, can come into being.

LOVATT EVANS (1930). Recent Advances in Physiology, 4th ed. (Chap. V. The Reaction of the Blood). (Churchill.)

THE OSMOTIC PRESSURE OF THE BLOOD. Since the blood serves as a circulating medium, by means of which the composition of the tissue juices is maintained constant, its osmotic pressure must be of considerable importance. The osmotic pressure of the blood depends on its molecular concentration and can be determined by any of the methods mentioned earlier (p. 58), *e.g.* by the determination of the freezing-point. The depression of freezing-point, Δ, of mammalian blood in equilibrium with air is about 0·53°. This is equal to that of a 0·9 p.c. (= 155 milli-equivalents per litre) sodium chloride solution, which is therefore often taken as isotonic with the blood.

By the use of Hill's thermopile method for vapour pressure, Magaria * found the average osmotic pressure of the blood of adult men to be equal to that of 0·945 per cent. NaCl ($\Delta = 0{\cdot}553°$ C.) when the blood was in equilibrium with 5 per cent. CO_2. The blood of women had a lower osmotic pressure = 0·927 per cent. NaCl ($\Delta = 0{\cdot}543°$ C.). Under normal conditions the osmotic pressure is remarkably constant ; it is reduced slightly by large ingestions of water and increased slightly during severe muscular exercise.

Actually the osmotic pressure of the contents of the red corpuscles is a little lower than that of the plasma, but the difference is not great enough for hæmolysis appreciably to alter the freezing-point or osmotic pressure of the blood.

For frog's blood Hill and Kupalov found an osmotic pressure = 0·725 per cent. NaCl.

THE ELECTRICAL CONDUCTIVITY OF THE BLOOD. In a solution it is only the dissociated ions which have the power of carrying electric charges. The conductivity of blood serum is therefore determined almost entirely by its content in salts. Since this is approximately constant, the conductivity of serum varies within very narrow limits. The conductivity of blood varies, however, within wide limits. The corpuscles present a resistance to the passage of the charged ions and therefore of the electric current through them, so that the larger the number of corpuscles contained in a given specimen of blood the lower will be the conductivity of the latter. Stewart made use of this fact as a basis for a method of determining the relative volume of corpuscles and plasma. Owing to the fact that the red cells carry a negative charge, they move towards the anode when an electric current is passed through the blood.

---

* MAGARIA. *J. Physiol.*, 1930, **70**, 417

THE GENERAL COMPOSITION OF THE BLOOD

Human blood contains from rather over one-third to one-half of its weight of corpuscles. It contains from 20 to 25 per cent. of solids.

The following table shows a typical percentage composition of human blood :—

Normal Human Blood

	Per cent. in Whole Blood	Per cent. in Plasma	Per cent. in Corpuscles
Total solids	22·0	9·3	34·6
Inorganic solids	0·75	0·8	0·7
Serum albumin	2·8	4·6	—
Serum globulin	0·95	2·2	—
Fibrinogen	0·25	0·4	—
Hæmoglobin	15·6	0·0	33·0
Non-protein nitrogen	·032	·025	·044
Urea nitrogen	0·012	·012	·011
(= urea)	0·026	—	—
Amino nitrogen	0·006	0·005	0·008
Creatinine	0·002	—	—
Creatine	0·005	—	—
Uric acid	0·003	—	—
Reducing power (as glucose)	0·10	0·09	0·10
True glucose	0·07	0·08	0·06
Lactic acid	0·020	0·025	0·014

Bicarbonate (as HCO_3)	—	0·15	—
,, (as $NaHCO_3$)	—	0·21	—

Blood Plasma is resolved by clotting into serum and fibrin. The fibrin forms only 0·2 to 0·4 per cent. of the total weight of blood. The *serum* contains, in 100 parts, 8 to 9 parts of solids, of which 7 to 8 parts consist of proteins, while the salts make up to about 1 part.

The chief salt present in the serum is sodium chloride, and next to this comes sodium bicarbonate, and besides these two we find traces of potassium, sodium and calcium, and phosphates. Ammonia is absent from fresh blood, but after shedding appears in amount up to 0·1 mg./100 c.c. This is formed by deamination of adenylic acid derivatives.*

The anions and cations of the plasma are often expressed in terms of milli-equivalents per litre. The total base of the serum in man is kept remarkably constant at the isotonic value of 155 milliequivalents per litre. The distribution of ions is roughly as follows :—

---

* Conway and Cooke. *Bioch. J.*, 1939, **33**, 457.

	Cations. m.eq./l.		Anions. m.eq./l.
Na =	142.	Cl' =	103
K =	5.	HCO_3' =	28
Ca =	5.	HPO_4'' =	2
mg =	3.	Protein′ =	16
		SO″ and organic =	6
	155		155

The distribution of the anions is more variable than that of the cations. but the sum of anions is normally constant and equal to that of the cations.

Traces of fats, cholesterol (about ⅓ free and ⅔ as esters), lecithin, glucose, urea, amino-acids and other nitrogenous extractives are constantly found in the serum. Tiny particles called *hæmokonia* or chylomikrons are always visible in plasma under dark-ground illumination. They consist of fat. The fats are much increased after a meal rich in them and may give the serum a milky appearance. The yellow colour of the plasma is due to the presence of small amounts of bilirubin, carotene (C_{40} H_{56}) and xanthophyll ($C_{40}H_{56}O_1$).

The Proteins of the Plasma. Dried plasma, and various protein fractions of plasma have found extensive use in the clinic, as blood substitutes, etc. The plasma contains a number of different coagulable proteins. We may divide them into those which are the precursors of fibrin and those which remain in the serum.

FIBRINOGEN is a globulin converted on coagulation into fibrin. It has a high molecular weight (500,000) and its molecules are large and elongated (900 × 33 Å). It is formed in the liver. This is proved by the fact that after excision of the liver the fibrinogen content of the blood slowly declines.* If the circulating blood is defibrinated (by removing it, whipping and re-injecting) the fibrinogen content is restored in a few hours ; no restoration occurs if the liver has been previously removed, but rather a continued loss.† The plasma contains normally about 0·25 per cent. (0·19 to 0·38 per cent.) of fibrinogen.

Prothrombin is also a globulin (p. 529), which is concerned in fibrin formation.

Fibrin. Fibrin is easily obtained by whipping blood as it flows from the vessels with a bundle of wires or twigs, and then washing the stringy threads so obtained (see p. 527). Fibrin is insoluble in water and in dilute salt solutions. It slowly dissolves in 5 per cent. sodium chloride, but it is probable that its solution is effected by the agency of minute traces of proteolytic enzymes adherent to the fibrin as it is precipitated. In dilute acid, such as 0·2 per cent. hydrochloric acid, fibrin swells into a clear jelly which very slowly undergoes solution with the formation of acid metaprotein and proteoses.

THE PROTEINS OF THE SERUM. The serum proteins are generally grouped in two classes : the serum albumins and the serum globulins. All the proteins are precipitated by saturation with ammonium sulphate, but only the globulin by half-saturation. The normal range for albumin in human plasma is 3·7 to 4·7 per cent. and for globulin (plus fibrinogen)1·9 to 3·6 per cent. The ratio of globulin to albumin is known as the "protein quotient". It varies in different animals, but in the same individual it is almost constant in the blood, serum, lymph and transudates, though the total amounts of protein in these may be very different. Globulins are probably the more important because they include (in the γ-fraction) the various anti-bodies, such as precipitins, antitoxins, lysins, agglutinins, etc., which play a large part in the phenomena of immunity (*v.* Chapter XXXVIII). The serum proteins are formed in the liver ; the albumin provides 80 per cent. of the colloid osmotic-pressure of the plasma ; they also act as a reserve of protein for the body in time of need.

Serum albumin is a mixture of proteins of relatively small molecular weight (69,000) and size (150 × 38 Å). It can be precipitated by complete saturation with ammonium sulphate. The fraction also contains a glyco-protein called globoglycoid.*

* NOLF. *Arch. internat. de physiol.*, 1905, **3**, 1.

† MCMASTER and DRURY. *Proc. Soc. Exp. Biol. Med.*, 1928, **26**, 490 ; JONES and SMITH *Amer. J. Physiol.*, 1930, **94**, 144.

The *serum globulins* are mixtures of proteins of greater molecular weight and size (*e.g.* γ-globulin mol. wt. 150,000 and size 320 × 36Å). They can be divided into three fractions, namely, *euglobulin I*, insoluble in water at *p*H 7, *euglobulin II*, insoluble in water at *p*H 6 (precipitated by CO_2), and *pseudo-globulin*, "soluble" in water. Pseudo-globulin is, however, not soluble in *complete* absence of salts, and is therefore thrown down by electro-dialysis.

Hardy † showed that with acids or alkalies the globulin forms "salts" which ionise in solution so that in an electric field the protein ions move with a speed dependent on their weight, size and shape. According to these speeds of migration, they have been grouped into α, β and γ fractions. The usual proportions are $\alpha = 0{\cdot}84$, $\beta = 0{\cdot}78$, $\gamma = 0{\cdot}66$ g./100 ml.

THE CONDITION OF THE PROTEINS IN THE BLOOD SERUM. Although it is easy to separate one or more different forms of protein from serum, we have evidence that these proteins in the serum are present in a somewhat different form. When examined by the ultra-centrifuge there are found to be less of the large molecules resembling globulin than would be expected from salting-out, and correspondingly more of the smaller molecules of albumin dimensions.‡ On dilution this distribution is altered until finally it agrees with the proportions found on analytical separation.

Serum can be readily filtered through a porous cell, and this method is adopted for obtaining it free from contamination by micro-organisms; yet globulin when isolated in solutions will not pass through a porous cell.

In explanation of these and other facts, it is now considered that the serum proteins consist of numerous closely related substances, separable roughly into the various groups, *e.g.* albumin, the globulins, etc., but each member of which is in fact an association of mutually interacting systems of colloids.§ By simple means, such as dialysis, dilution or addition of salt, fractionation by alcohol, electrophoresis at given *p*H, etc., these complexes can be broken up into various fractions.

THE RED BLOOD CORPUSCLES

The red blood corpuscles, or *erythrocytes*, in man are non-nucleated bi-concave discs, which, when in the body, are about 8·8 μ in diameter and about one-third of this in thickness. In the dried, fixed film they are, owing to shrinkage, on the average only about 7·2 μ in diameter, extreme values being between about 6·7 and 7·7 μ. The actual size-distribution in normal people is shown in Fig. 327, which illustrates the narrow range of variation in size.‖ The *average* size of the red cells can be determined in a film, fresh or dried, by a diffraction method,¶ using an instrument called an eriometer or halometer.

The red corpuscles are not of rigidly fixed size when in the body. The circumstance which is chiefly responsible for change of size in the body is alteration in the reaction of the blood plasma; reduction of the alkalinity of the

plasma causes swelling of the corpuscles, and *vice versâ*. Hence it follows that the corpuscular volume is slightly greater in venous than in arterial blood.

The colour of a single corpuscle when viewed under the microscope is yellow, the red colour being apparent only when larger numbers are seen together. The red corpuscles form about 50 per cent. of the total mass of the blood. They are soft, flexible and elastic, so that they can readily squeeze through apertures and canals narrower than themselves, without undergoing permanent distortion. When examined by the usual histological methods, or by dark-ground illumination, the normal erythrocyte appears quite structureless. Each red corpuscle has been described as consisting of a framework or stroma, composed chiefly of protein and lipide material, containing in its meshes a red colouring matter, hæmoglobin, to which is due the colour of the corpuscles and of the blood itself. No limiting envelope is histologically demonstrable, though a convenient view is that a monomolecular layer of some material—probably lipides, such as lecithin—exists at the surface.

In nearly all mammalia the red corpuscles are of the character described (Fig. 328). In the camel they are oval in shape, but otherwise resemble the corpuscles of other mammals. In all other classes of vertebrata the red corpuscles are oval, nucleated cells; the hæmoglobin is diffused through the protoplasm of the cell body and does not extend to the nucleus. During the early part of fœtal life the corpuscles of mammals are also nucleated, but in the adult condition the erythrocytes, except under abnormal conditions, lose the nucleus before entering the blood

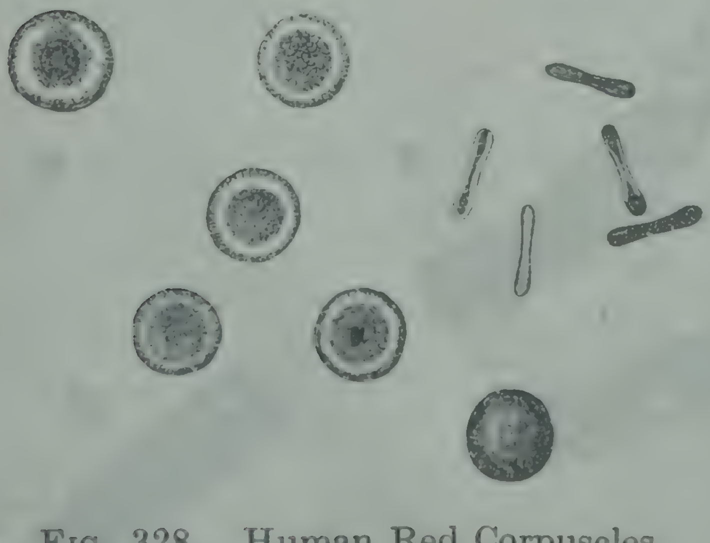

Fig. 328. Human Red Corpuscles. On the right of the figure the corpuscles are seen on edge. (Swale Vincent.)

stream. The small size and great number of the red corpuscles determine that a very large area of surface of red corpuscles is exposed to the plasma. This great extent of surface is of importance in facilitating the exchange of material, especially oxygen, between the corpuscle and the surrounding plasma.

The volume of each corpuscle has been estimated as about 90 μ^3 (= ·000000090 c. mm.), and its surface as ·000128 mm.^{2}, so that the total surface of red corpuscles in the blood of a man weighing about 70 kilos (assuming his total blood as $\frac{1}{13}$ of the body weight) would be about 3,000 sq. metres, or 1,500 times the surface of the body itself.

Bürker has shown that in various species there is a close relation between the surface area of the red cell and its hæmoglobin content, the ratio being constant at about 32 × 10^{-14} g. of hæmoglobin per square μ of corpuscle surface.

Osmotic Relationships of the Red Corpuscle. If the blood plasma be concentrated by evaporation or by the addition of neutral salts, its osmotic pressure rises, and water diffuses from the corpuscles into the plasma to equalise the osmotic pressure within and without the corpuscle. The latter therefore becomes wrinkled or *crenated*. On the other hand, dilution of the plasma diminishes its osmotic pressure to below that of the corpuscles, and water therefore passes into the latter, which swell up and become spherical ; and, if the plasma be made sufficiently dilute, the corpuscles liberate the hæmoglobin they contain, leaving the colourless swollen *stromata* floating in the plasma. At the same time the blood becomes transparent and darker in colour, and is called " laked " or hæmolysed blood. This is called *hæmolysis*. In partial hæmolysis the corpuscles do not all burst ; microscopical examination of the process, with dark-ground illumination, shows that many corpuscles merely swell to a great size, the " ghosts ", which remain after hæmolysis but are nearly invisible to ordinary observation. They become more visible, and return to their former size, if the solution is made isotonic again. We may perhaps attribute the ultimate escape of the contents to the fact that the cell contains insufficient lipide to form a continuous layer over so large a surface.

Blood may be laked by any of the following means :—

(*a*) Addition of a small amount of ether or other lipide solvent.
(*b*) Free dilution with water, or dialysis.
(*c*) Alternate freezing and thawing of the blood.
(*d*) Addition of bile salts or of saponin.
(*e*) The action of foreign blood serum or of various hæmolysins whose nature we shall discuss later.

The erythrocytes of different individuals, especially in certain pathological states, exhibit different amounts of resistance to hæmolysis. As a measure of the " fragility " or ease with which hæmolysis may be induced by hypotonic solutions, we may plot a curve showing per cent. hæmolysis at different concentrations of NaCl * and find the concentration at which 50 per cent. hæmolysis occurs. In normal blood this is at 0·334 to 0·398 per cent. NaCl : in hæmolytic jaundice it may be as high as 0·7 to 0·8 per cent. ; after splenectomy fragility is reduced to 0·25 to 0·35 per cent. Cells of venous blood are slightly more fragile than those of arterial blood, and in general an increase in the ratio thickness/diameter of the cells increases fragility. Fragility is increased by change of pH above or below 8·1 and by cold.† The corpuscles of normal mammalian blood in presence of air neither gain nor lose volume in a solution containing 0·9 per cent. sodium chloride. The osmotic pressure as determined by the freezing-point of such a solution is identical with that of the blood, which in most mammals has a freezing-point of about — 0·53° C. When the CO_2 is prevented from escaping from human blood, its osmotic pressure is nearer to that of 0·95 per cent. NaCl (men), or 0·93 per cent. NaCl (women). The salt solution which is normal for frogs' blood contains only 0·725 per cent. sodium chloride.

† Dacie and Vaughan. *Ibid.*, 1938, **46**, 341.

The behaviour of the red corpuscle, when immersed in various solutions, suggests that its external layer is impermeable to most cations and neutral salts as well as to cane sugar and glucose, but this is not strictly true. We can, however, make isotonic solutions with sodium chloride, sodium sulphate, potassium nitrate, or cane sugar. On the other hand, a solution of urea behaves towards the corpuscles like distilled water. If some red corpuscles be added to a 1 per cent. solution of urea in normal salt solution, they neither shrink nor swell, but if added to plain aqueous urea solutions of any strength the corpuscles will be laked. There are many substances to which the corpuscles are permeable, *e.g.* alcohol, chloroform, ether, etc. In their permeability the corpuscles resemble most other vegetable and animal cells in permitting the passage of those substances that are soluble in lipides, which are invariable constituents of all living cells.

Ponder (1948). Hemolysis and related Phenomena. (London : Churchill.)

Chemistry of the Red Blood Corpuscles. The chief constituent (95 per cent.) of the solids of the red cells is the chromoprotein, hæmoglobin, which is present chiefly as a potassium salt. It is to this substance that the red colour of blood is due. The other 5 per cent. corresponds to the stroma, consisting of stroma protein (nucleo-protein), lecithin, cholesterol and salts. There is a striking contrast between the salts of the corpuscles and those in the plasma, the former consisting, in man, chiefly of potassium salts, *e.g.* hæmoglobinate, diphosphoglycerate, the latter of sodium chloride, which in some animals is entirely wanting in the corpuscles.

This is due to active excretion of $\mathrm{Na}^{\cdot}$ by the corpuscle, $\mathrm{K}^{\cdot}$ then being absorbed into it passively to maintain the cation concentration. When shed (citrated) blood is stored, as for blood transfusion, at 2° to 4° C. the K of the plasma rapidly rises to 8 to 10 times its initial value, because of loss of K from the cells when the " sodium pump " ceases to act : incubation with glucose restores the normal relation by providing energy to restart it.

The total base concentration in the red cells is greater than that in the serum, and the anions are correspondingly less, in accordance with the Donnan equilibrium (p. 83), which tells us that :—

$$\frac{\text{anions (cells)}}{\text{anions (plasma)}} = \frac{\text{cations (plasma)}}{\text{cations (cells)}} = \frac{\mathrm{H}^{\bullet}\text{ (plasma)}}{\mathrm{H}^{\bullet}\text{ (cells)}} = \frac{\mathrm{Cl}'\text{ (cells)}}{\mathrm{Cl}'\text{ (plasma)}}, \text{ etc.}$$

The Donnan ratio $\frac{\text{anions (c)}}{\text{anions (p)}}$ is usually about 0·75.

The non-diffusible anions to which this phenomenon is due, are hæmoglobin, diphosphoglycerate, and adenosine triphosphate : the last two are the chief sources of acid-soluble phosphorus in the corpuscles.

The blood corpuscles contain a greater percentage of solids than any soft tissue of the body. The blood corpuscles have 37 per cent. solids, as against muscular tissue with 25 per cent. or nervous with 22 per cent. solids. Hence the cells contain at least 30 per cent. hæmoglobin, which is far beyond its solubility. Some form of combination therefore exists in the corpuscles, which keeps the hæmoglobin from separating out in crystalline form.

In investigations on the chemistry of the red cells it is usual first to remove the plasma by centrifugalisation and washing. The blood, which has been defibrinated, or prevented from clotting by the addition of oxalate, is centrifuged until all the formed elements are thrown down. The sediment is then mixed with normal saline and again centrifuged, and this process repeated twice in order to wash away adherent plasma or serum. After the final washing the paste of corpuscles can be laked ; for this, two volumes of distilled water saturated with ether are added to one volume of caked corpuscles. The fluid is once more centrifuged in order to throw down white blood corpuscles. A 1 per cent. solution of acid sodium sulphate is now added drop by drop until the solution acquires the opaque appearance presented by ordinary blood. On centrifuging, the stromata are thrown down and can be collected and washed with distilled water several times on the centrifuge. Removal of stromata from laked cell solutions can also be effected by shaking for an hour or two with asbestos pulp and then removing this, with adherent stromata, by centrifugalisation. The cells also contain about 0·3 per cent. lipides, which is all in the stroma. About 10 to 15 per cent. of the dry weight of stroma material consists of lipides, of which 60 per cent.

is phospholipide (half of it cephalin), 30 per cent. free cholesterol and 10 per cent. cholesteryl esters and fats.*

From a laked solution of corpuscles, oxyhæmoglobin can be obtained in a crystalline form with varying readiness according to the animal from which the blood is derived. Thus in the case of the rat, the guinea-pig, the dog and the horse, it is sufficient merely to cool the laked blood, to about − 10° C., in order to obtain a large crop of hæmoglobin crystals. Crystallisation is facilitated by the addition of 25 per cent. of alcohol to the mixture, but this partly denatures the hæmoglobin. To avoid this, the following simple method depends on the fact that oxyhæmoglobin is less soluble than reduced hæmoglobin. Washed horse corpuscles are dialysed in collodion sacs against the osmotic pressure of the hæmoglobin. When fully laked, *débris* is removed by centrifugalisation, and then the cooled solution well oxygenated, when oxyhæmoglobin crystals separate out. These can be collected, suspended in distilled water, and reduced *in vacuo*, when they dissolve ; on re-oxygenation the solution again crystallises.†

Properties of Hæmoglobin. The crystals thus obtained are as a rule microscopic in size. Most animals yield an oxyhæmoglobin which crystallises in rhombic prisms or needles belonging to the rhombic system, though there are exceptions to this (Fig. 329). The solubility of the crystals differs according to the animal from which they have been derived. They are more soluble in alkalies than in water and contain carbon, hydrogen, nitrogen, oxygen, sulphur and iron. The chief differences between various animals appears to have relation to the sulphur, and to the varying avidity with which the hæmoglobins combine with oxygen.‡ All specimens are alike in containing a constant proportion of iron, viz. 0·335 per cent. It is in the *ferrous* state.

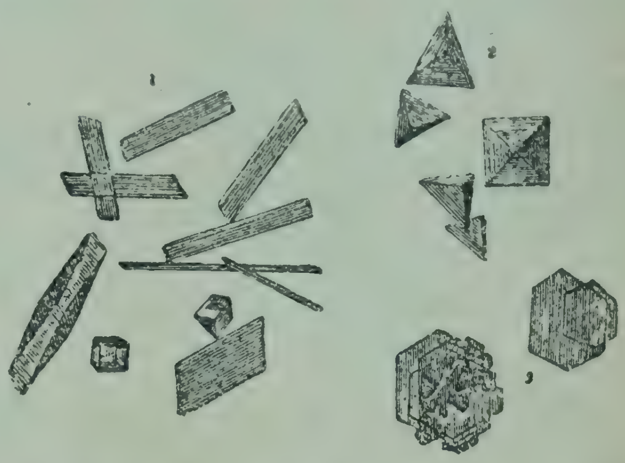

Fig. 329. Crystals of Oxyhæmoglobin. 1. From rat. 2. From guinea-pig. 3. From squirrel.

Hæmoglobin readily combines with free oxygen to form *oxyhæmoglobin*,§ and it is found that for each atom of iron two atoms of oxygen can be taken up, *i.e.* 393 c.c. of oxygen per gramme of iron present in hæmoglobin. This corresponds to an oxygen capacity of about 1·3 c.c. oxygen per gramme of hæmoglobin, if we take 17,000 as the molecular weight of Hb containing one atom of iron. The figure usually taken is 1·34 c.c. O_2 per g. Hb, but it is so difficult to prepare hæmoglobin pure that this figure is provisional. Oxyhæmoglobin is thus a compound, in definite proportions, of oxygen and hæmoglobin. It can be easily dissociated and is split up by such simple means as exposure to a vacuum (*v.* Chapter XXXIX) ; the fluid then gives off oxygen and the colour changes from a scarlet to a dull bluish red. The same change can be effected by treating a solution of oxyhæmoglobin with reducing agents such as hydrazine, sodium dithionite (hydrosulphite) ($Na_2S_2O_4$), or ammonium sulphide. The oxygen in oxyhæmoglobin can be replaced by equivalent quantities of some other gases. Thus if carbon monoxide be led through a solution of oxyhæmoglobin, oxygen is given off, and its place is taken by an equal volume of carbon monoxide with the formation of a more stable compound, carbon monoxide hæmoglobin, or *carboxyhæmoglobin*. This body is dissociated only with extreme slowness and is unaffected by the addition of reducing agents. By using special precautions to prevent oxidation of the gas, the carbon monoxide can be replaced in this compound by nitric oxide, NO. We have therefore a series of three compounds which can be arranged in order of diminishing stability, thus :

NO-hæmoglobin.
CO-hæmoglobin.
O_2-hæmoglobin.

---

* Erikson, *et al.* *J. Biol. Chem.*, 1938, **122**, 515.

† Dudley and Lovatt Evans. *Bioch. J.*, 1921, **15**, 487.

‡ McCarthy. *J. Physiol.*, 1935, **86**, 77.

§ Normal blood may contain up to 5 per cent. of its Hb in an inactive form, incapable of carrying oxygen : the nature of this inactive Hb is unknown.

The poisonous properties of carbon monoxide are chiefly due to its power of turning out the oxygen from the oxyhæmoglobin, thus depriving the tissues of the oxygen which is normally carried to them by the red corpuscles. Small amounts of CO-Hb are found in the blood of smokers.

Another compound of interest is *sulphæmoglobin* which is formed by the addition of H_2S to reduced hæmoglobin. Sulphæmoglobin is formed in the body when excessive intestinal putrefaction leading to formation of H_2S occurs, especially if certain drugs such as sulphonamide are being administered. The resulting condition of sulphæmoglobinæmia may be dangerous.

Hæmoglobin and its derivatives give well-marked absorption spectra. Thus dilute solutions of oxyhæmoglobin show two well-marked absorption bands between Fraunhofer's lines D and E. The centre of the band nearest to D corresponds to λ 579, and is often spoken of as the α band, while the second band, the one next to E, called the β band, is broader, has less sharply defined edges, and its centre corresponds approximately to λ 542. On concentrating the solution or using thicker layers, a point is reached at which the two bands fuse into one, and with a still stronger solution the whole of the spectrum is absorbed with the exception of the red end.

If a reducing agent be added to the solution of oxyhæmoglobin, the two bands disappear and their place is taken by a more diffuse band lying midway between the two (Fig. 330), its centre corresponding to λ 559. This is the absorption spectrum of hæmoglobin (*reduced hæmoglobin*).

The spectrum of carboxyhæmoglobin is very similar to that of oxyhæmoglobin, the α band being slightly ($\lambda = 570\ m\mu$) nearer to the violet end. In a mixture of oxy- and carboxyhæmoglobin, the shift of the α band is proportional to the fraction of the hæmoglobin present as the carboxy-compound, a fact which has been utilised by Hartridge for the determination of carboxyhæmoglobin by means of his reversion-spectroscope.* It is of a brighter red than oxyhæmoglobin. The fact that CO-hæmoglobin is not altered by reducing agents can be shown by adding sodium dithionite to CO-hæmoglobin, when no change is observed. The amount of CO present in a blood may be estimated chemically by expelling all the blood gases by acidified ferricyanide solution, and subsequent analysis of the gases, by the Van Slyke apparatus.†

All these derivatives of hæmoglobin, besides their absorption bands in the visible spectrum, have characteristic absorption of light in the ultra-violet spectrum. In the case of oxyhæmoglobin this absorption causes a band (Soret's band) which occupies the greater part of the spectral region between Fraunhofer's lines G and H with its centre at $\lambda = 415\ m\mu$. In reduced hæmoglobin this band is displaced towards the visible part of the spectrum.

Another derivative of hæmoglobin is *methæmoglobin.* This is normally only present in traces in the blood. It may be prepared by the addition of a ferricyanide, permanganate, or certain other oxidising agents to solutions of oxyhæmoglobin. It is a chocolate-brown substance, crystallisable, and gives an absorption band in the red between Fraunhofer's lines C and D ($\lambda = 634\ m\mu$). It is unaltered by exposure to a vacuum. It contains no available oxygen, but may contain a hydroxyl group. Its iron is in the *ferric* state.‡ Dithionite reduces this to the ferrous state, giving reduced hæmoglobin, from which, by shaking with air, oxyhæmoglobin can again be obtained. When methæmoglobin is formed from oxyhæmoglobin the whole of the loosely bound oxygen of the latter is given off, a fact which is utilised for the estimation of the oxygen held in combination in the blood.

The formation of methæmoglobin is shown in the approximate equation :

$$HbO_2 + K_3Fe(CN)_6 + KOH \longrightarrow HbOH + K_4Fe(CN)_6 + O_2$$

[To face p. 512.

in which it is seen that the hæmoglobin molecule is converted into methæmoglobin by change of the iron to the ferric state, the ferricyanide being simultaneously reduced to ferrocyanide.

By adding a cyanide to methæmoglobin the latter is converted into cyanhæmoglobin (spectrum resembling reduced Hb); by spectroscopic observation of absorption of light at 630 mμ before and after adding cyanide, the amount of methæmoglobin in a blood may be determined.*

DERIVATIVES OF HÆMOGLOBIN. Hæmoglobin is a compound of an iron-containing coloured group, called *hæm*, with a protein which varies somewhat in different animals. The prosthetic group is identical in every case where it has been examined. A separation of the prosthetic group from the protein moiety can be effected with extreme ease, and occurs whenever the hæmoglobin is treated with weak acids, with alkalies, or is heated above 70° C. The protein group is known as *globin*.

It is a strongly basic protein, classified with the histones. It is by the formation of co-ordination linkages between the histidine groups of the globin and the N of the hæm ring that the union is effected. Unless prepared with great care the globin from blood is obtained in a denatured condition. Undenatured globin was prepared by R. Hill and Holden by breaking up oxyhæmoglobin solution with the smallest possible amount of dilute HCl at − 2° C., adding cold water, ether and kieselguhr and shaking well. It is then filtered and kept at − 2° overnight. Metaprotein is thrown down by adding ammonia, and is filtered off. The filtrate is freed from ether by vacuum treatment and the salts removed by dialysis.

Hæmoglobin yields about 94 per cent. of globin and about 4·5 per cent. of the chromogenic group, *hæmatin*. In order to obtain hæmatin in a pure condition, it is usual to start with the crystalline derivative *hæmin*. When some dried blood is heated with a crystal of common salt and glacial acetic acid on a slide, the residue contains reddish brown hæmin crystals (Fig. 331), and by a large-scale modification, hæmin may be prepared in quantity. It is a hydrochloride of hæmatin of the formula: $C_{34}H_{32}O_4N_4ClFe$ (Fischer). The iron is in the ferric state. By reduction in alkaline solution it yields the ferrous compound, *hæm* ($C_{34}H_{32}O_4N_4Fe$). By dissolving hæmin in alkalies and adding excess of acid, hæmatin is precipitated. It is insoluble in water, alcohol or ether. but is slightly soluble in glacial acetic acid and in absolute alcohol. It is easily soluble in concentrated sulphuric acid, with decomposition, losing its iron and being transformed into *hæmatoporphyrin*. The formula of hæmatin is probably $C_{34}H_{32}O_4N_4Fe.OH$. Its compounds with acids and alkalies are spoken of as acid and alkaline hæmatin, and each gives a characteristic absorption spectrum (Fig. 330).

Hæmochromogens. In the presence of certain foreign matters, alkaline hæmatin, when treated with reducing agents, forms a substance known as hæmochromogen. The same change is observed when crude alkaline hæmatin, made by the action of alkalies on ordinary blood, is reduced by ammonium sulphide. These facts receive an explanation from the discovery by Anson and Mirsky † that the hæmochromogens are co-ordination compounds of reduced hæmatin with one of many possible nitrogenous compounds. When made from blood, the nitrogenous compound is a denatured globin, but other proteins, or nicotine, hydrazine, pyridine or ammonia can take its place, to yield very similar hæmochromogens. When hæmochromogen is prepared from blood, the changes would be:

$$\text{Oxyhæmoglobin} + \text{alkali} \longrightarrow \text{Hæmatin} + \text{Globin (denatured)}$$
$$\text{Globin (den.)} + \text{Hæmatin} \,[+ \text{reducing agent}] \longrightarrow \text{Hæmochromogen.}$$

When prepared with other compounds, *e.g.* pyridine, the hæmochromogen is analogous, *e.g.* a compound of reduced hæmatin and pyridine. When reduced hæmoglobin is treated with alkali, the globin is denatured, but not

† ANSON and MIRSKY. *J. Physiol.*, 1925, **60**, 50.

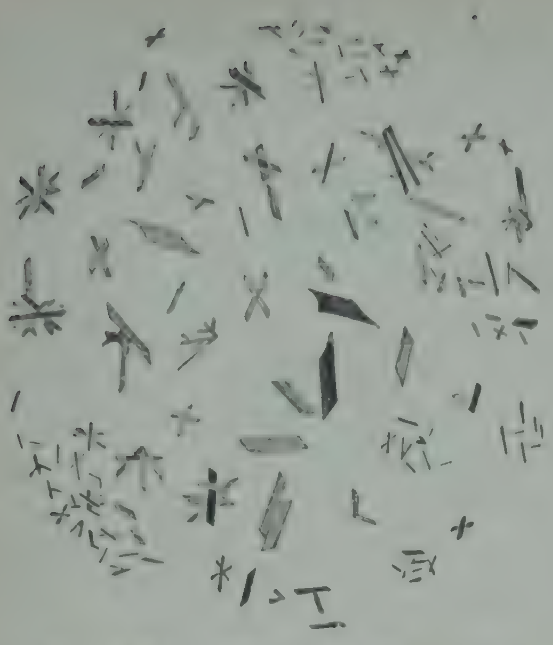

FIG. 331. Hæmin Crystals.

split off, and hæmochromogen results at once. It is evident then that "hæmochromogen" differs from hæmoglobin essentially in the fact that its protein is denatured, and in existing only in the reduced form; when oxidised it yields alkaline hæmatin and the protein or other nitrogenous body is split off.

The "blood" hæmochromogens in solution have a cherry-red colour, and when sufficiently diluted show two well-marked absorption bands (Fig. 330) which are situated between D and E; that nearest to D has very sharply defined borders; the positions of the two absorption bands are λ 555 to 559 and λ 525 to 528. The band nearest D is given by 1 in 25,000 hæmochromogen solutions, so that it is an even more delicate test for blood than is the spectrum of oxyhæmoglobin itself. Hæmochromogen does not combine with oxygen, but does so with carbon monoxide. When CO-hæmoglobin is treated with alkali in the absence of oxygen, the CO-hæmochromogen formed contains exactly the same volume of CO in combination as the original CO-hæmoglobin.*

Cytochrome. Hæmochromogens are found widely distributed in almost all tissues of animals and plants, and one series has been given the name cytochromes by Keilin. They exist in the oxidised and reduced forms, the latter of which shows a characteristic spectrum (Fig. 332). In living tissues examined by the microspectroscope the formation of the reduced cytochrome can be witnessed when oxygen is excluded, and it has been shown that cytochrome-*c* plays an important part in the execution of oxidative changes in the cells. When oxygen is excluded, the tissues reduce it; this is a result of the action of dehydrogenases, the cytochrome-*c* acting as hydrogen acceptor; when oxygen is readmitted, in presence of an enzyme, cytochrome oxidase, it is oxidised again and so it acts as an oxygen carrier. The amount of cytochrome in a tissue is closely related to the intensity of its respiration; moreover, when cyanide is added to the tissue, the cytochrome remains in the reduced state even when oxygen is allowed access to it, and at the same time the oxygen utilisation of the tissue is stopped. This is because cyanide paralyses the cytochrome oxidase.

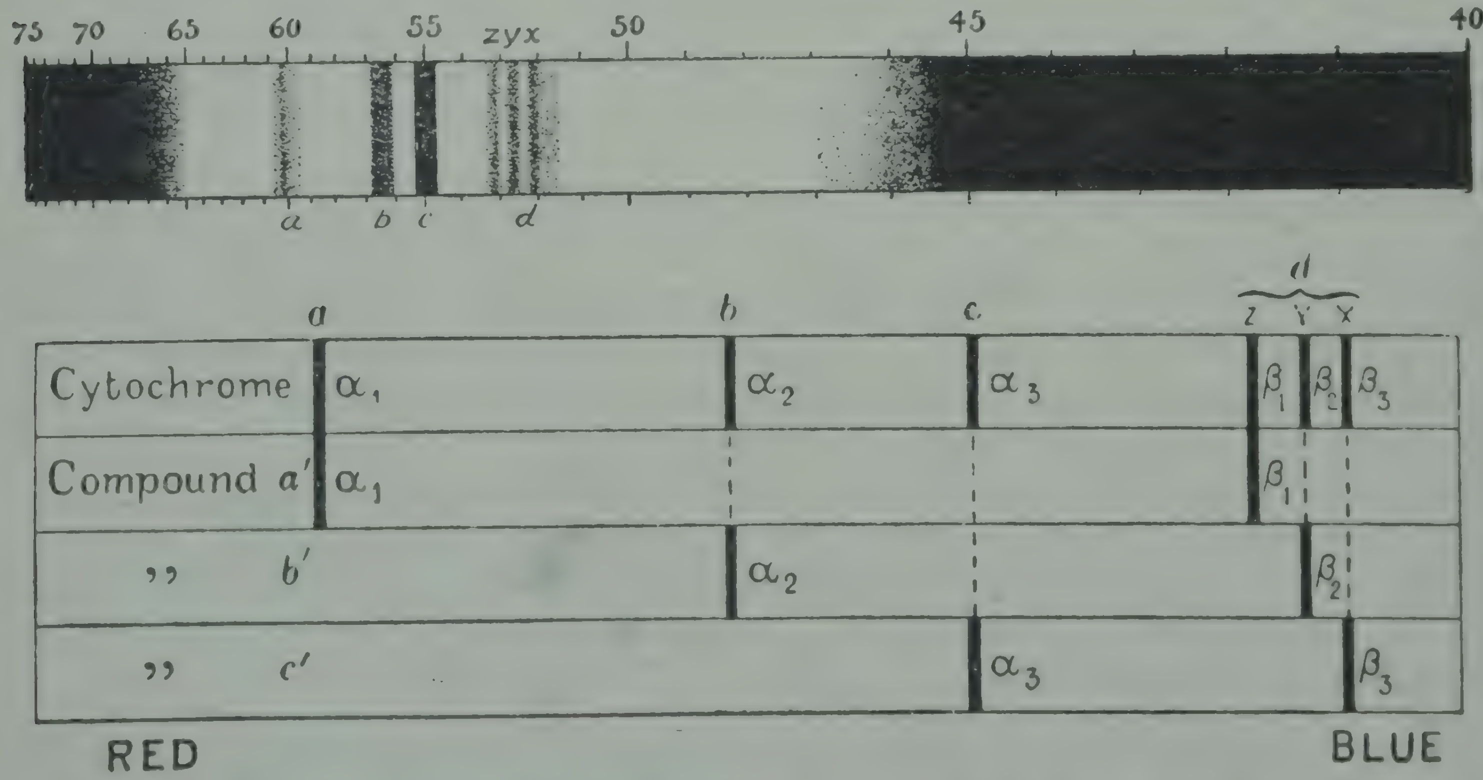

FIG. 332. *Above:* Absorption Spectrum of Cytochrome in Muscle of Bee. Reduced form as obtained by crushing tissue between two glass slips.
Below: Showing three of the separate spectra which together make up the above spectrum of mixed cytochrome. (Expanded scale.) These components and their bands, have now been re-named. Cytochrome *a′* now includes α and α_3, while *b′* and *c′* are called *b* and *c*. (After KEILIN.)

---

* ANSON and MIRSKY. *J. Physiol.*, 1925, **60**, 65.

Tissue-cytochrome is a mixture of four cytochromes, called α, α_3, b, and c of different properties* (Fig. 332).

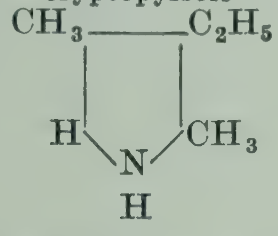
Hœmatoporphyrin. If hæmoglobin, hæmatin or hæmin be treated with a strong acid, it dissolves, forming a purple-red solution. On pouring this solution into a large quantity of water, hæmatoporphyrin is thrown down as a brown precipitate.

Hæmatoporphyrin is easily soluble in alkalies and somewhat less readily so in acids forming alkaline and acid hæmatoporphyrin respectively. Solutions of alkaline hæmatoporphyrin show four absorption bands.

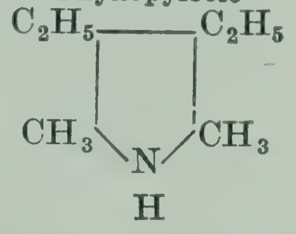
In the formation of hæmatoporphyrin from hæmatin, the iron of the latter has been split off by the action of the strong acid. The splitting off of iron occurs much more readily in the absence of oxygen. Porphyrins related to hæmatoporphyrin occur in minute quantities in normal urine and in larger quantities in certain toxic conditions, especially in poisoning by sulphonal, when the urine may have a red colour.

Chemical Relationships of Hœm Pigments. If hæmin or hæmatoporphyrin be reduced by the action of hydriodic acid we get a mixture of substituted pyrroles formerly known as hæmopyrroles. The hæmopyrroles, according to Willstätter, are three in number and have the following formula :

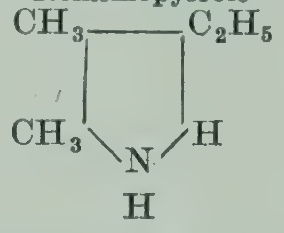
Cryptopyrrole



Phyllopyrrole

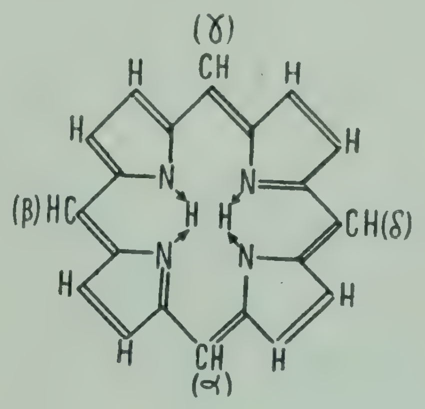


Isohæmopyrrole



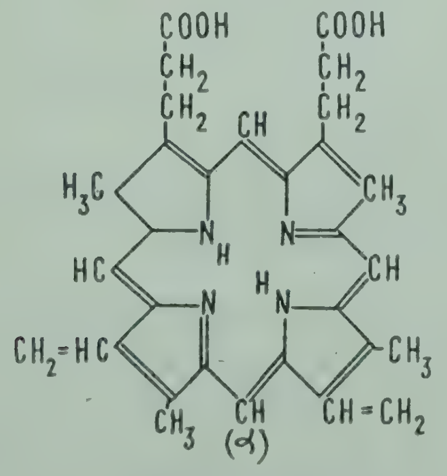
The same substances can be obtained from the chlorophyll of plants.

PORPHYRINS. Thus the same group forms the basis both of the substance which is responsible in the plant for the assimilation of carbon from carbon dioxide, and of the pigment which in the animal is the carrier of oxygen between the tissues and the surrounding medium. These and various other pigments found in animals and plants are derived from the chemical group of *porphyrins*, which consist of four substituted pyrrol rings. They are all derived from the parent substance *porphin* :—



The porphyrins of importance in the body are those known as I and III. These differ in their substituent groups. Hæmatoporphyrin may be taken as a type of III. Many porphyrins are known and some have been synthesised.

A possible structural formula for hæmatoporphyrin is :—



Hæmatoporpyrin.

---

* KEILIN and HARTREE. *Proc. R. S.*, 1939, 127B, 167.

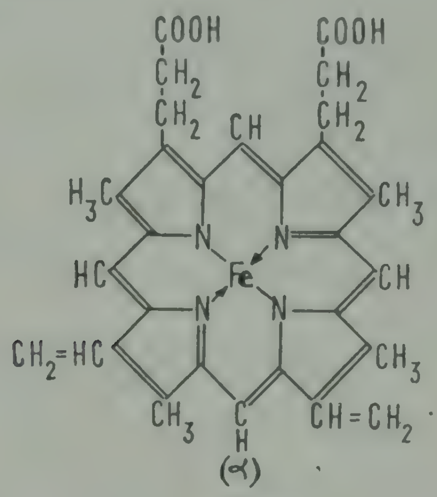
Derivatives of hæmatoporphyrin called uroporphyrins and coproporphyrins are found in urine and fæces respectively. They may belong to series I or III.

The relations of the chief simple porphyrins may be roughly shown as follows, designating the porphoryl group as Por :—

Protoporphyrin	Por : H_2
Uroporphyrin	Por : $(COOH)_6 . H_2$
Coproporphyrin	Por : $(COOH)_2H_6$

HÆMES. The porphyrins exist in various metallic derivatives called *metallo-porphyrins ;* those with iron form the group called *hæmes*, of which hæmatin and its derivatives are examples ; all the porphyrins form the corresponding ferri-porphyrins when treated with ferric chloride and sodium acetate. Thus protoporphyrin gives hæmatin.

The following is a suggested formula for hæm, the ferro-porphyrin group of hæmoglobin



Hæm.

Of the iron porphyrins there are two series, according to whether the iron is ferrous, or ferric :—

Ferro-porphyrins—	
Reduced hæmatin (hæm)	Por : Fe$^{\cdot\cdot}$
Reduced hæmoglobin	(Globin) (Por : Fe$^{\cdot\cdot}$)
Oxyhæmoglobin	(Globin) (Por : Fe$^{\cdot\cdot}$)O_2
Hæmochromogen	(Denatured globin) (Por : Fe$^{\cdot\cdot}$)
Ferri-porphyrins—	
Hæmatin	Por : Fe$^{\cdot\cdot\cdot}$OH
Hæmin	Por : Fe$^{\cdot\cdot\cdot}$Cl
Methæmoglobin	(Globin) (Por : Fe$^{\cdot\cdot\cdot}$OH)
Cyanhæmoglobin	(Globin) (Por : Fe$^{\cdot\cdot\cdot}$CN)

The power of loosely combining with O_2, CO and NO is confined to the ferrous compounds. Cyanhæmoglobin is, on the other hand, a CN derivative of a ferric compound, *e.g.* of methæmoglobin and is not formed by addition of HCN to oxyhæmoglobin.

Metallo-porphyrins containing metals other than iron are also known to occur naturally, *e.g.* turacin, a feather pigment containing copper ; and compounds containing cobalt, nickel, zinc, etc., have been artificially prepared. Again, iron porphyrins in which the porphyrin part is different, *e.g.* the respiratory pigment chlorocruorin, found in certain worms, have also been subjected to study.

The Synthesis of the Blood Pigments. Many of the porphyrins can be made synthetically, and H. Fischer and his pupils succeeded in synthesising hæmatoporphyrin, hæmatin and hæmin. Given hæmatoporphyrin, moreover, Laidlaw * showed that the iron could easily be introduced by adding ferrous sulphate and ammonia : in the presence of hydrazine hydrate hæmochromogen was formed, and from this hæmatin.

Laidlaw also succeeded in synthesising turacin, by treating hæmatoporphyrin with ammoniacal copper solution, showing that it is a compound corresponding to hæmatin, in which the place of iron is taken by copper.

The combination of globin and hæmatin to form hæmoglobin was effected by R. Hill and Holden.† They prepared globin from oxyhæmoglobin without denaturation, as described above ; the globin after purification was mixed with hæmatin in sodium carbonate, when methæmoglobin resulted. This on reduction gave reduced hæmoglobin, which on shaking with air gave oxyhæmoglobin, recognisable by its absorption spectrum. If denatured globin is employed, hæmochromogen is formed instead of methæmoglobin.

THE LIFE-HISTORY OF THE RED BLOOD CORPUSCLES

Before Birth. At a very early stage of development there arises from the mesoderm in various situations the primitive connective tissue, or *mesenchyme*, and it is in this tissue, or from its direct descendants, that both blood cells and vessels are developed.

The first appearance of blood cells is in mesenchyme tissue situated outside the embryo itself, in the *area opaca* of the yolk sac, and in the amnion and chorion. Here are formed the blood islands, groups of cells in which the peripheral mesenchyme cells form the endothelium of the vessels, an intercellular fluid, the plasma, and the more centrally placed cells, the *primitive blood cells*, all of which latter are nucleated cells which closely resemble the parent mesenchyme cells. In man the earliest vessels appear in this way on the undersurface of the yolk sac and gradually extend over its surface, finally establishing connection with the similar vessels of the chorion. By the third week communication has been established between this system and another system of vessels, namely the blood vessels and heart of the embryo itself. The vessels of the embryo are likewise developed from the mesenchyme, but with the difference that in these vessels the differentiation of the mesenchyme is into *endothelium* and plasma only, with practically no primitive blood cells. The first blood cells of the embryonic circulation, therefore, represent an invasion of primitive blood cells from the yolk sac vessels into the vascular system of the embryo, when connection has been established between the two systems.

The primitive blood cells undergo further differentiation, and from them are derived cells called *hæmocytoblasts*. These cells are the primitive stem cells from which, according to some authorities, all the cells of the blood are ultimately derived. In the formation of the red cells, these cells are converted into the immediate precursors, called *erythroblasts*, and these, by the formation of hæmoglobin, into the fully formed red cells (Fig. 333).

At later stages of fœtal life, erythrocytes are produced, not only in the bone marrow, but also in the liver, spleen and lymph nodes.

Origin after Birth. In the fœtus the cells reach the circulation in an immature form and are nucleated, but soon after birth all the corpuscles are of the non-nucleated type. They are now formed, normally, only in the red marrow of the bones, and can be shown to be derived from nucleated erythroblasts by a process of degeneration and solution of the nucleus. We have definite proof that a continual formation of red corpuscles is proceeding throughout the whole of adult life. In an adult the total number of corpuscles remains approximately constant. By bleeding an animal we can diminish the total amount of corpuscles. The first effect of such a bleeding is that the fluid parts of the blood are made up, so that the volume of the blood is restored to normal and the blood therefore becomes relatively poor in corpuscles. In a few weeks, however, the corpuscular content of the blood is found to be once more normal, showing that the loss of corpuscles has been followed by a compensatory regeneration. The fact that the pigments constantly leaving the body with the urine and fæces, namely, urobilin and stercobilin, are derived from bilirubin, which arises from hæmoglobin, indicates that constant destruction of red blood cells must be proceeding. Since the number of corpuscles remains unaltered, this loss must be made good by a continual regeneration of fresh red corpuscles.

That the marrow is involved in the process is shown by the fact that it is the only tissue of the body which undergoes an alteration in appearance when blood formation is reduced by starvation, or stimulated by such means as repeated bleeding or by destruction of corpuscles by the injection of toxic agents. In adult animals there may be three forms of bone marrow, yellow, gelatinous and red. By starvation, especially in birds, the amount of yellow marrow is increased, at the expense of the red; when the animal is fed again the yellow marrow is changed first to the gelatinous and then to the red form. In the yellow marrow there is an abundance of fat cells, and the blood-forming tissue is small in amount, and dormant. In adult mammals, the yellow marrow normally occupies the shafts of the long bones, and the red marrow the cancellous spaces in such bones as the vertebræ, ribs and epiphyses. After extensive blood destruction, the red marrow is found to have increased in extent and in many cases to have invaded the greater part of the shaft of the bone, taking the place of the yellow marrow. It is in the red marrow, therefore, that we must seek the precursors of the red blood corpuscles.

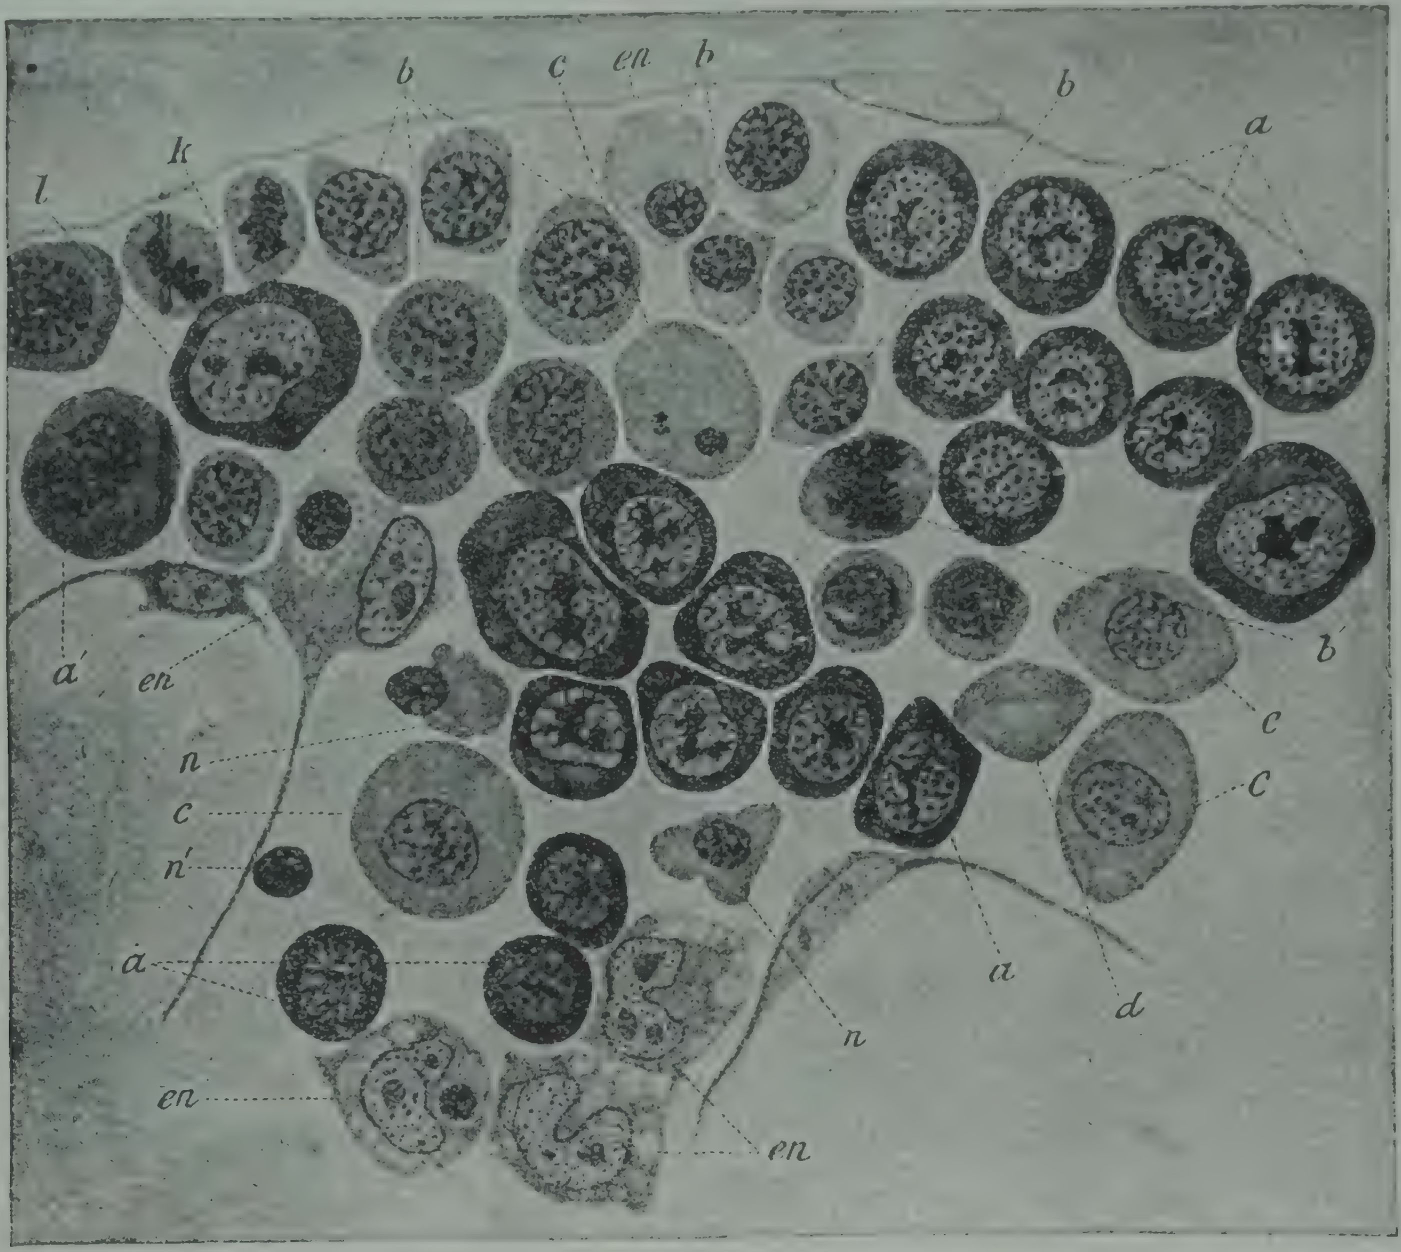

FIG. 333. Part of a blood vessel from the yolk sac of a rabbit embryo, showing the changes which occur in the formation of erythrocytes. (From SCHAFER after MAXIMOW.)

a. Megaloblasts.
b. Normoblasts, changing into erythrocytes.
c. Erythroblasts, in which the nuclei are dividing.
d. An erythrocyte fully formed, but not yet disc-shaped.
en. Phagocytic endothelial cells.

The blood vessels in the bone marrow are quite entire,* *i.e.* completely lined by endothelium, and consist, in addition to arteries and veins, of a very rich plexus of sinusoids. But it is a fact of great importance that not all of these sinusoids are open at any one time, many of them being collapsed and admitting no passage of corpuscles through them. This is particularly evident in the gelatinous marrow.

---

* DRINKER, DRINKER and LUND. *Amer. J. Physiol.*, 1922, **62**, 1.

The changes concerned in red-cell formation are most easily studied in birds in which the process has been checked by starvation. If such an animal is fed, it is found that many of the sinusoids become shut off as soon as blood formation commences, and it is in these closed vessels that the process of formation of the red cells occurs (Fig. 334); as soon as it is complete, the sinusoids open up, and the new cells are swept into the circulation.

The red cells are formed from the endothelial cells of the closed sinusoid; these swell and divide and become so-called *megaloblasts*. These then become *erythroblasts* and then *reticulocytes* by change and loss of the nucleus, and end by becoming *erythrocytes*. In the process of maturation, hæmoglobin is formed, probably at the expense of the nucleus, which, however, is still retained in the erythrocytes of ovipara.

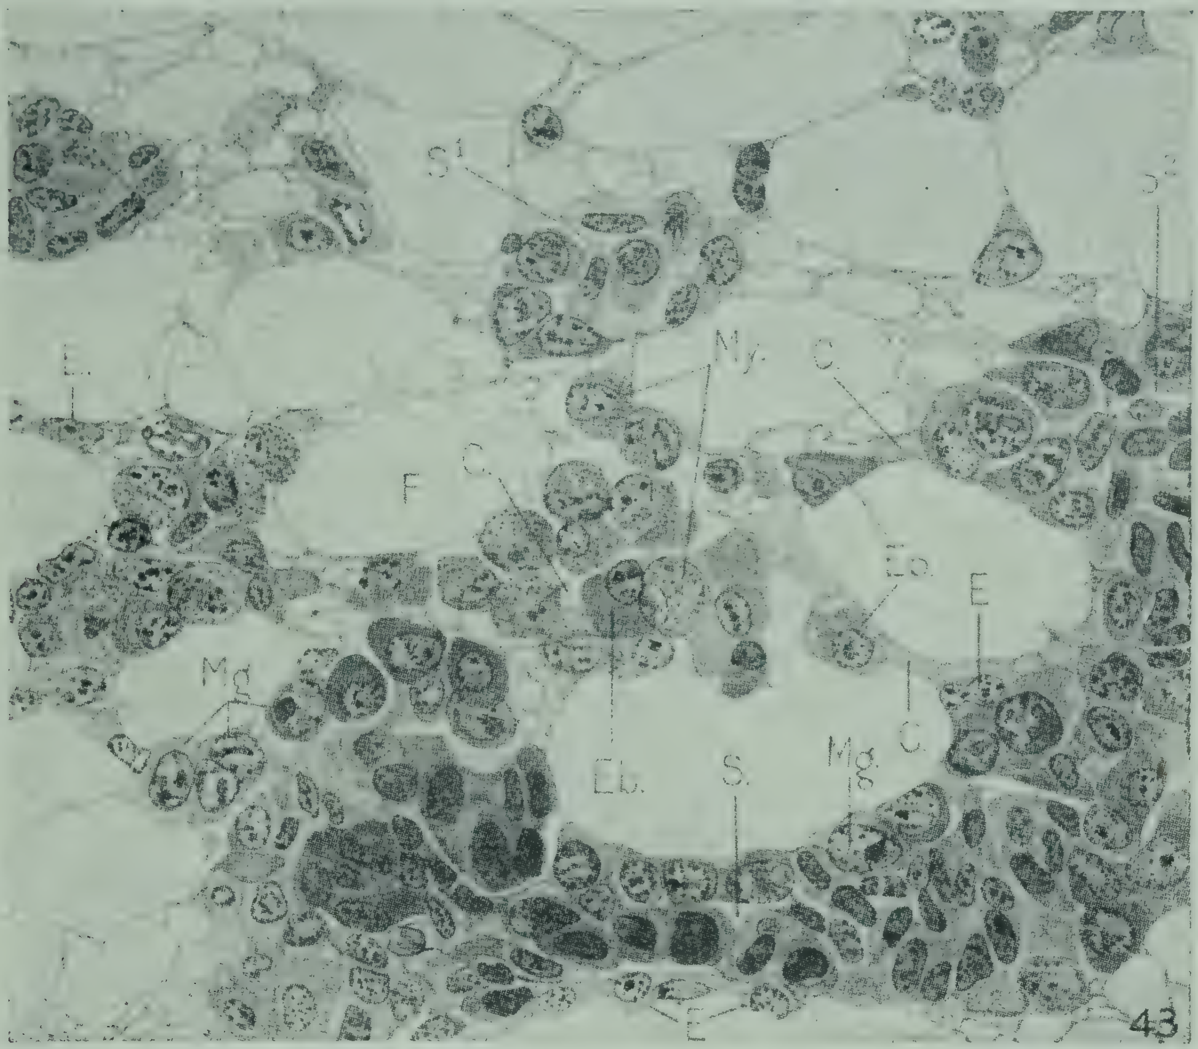

FIG. 334. Section of bone marrow of pigeon showing regeneration of red cells. Three sinuses, S, S^1, S^2, are seen filled with developing red cells. Along the inner wall are cells of the earlier phases—megaloblasts and early erythroblasts: note the difference in the depth of shade of cytoplasm as the hæmoglobin develops; in the centre of the sinuses are the older erythroblasts. In the middle of the field is a group of young myelocytes, *outside* a capillary, within which is a single erythroblast. Towards the right this capillary branches into two vessels, each containing a single erythroblast: one branch joins the sinus S^1, and the other joins sinus S^2.

C, capillary; E, endothelial cell; Eb, erythroblast; F, fat-cell; Mg, megaloblast; My, myelocytes; S, S^1, S^2, sinuses. (DOAN, CUNNINGHAM and SABIN. *Contrib.* to *Embryol.*, 1925, **83**, 165.)

In mammals the process is very similar, except that *megaloblasts* are not normally seen. The *erythroblasts* are often to be seen in process of division, and the nucleated daughter-cells appear to undergo a process of karyolysis, the nucleus slowly disappearing, sometimes with preliminary fragmentation, as the hæmoglobin increases in the developing cell. When blood formation is quickened as the result of previous destruction or loss, some immature and still nucleated blood discs may make their way into the circulation and be found in the blood, where they are spoken of as *normoblasts*. Other young, though non-nucleated, cells (*reticulocytes*) can also be distinguished by the fact that they stain with cresyl blue, while the older erythrocytes do not. In the blood of normal adults only about 1 per cent. of the red cells are reticulocytes. It takes about seven days for the passage from megaloblast to reticulocyte, and a further two days for conversion to the erythrocyte.

Examination of the bone marrow in the human subject (marrow biopsy) is carried out by puncture of the sternum and making a smear preparation of the extracted marrow.[*]

In various pathological states erythrocyte formation may, as in the fœtus, occur in liver, spleen or lymphatic tissue, as well as in the marrow: this is called extramedullary blood production.

Conditions for Red Cell Formation. The fact that the rate of formation of new red cells keeps pace with the rate of their destruction, indicates that there must be some stimulus which acts appropriately on the red marrow. The stimulus is more effective in the presence, or else is supplemented by the prevalence, of low oxygen pressures and *vice versâ*. Hence, the blood of animals exposed to atmospheres deficient in oxygen soon contains more corpuscles than when the animals breathe ordinary air, while in animals breathing oxygen-rich air the corpuscles are reduced in number.[†] Alternatively, increase of CO_2 in the blood, or of H-ion concentration, may be the effective stimulus.

Some factor is also necessary to promote maturation. We do not know its exact nature, but it is certainly in part of a chemical nature and emanates from the liver. Minot and Murphy[‡] discovered that feeding with raw liver has a most beneficial effect in pernicious anæmia, in which, in spite of great hypertrophy of the red marrow, conversion of megaloblasts to erythroblasts is deficient, and extracts of liver having the same effect can be prepared.[§] The administration is followed in four days by a sudden increase in the reticulocytes, which reach a maximum at about the eighth day. The active compound is called the *hæmopoietic factor*. A similar substance *ventriculin* has been prepared from hog's stomach, and there are indications that the substance in fact always originates in the stomach from which it is carried to, and stored in, the liver. The origin of the substance in the stomach has been supposed to be from a thermostable *extrinsic factor* soluble in 80 per cent. alcohol, present in certain foods, *e.g.* meat, yeast, and a thermolabile *intrinsic factor* (hæmopoietin), possibly an enzyme, formed in the stomach itself.[||] It has been suggested that folic acid, or a derivative of it, may be the extrinsic factor (Ch. XLII), but the nature of the factor is a complex question not yet capable of a final answer.[¶] In pernicious anæmia the intrinsic factor is lacking. It is a significant fact that pernicious anæmia is always associated with diminished gastric juice formation, achlorhydria and atrophic gastric mucosa.

The problem of the hæmopoietic factor was brought to a fresh focus by the extraction from proteolysed liver of a deep red substance having prodigious activity,[**][††] the maintenance dose being of the order of 1 to 2 μg daily. The compound has a molecular weight of about 1,500 and contains 4 per cent. of cobalt[‡‡]—an element previously shown to be essential for normal hæmopoiesis in some species.

Iron is, of course, essential for new red cell formation, and an iron protein complex, *ferritin*, plays a part in the absorption, transport and storage of iron.[§§] In rats this is more efficiently carried out if traces of copper are also present in the diet.[||||] The copper accelerates the conversion of assimilated iron into hæmoglobin.* Copper is present in the blood in organic combination with protein.† Riboflavin also accelerates hæmoglobin production: the protoporphyrin fraction of hæmoglobin is largely derived from glycine and acetic acid‡, and so can be synthesised in the body.

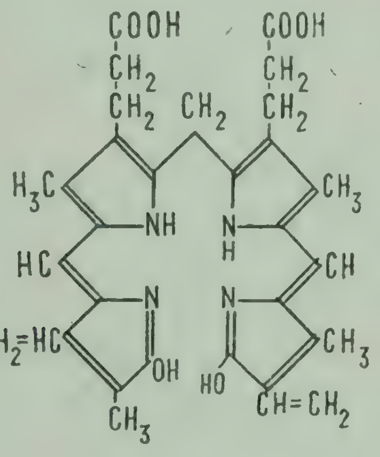
Destruction of Red Cells. How long a corpuscle continues to exist in the circulating blood has been variously estimated, but feeding experiments with glycine labelled with N^{15} point to a life-span of about 127 days.‡ Sooner or later, however, every corpuscle undergoes disintegration, a process generally ushered in by the ingestion of the corpuscle by some phagocyte cell. Thus, in the hæmolymph glands and in the spleen, we find large reticulo-endothelial cells which have englobed red corpuscles and in which we can recognise pigment granules derived from their destruction; this process of destruction of red cells by macrophage cells has been seen to occur in tissue cultures under the microscope.§ The chief places of disintegration are certainly the liver and spleen, and in these organs the hæmoglobin is converted first into the bile pigment biliverdin and then into bilirubin, which is then excreted by the liver. The liver cells proper do not form bilirubin, but merely excrete the bilirubin which is formed in the various cells of the reticulo-endothelial system. Any methæmoglobin, however, is not so converted, but may be in part changed to coproporphyrin III.

A probable structural formula for bilirubin is:—



Bilirubin

In addition to removal of the globin from Hb, it will be seen, by comparison with the formula of hæm (p. 516), that the ring has been opened by oxidation at the α-position, the CH group at γ reduced, and, most important of all, the iron removed from within the molecule. These changes are probably effected in stages || and can be demonstrated *in vitro*. The opening-up probably comes first and may occur while the ferroporphyrin part is still attached as a prosthetic group to the globin, or to a denatured globin. It results from the coupled oxidation, by free oxygen, of hæmoglobin or (more easily) of hæmochromogen and of oxidisable substances, such as ascorbic acid or glutathione, and leads to the formation of a variety of green compounds, known as choleglobins, cholehæmochromogens, verdohæmochromogens, etc.

Since hæmochromogens are most easily oxidised in this way, yielding cholehæmochromogens, it has been suggested that one function of the reticulo-endothelial cells is to denature the globin part of the Hb molecule, so forming hæmochromogens, which then are oxidised to cholehæmochromogens. Verdohæmochromogen is a simpler analogue derived from pyridinehæmochromogen.¶

From compounds of the verdohæmochromogen type the iron is readily

The iron remains in combination in the cells of the liver, spleen, etc., in the form of brown granules of a substance called *hæmosiderin*. This contains about 17 per cent. of iron, probably as a colloidal ferric oxide adsorbed on an organic substratum.* It is probably re-utilised for the formation of fresh hæmoglobin in the bone marrow. A section of normal liver immersed in potassium ferrocyanide and then in acid alcohol shows the presence of iron by blue granules in the liver cells. The amount of iron which can be demonstrated in the liver in this way is enormously increased in any condition which augments the rate of blood destruction, *e.g.* in pernicious anæmia or by the action of poisons which cause extensive hæmolysis.

Reduction of biliverdin to bilirubin is probably effected by enzymes, *e.g.* lactic dehydrogenase, and is correlated with carbohydrate metabolism ; in individuals or species with low liver glycogen biliverdin is excreted as such.

The formation of bile pigment *via* cholehæmochromogens may possibly occur under certain conditions in the blood itself, though its principal seat is in the cells of the reticulo-endothelial system.

---

* Cook. *J. Biol. Chem.*, 1929, **82**, 595.

That the liver is by no means the sole seat of bile pigment formation is shown by the results of experiments by Whipple, F. C. Mann and their colleagues. The latter find that the liver can be completely removed from dogs, provided sufficient glucose is given to prevent the occurrence of hypoglycæmic symptoms ; ten hours or less after removal of the liver definite jaundice develops, and the urine, blood plasma and adipose tissue are stained with bilirubin. The jaundice is increased if hæmolysed blood is injected.

When hæmoglobin is set free into the circulation by hæmolysis, or is injected, it is removed in three ways ; by excretion in the urine, by absorption by reticulo-endothelial cells, to form bilirubin and hæmosiderin, and by breakdown in the blood stream forming methæmalbumin, an analogue of methæmoglobin.* This is eliminated by the liver and finds its way into the fæces as coproporphyrin III.

Bilirubin is present in small amount (0·15 mg./100 c.c.) in normal blood plasma in some species, including man, but in jaundice the amount is largely increased. Its presence can be demonstrated spectroscopically, or by the *van den Bergh reaction.* In this test, the serum is precipitated with alcohol and the filtrate added to a freshly prepared mixture of sulphanilic acid, hydrochloric acid and sodium nitrite, when a violet-red colour is produced.

THE WHITE BLOOD CORPUSCLES

These number usually about 9,000/c.mm., and are of various kinds, some of which exhibit amœboid movements. Ehrlich showed that some corpuscles contained granules which were stained by acid dyes such as eosin, and these corpuscles he called *eosinophile.* Others, the *basophile* cells, were stainable with basic dyes, while a third type were only lightly stainable, and were called *neutrophile* leucocytes. The white corpuscles are classified as shown (Fig. 335), the figures expressing the average results of what is called a *differential cell count.* This shows, out of a total of 100 white cells :

(1) Granulocytes.
  (*a*) Neutrophile. Approximate average, 68 to 70 per cent.
  (*b*) Eosinophile. Average, 3 per cent.
  (*c*) Basophile (mast cells). Average, 0·5 per cent.

(2) Monocytes.
  (*a*) Large mononuclears. } Average, 4 per cent.
  (*b*) Transitional. }

(3) Lymphocytes. Average, 23 to 25 per cent.

The various white cells have the following characters :

(1) Granulocytes. (*a*) *The Neutrophile Cells,* or *polymorphonuclear leucocytes.* These present a lobed nucleus and their protoplasm contains abundant fine neutrophile granules

---

* Fairley. *B.M.J.*, 1940, *ii.*, 213.

which stain with Ehrlich's triacid and with the May-Giemsa stains. The cytoplasm contains proteolytic enzymes capable of causing autolysis (hence the liquefaction of pus on standing). These cells are actively amœboid and phagocytic, and their numbers rapidly increase in pyogenic infections, in which they form pus cells.

(*b*) *The Eosinophile Cells.* The nucleus is generally single, but is often crescent-shaped or reniform. The protoplasm is crammed with large, discrete, highly refractive granules, which stain deeply with eosin and give micro-chemical reactions for iron as well as phosphorus. A large fraction of the histamine of the blood is present in these cells.* The eosinophile cells are not normally phagocytic.

(*c*) *The Basophile* (*or Mast*) *Cells.* These, which are somewhat smaller than the polymorphonuclear cells, have a lobed or tri-lobed nucleus and present in their protoplasm a number of granules which stain deeply with basic dyes. In normal blood the basophile cells are rare, though they appear, sometimes in large numbers, in disease, and are normally present in the blood of some of the lower animals.

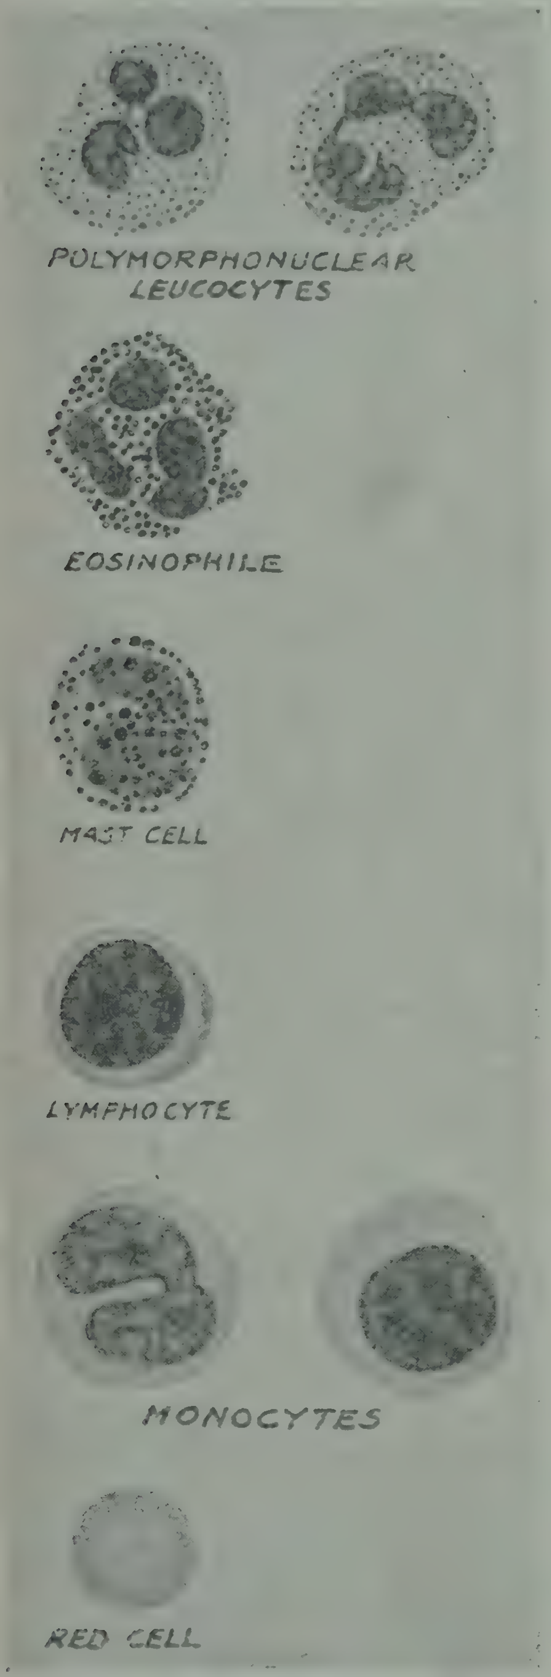

Fig. 335. Various forms of Blood Corpuscles.

(2) Monocytes. These are large vacuolated cells with a single nucleus, and with fairly abundant faintly granular cytoplasm. The large mononuclears are rare cells in normal blood, but they are of considerable importance. They have the property of ingesting foreign particles of almost any sort, and for this reason are able to take up certain intravitam dyes, such as pyrrol or trypan blue, or granules of Indian ink or carmine.

The *transitional cells* are more numerous, as a rule, than the large mononuclears, forming about 4 per cent. of the total whites. Their general structure resembles that of the monocytes, but they are smaller. Their nucleus is indented or slightly lobed, and the cytoplasm has fine granules which stain with azur.

(3) Lymphocytes. These abundant cells, smaller than the other mononucleated white cells, and of more uniform diameter (about 8 μ), have a round nucleus and only a small amount of cytoplasm, which has very few granules, but such as it has are coarse and stain with azur.

The total white count is high in infants and during pregnancy.

The errors incidental to both total white and differential counts are considerable, but after due allowance has been made for them, surprisingly large and rapid fluctuations in the leucocyte count and differential are demonstrable. Such rapid alterations are due, not to altered rates of formation and destruction, but to altered distribution within the circulation. In the smallest veins, and in wide capillaries, neutrophiles dawdle in the peripheral stream, particularly when the flow is slowed down, and, similarly, lymphocytes tend to lag in the lymphatic system. Any circumstance which alters the circulatory conditions is therefore liable to accentuate or diminish these tendencies; hence, exercise causes an increase in the total count, with an altered differential picture: if carried to the point of fatigue the total count may show a 300 per cent. increase on the resting figure.

Formation of the Leucocytes. The white cells are continually being lost and replaced. The normal life of a leucocyte is variously estimated at four days or upwards, but many die prematurely. The question as to the origin of each kind of leucocyte cannot be regarded as settled. According to Maximow and others, all the cells, red and white, are derived from one kind of cell called a *hæmocytoblast.* This opinion seems now to be losing ground, in favour of the view of Sabin, according to which erythrocytes and macrophages are of endothelial origin, while the granulocytes, lymphocytes and monocytes arise from a common parent cell. This parent, or *reticular cell* is converted to a *primitive white cell*, examples of which are found in lymph glands, spleen and bone marrow. The subsequent history of these cells differs according to their situation, the two chief sites being lymph gland and marrow.

---

* Code. *J. Physiol.*, 1937, **90**, 349, 485.

Lymphocytes are derived from the reticular cells of the lymphatic glands and the lymph nodules surrounding mucous cavities. These lymphatic nodules present towards their centre a clearer zone, consisting of lymphoblasts. By the division of these cells lymphocytes are formed, pushing towards the periphery of the nodule, where they make their way into the lymph sinus and are carried in large numbers (200 million hourly in the dog) by the lymph into the blood. Where they then go, or what their fate may be, is unknown.

In the red bone marrow granulocytes originate, outside the blood vessels, from the primitive white cells, which may be seen to be formed in abundance from the reticular cells during the gelatinous phase of the marrow. From these, *myeloblasts*, and then *myelocytes* of various types are formed, and divide actively, forming groups of cells. These contain a single rounded nucleus and a well-marked protoplasm which may contain granules, generally eosinophile in character, but sometimes basophile. All intermediate states are to be found in the bone marrow between these myelocytes and the polymorphonuclear and eosinophile leucocytes. When mature, the granulocytes pass through the walls of the sinusoids into the blood stream. In leukæmia there may be myeloblasts in the blood as well as an increase either of eosinophile cells or of neutrophile cells, and either condition is associated with changes in the red bone marrow.

The monocytes are principally formed from reticular cells in the lymph glands and spleen, though exceptionally they, and also lymphocytes, may arise in the marrow. In certain abnormal states, clasmatocytes may also be present in the blood. We may therefore provisionally arrange the leucocytes of the blood according to their origin as follows :

(1) Small lymphocytes derived from lymphoid tissue.

(2) Monocytes, formed in the lymph glands and spleen, or exceptionally from reticulo-endothelial cells in other situations.

(3) Polymorphonuclear leucocytes formed in bone marrow.

(4) Eosinophile cells derived from similar cells in the bone marrow.

In certain diseases, the primitive white cells may develop along lines which are abnormal for the situation in which they occur ; thus myeloblasts may appear in the spleen, or even in lymph glands, and monocytes in the marrow.

Functions of the Leucocytes. The polymorphonuclear leucocytes present two phenomena, that of amœboid movement and that of ingesting foreign particles by a process known as "phagocytosis." Many unicellular organisms and the undifferentiated cells of many kinds of tissue behave similarly. All the phenomena connected with the process of *inflammation* in higher animals are directed to the assemblage of polymorphonuclear leucocytes at the spot which is the seat of injury or of infection, so that they may devour and remove either the injured tissue or the invading micro-organisms. This process therefore plays an important part in determining the immunity of any animal against infection.

The Reticulo-endothelial System. In addition to the polymorphonuclear leucocytes, certain other cells have phagocytic properties. These are the monocytes of the blood, and certain widely dispersed tissue cells. All of these arise, like the blood cells, from the mesenchyme of the embryo. Of the mesenchyme cells, some become the *fibroblasts* of the connective tissues. A number, however, retain their embryonic developmental potentialities, and become converted into tissue histiocytes belonging to one of two types, called respectively the *free and the fixed histiocytes.* The *free histiocytes,* wandering cells, or macrophages, have phagocytic properties, and are to be found in the connective tissues. By a change in their granulation they may become the *mast cells,* familiar as inhabitants of the connective tissues. The *fixed histiocytes,* or "resting wandering" cells, are to be found in large numbers in the serous membranes, especially in the omentum, and also as histiocytes which have taken up the position of an endothelial lining. This scattered system of specialised "endothelial" cells is sometimes called the *reticulo-endothelial system.* Examples are the so-called "endothelial cells" which form the incomplete lining of the sinusoids of the liver and spleen. In the *liver* the cells are known as the *Kupffer* or stellate cells. This widely dispersed system comprises cells of very differing function, shape and appearance, but they all possses in common the property of ingesting foreign particles of varying grades of size. Even relatively coarsely particulate matter is taken up by these cells, *e.g.* by the Kupffer cells of the liver. Thus, if Indian ink or carmine is injected intravenously, granules of the pigment are to be found shortly afterwards in the Kupffer cells, and in the similar cells of the spleen and marrow, as well as in the polymorphonuclear leucocytes and monocytes of the blood stream. All foreign colloidal matter, including colloidal dyes, *e.g.* pyrrol blue, is also taken up by these cells.

Whenever any surplus or dead tissue has to be cleared away, whether as the result of injury or in the course of the metamorphosis of organs, *e.g.* the tail of the tadpole, the phagocytic cells of the tissues play an important part. In mammals, including man, the moulding of the long bones which occurs in the process of growth is effected by continual and coincidental processes of absorption and new formation of bone. The absorption is carried out by means of special phagocytes called osteoclasts.

The other functions, which have been ascribed to leucocytes, are all of them questionable. Thus some authors ascribe to leucocytes a significant part in the taking up of fat from the intestine and its carriage into the lymphatic system. In the coagulation of the blood, the leucocytes have been supposed to act by the discharge of substances which may be precursors of thrombin. The leucocytes and lymphocytes are also believed to play a part in the formation of anti-toxins.

THE BLOOD PLATELETS

In addition to red and white cells, appropriately fixed and stained blood films also present a number of granular bodies, most of which are about 2μ in diameter, and which tend to aggregate together in clumps. These are the platelets or thrombocytes. Their number usually ranges from 280,000 to 760,000 per cubic millimetre. Their shapes vary considerably. Their central part is more strongly refracting than the periphery and stains with basic dyes, but is not regarded as a nucleus (Figs. 336, 337).

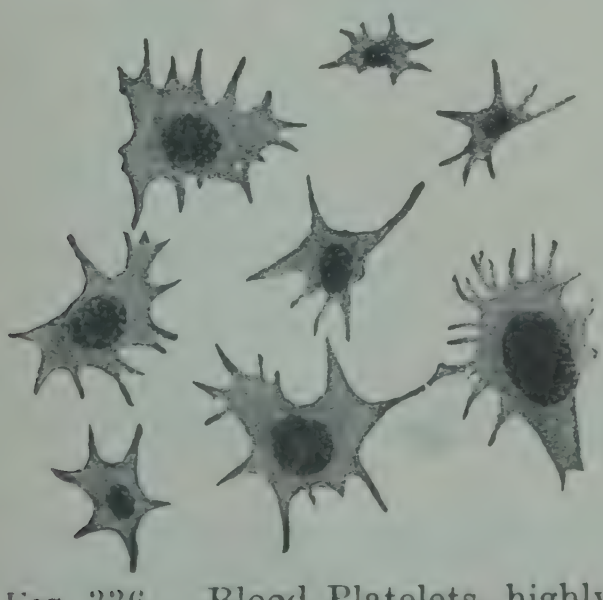

FIG. 336. Blood Platelets, highly magnified, showing the amœboid forms which they may assume. (After KOPSCH.)

Similar platelets are observed when the blood is received into normal salt solution; as the mixture clots, the filaments of fibrin can often be seen to radiate from a clump of disintegrated blood platelets as from a centre. They are enumerated by pricking the finger through a drop of 2·5 per cent. sodium citrate solution in normal saline. A drop is transferred, after further dilution with citrate-saline in marked vessels, to a slide, and the platelets and red cells counted in appropriate fields. From the ratio between the two, and a separate red cell determination, the number per cubic millimetre are calculated. If the blood of an animal be defibrinated and returned to the circulation, it will be found for the next few days to be quite free from blood platelets. Adrenaline injections raise the platelet count, and so does splenectomy, from which facts it may be inferred that depôts of platelets are lodged in the spleen. Most histologists regard the platelets as derived by fragmentation from the cytoplasm of the giant cells, or *megakaryocytes*, of the bone marrow or, as some say, of the lungs. Injection of pyridine appears to release showers of new and sticky platelets into the blood stream.*

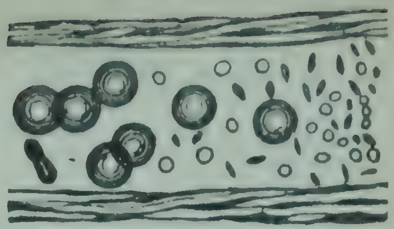

FIG. 337. Blood Corpuscles and Blood Platelets within a small Vein. (SCHAFER after OSLER.)

THE COAGULATION OF THE BLOOD

The subject of blood coagulation presents so many aspects on which there is disagreement that it will be necessary here to deal chiefly with what appear to be facts, and, since no other course is consistent both with brevity and with clarity, to treat the theory in a brief and dogmatic manner. The particular theory which will, for this purpose, be upheld, is that originally due to Morawitz.†

In the process of coagulation, while the red and white corpuscles remain almost or quite intact, the plasma becomes solid from the production in it of a network of fibrin. The coagulation takes place most rapidly at body temperature and is greatly slowed by cold. There are many patterns of coagulometer by which the clotting time can be measured,‡ or graphically recorded.§ Under constant conditions the time is constant for any individual. Under the ultramicroscope, the fibrin is seen to have a crystalline structure.‖ The question of coagulation involves the consideration of the precursor of fibrin and of the conditions which determine its conversion into fibrin.

It will be clearer if the theory is outlined to begin with. The factors in the blood which are concerned with clotting are, fibrinogen, prothrombin, platelets and calcium ions. Briefly, the precursor of fibrin which is present in the fresh plasma is the protein *fibrinogen*. It is converted into fibrin through the agency of an enzyme-like substance called *thrombin*, which is formed in the shed blood from a precursor called *prothrombin ;* prothrombin exists in the normal plasma. The prothrombin is converted into thrombin by an activator, *thromboplastin* (or *thrombokinase*) ; thromboplastin alone only slowly activates prothrombin, but in presence of calcium salts the activation is rapid. Thromboplastin is not present in circulating blood, but is formed from many kinds of tissue when these are damaged, and, among others, from the blood platelets. Hence, normal blood contains all the factors for clotting—platelets which form thromboplastin ; and prothrombin, which this activates in presence of the calcium salts, thus forming thrombin. The thrombin converts the fibrinogen into fibrin.

According to this theory, then, the prime mover in the series of changes terminating in coagulation is thromboplastin. We may now consider some of the facts.

Methods of Preventing Coagulation. It is evidently impossible directly to arrive at any conclusions during the few minutes which elapse before the appearance of the clot. By retarding coagulation we can obtain a cell-free plasma by centrifugalisation, after which the clear supernatant plasma can be drawn off and its coagulation studied.

(1) Normal blood in contact with the normal uninjured vessel intima remains fluid. If a vein be tied in two places and excised, the blood contained between the ligatures will remain fluid, sometimes for days. On bringing it into contact with foreign substances, it undergoes coagulation.

§ STOKER. *J. Scientif. Inst.*, 1934, **11**, 315.

‖ HOWELL. *Amer. J. Physiol.*, 1914, **35**, 143.

(2) When an incision is made in the ordinary way into a blood vessel of a bird, the issuing blood clots very rapidly. But if the vessel be isolated and a perfectly clean glass cannula be inserted into it, blood drawn off into a clean sterilised beaker will remain unclotted for days.* It is very difficult to carry this out in the mammal.

(3) Clotting can be excited even in the living vein by introducing into the blood any foreign solid, *e.g.* a thread, which is wetted by the blood. If contact of shed blood with such substances be prevented by receiving it into vessels made of perspex, or of glass coated with a water-repellant layer, *e.g.*, paraffin, or with a monomolecular layer of *silicone*, and scrupulously free from dust, clotting may often be delayed for many hours.

(4) *Action of Cold.* If horses' blood, which always clots slowly, is cooled rapidly to between 0° C. and 1° C., it remains fluid for an indefinite time. The corpuscles sink, and the supernatant plasma can be decanted and even filtered.

(5) *Methods involving Mixture with Neutral Salts.* Blood is received into one-quarter its bulk of a 25 per cent. solution of magnesium sulphate, or into an equal volume of half-saturated sodium sulphate solution.

(6) *Methods depending on Decalcification of the Blood.* Oxalate plasma is obtained from blood received direct into a solution of sodium oxalate, so that the total blood contains 0·1 per cent. of the oxalate. Instead of oxalate we may use sodium fluoride (0·3 per cent.) or sodium citrate (0·35 per cent.).

(7) *Methods depending on the use of certain Substances of Animal or Plant Origin.* (*a*) *Peptone* plasma got from blood obtained by injecting rapidly into the veins of a dog or cat in a fasting condition a solution of commercial peptone in the dose of 0·1 g. per kg. of the animal. This causes a state of shock. On drawing blood immediately after the fall of blood-pressure has taken place, it is found to be incoagulable. The addition of peptone to blood *in vitro* does *not* inhibit clotting.

(*b*) *Leech Extract or Hirudin.* There is an anticoagulating substance in the buccal glands of the leech.† It will abolish the coagulability of the blood *in vitro*.

(*c*) *Heparin.* An anticoagulant substance, heparin, was first prepared from liver.‡ It is present also in muscle, lung, and various other tissues,§ and may be obtained as a powder, of which 1 mg. will prevent the coagulation, at 0° C., of from 100 to 500 c.c. of blood. At room temperature 1 mg. will inhibit coagulation of 10 to 20 c.c. of blood. A unit is 0·01 mg. of beef heparin.‖ (The activity varies with the species.) It acts equally well *in vivo* or *in vitro*. Chemically, heparin is a polysulphuric ester of mucoitin, a substance related to chondroitin. Mucoitin is a condensation compound of glucuronic acid and acetylated glucosamine.¶ Heparin is precipitated by protamine, and although either substance alone will prevent coagulation, the two together are ineffective.

(*d*) "*Dicoumarin*" present in spoiled sweet clover, when injected, or even when taken by mouth, causes reduction or loss of blood coagulability *after a few days*.

(8) *Methods depending on the use of Synthetic Organic Substances.* (*a*) *Chicago Blue*, 6B, injected intravenously or added to blood *in vitro* prevents coagulation.**

An even better, and less strongly coloured dye is *chlorazol fast pink*, B.K.S.††

(*b*) "Bayer 205" ("Germanin") ‡‡ or "Liquoid" (Roche), described as a sodium poly-anetholesulphonate,§§ injected intravenously also causes incoagulability.

Factors in Coagulation. By centrifugalisation of blood the coagulation of which has been delayed or prevented in any of these ways, we obtain blood plasma. The conditions which will bring about coagulation in such plasmata are strikingly diverse. Thus, in cooled plasma a rise in temperature is sufficient, though if the cooled plasma be filtered at 0° C. through a fine filter, it loses this spontaneous coagulability on warming. It can still be made to clot by the addition of certain substances, such as blood serum or the washings of a blood clot, and in some cases by the addition of tissue extracts. Oxalate plasma clots on addition of calcium salts.

Calcium Ions. We may take oxalate plasma as our type. It contains fibrinogen, prothrombin, a little thromboplastin, and an excess of oxalate. If calcium chloride be added in slight excess, and the plasma kept warm, it will clot. The place of calcium can be taken by strontium. Coagulation is also prevented by sodium fluoride, which precipitates calcium, and by sodium citrate, metaphosphate or pyrophosphate, which lead to the formation of a salt in which the calcium is in a complex anion. This shows that calcium must be present in the ionic form. The optimal $Ca^{\cdot\cdot}$ concentration is 5 mg./100 c.c., which is about that present in normal plasma, where about half the calcium is present in the ionic state. Calcium ions probably accelerate the activation of prothrombin by thromboplastin.*

FIBRINOGEN. Plasma contains a protein, *fibrinogen*, not present in the serum, and which is the precursor of fibrin. Fibrinogen is a globulin precipitated by half-saturation with sodium chloride; it coagulates between 56° and 60° C., whereas serum does not give any precipitate at 60° C. For coagulation experiments it is best made from acidified oxalated plasma by freezing and slowly thawing out, by which it is precipitated; it is then collected in cold saline and dissolved by warming.† The solution of fibrinogen thus purified is perfectly clear and colourless.

THROMBIN. If calcium chloride be added to a purified solution of fibrinogen, no clotting occurs; but the purified fibrinogen can still be made to clot by the addition of fresh serum, due to the presence of thrombin in the serum. The last change in the act of clotting is therefore the change from fibrinogen to fibrin by the intervention of thrombin. It cannot be at this stage of the process that the calcium salts exercise their influence, since thrombin will cause the coagulation of oxalate plasma. Thrombin is a protein substance, is usually regarded as an enzyme (probably proteolytic), and is active in minimal quantities. When in watery solution it is readily destroyed at 60° C.; up to 50° C., rise of temperature hastens its action. The speed with which clotting occurs in fibrinogen solutions or oxalate plasma is directly proportional to the thrombin concentration; hence dilution retards clotting. After formation of fibrin much thrombin is adsorbed on it.

Thrombin may be provisionally defined as an enzyme capable of producing clotting in calcium-free fibrinogen solutions. Accepting this definition, we can show that thrombin is absent from circulating blood. If blood be received direct from the vessels into absolute alcohol and the precipitate, after coagulation by alcohol, be extracted by water, the extract is found to contain no trace of thrombin. Nor is thrombin present in fresh oxalate plasma. But this contains the precursor of thrombin, a protein which is called *prothrombin*, together with traces of another substance essential for the formation from it of thrombin, namely *thromboplastin*. Thrombin is best prepared from prothrombin by the action of thromboplastin in presence of calcium ions. Hence, addition of calcium salts causes oxalate plasma to clot, and the serum formed is found to contain thrombin. In the early stages of coagulation, therefore, there is an actual formation of thrombin. A *crude* solution of fibrinogen treated with calcium chloride also rapidly clots. This is because it also contains both prothrombin and thromboplastin. Our next step must be to inquire into the precursors of thrombin and the conditions of its formation.

PROTHROMBIN is present in normal blood plasma. Controversy has centred round the methods for estimating the prothrombin content of the blood: essentially Quick's method depends on determining the clotting time of recalcified oxalate plasma to which excess of thromboplastin has been added. For man the time is about 12–13 seconds.

In the two-stage method ‡ oxalated plasma is first defibrinated by adding a small amount of thrombin and removing the clot. The serum is then treated with calcium chloride and thromboplastin to convert all its prothrombin to thrombin. The concentration of the latter is then determined by finding the dilution of the serum needed to coagulate a standard fibrinogen solution in 15 seconds. The total final dilution of original plasma represents the number of " units " of prothrombin per c.c. (normal = 300–400 units/c.c.).

The results of the two methods sometimes differ seriously, and one reason advanced for the discrepancy is that another factor is necessary for rapid conversion of prothrombin to thrombin. Quick called this "prothrombin-A" a labile factor not absorbed by alumina. Owren * calls it factor 5, and studied a clinical case in which prothrombin time was prolonged because this factor was lacking: addition of small amounts of normal plasma restored the prothrombin-time to normal. A somewhat similar new factor is described by Seegers as Ac-globulin. The matter is still not settled satisfactorily.

* MELLANBY and PRATT. *Proc. R. S.*, 1940, **128B**, 201.

† WARE *et al.* *Archiv. Biochem.*, 1947, **13**, 231.

‡ WARNER, BRINKHOUS and SMITH. *Amer. J. Physiol.*, 1936, **114**, 667.

The usual source of prothrombin is oxalated plasma. By an elaborate combination of isoelectric precipitation, adsorption on magnesium hydroxide, elution, dialysis, salt fractionation, etc. a pure preparation of prothrombin has been obtained † as a snow-white water-soluble glucoprotein. Pure prothrombin is not altered by calcium ions, but if thromboplastin is also present the prothrombin is converted into thrombin, the Ca ions acting as a catalyst.

For maximal speed of conversion a further factor of a catalytic character is requisite. This is one of the serum globulins, called the Ac-globulin,‡ and it is formed from a plasma Ac-globulin by the action on it of thrombin :—

(1) Prothrombin and Thromboplastin $\xrightarrow{(\text{Ca}^{\cdot\cdot})}$ Thrombin.

(2) Plasma Ac-globulin $\xrightarrow{(\text{Thrombin})}$ Serum Ac-globulin.

(3) Prothrombin and Thromboplastin $\xrightarrow[(\text{Serum Ac-globulin})]{(\text{Ca}^{\cdot\cdot})}$ Thrombin,

The blood of new-born infants is poor in prothrombin, as is also the blood in obstructive jaundice and in vitamin K lack. Administration of vitamin K, with bile salts, by mouth, restores clotting time of the blood to normal. It is therefore believed that the presence of vitamin K is essential to the formation of prothrombin, which is believed to be manufactured in the liver. When dicoumarin is administered, it competes with the vitamin K, and the plasma prothrombin falls, because the circulating prothrombin only has a life of two or three days, and new formation of prothrombin is suspended.

THROMBOPLASTIN. If oxalate plasma be cooled to 0° C. and centrifuged at high speed, a scanty granular precipitate is produced. This consists largely of *débris* from platelets. It is then found that the filtered plasma no longer clots on recalcification, although it still contains fibrinogen and prothrombin. But if the precipitate be treated with calcium chloride and the mixture added to the filtered plasma, the latter clots (although the precipitate freed from adherent contamination will not clot pure fibrinogen). We must conclude that the precipitate contains no thrombin, but will generate thrombin on treatment with prothrombin and calcium salts. It contains the activator, *thromboplastin* (sometimes called "*thrombokinase*").

Oxalate plasma, separated from the precipitate of platelets, can also be made to coagulate by the addition of calcium salts together with extracts of almost any animal tissues, and these therefore also contain thromboplastin. For use as thromboplastin it is usual to employ an extract made from fresh brain or lung §; placenta is also rich in it.‖ These extracts, even on admixture with calcium, are without effect on pure solutions of fibrinogen, since they contain no prothrombin. But if the thromboplastin be treated with prothrombin solution and calcium salts, the mixture when added to fibrinogen causes speedy clotting.

Citrated or oxalated blood can also be caused to clot by the addition of trypsin, and by certain proteolytic snake venoms, which seem to act as thromboplastin. It may indeed be that the thromboplastin-Ca complex is of the nature of a proteolytic enzyme.* The Russell viper venom is a convenient source of thromboplastin for estimations of prothrombin.†

‖ SCHNEIDER. *Amer. J. Physiol.*, 1947, **149**, 123.

It was shown by Howell that the phosphatid *cephalin* is an essential constituent of thromboplastin, in which it probably occurs in association with a protein. Similar substances are present in nearly all tissues, and are set free when the cells are injured. Separation of the blood platelets by cooling and filtration abolishes the spontaneous coagulability of any form of plasma by removing the source of thromboplastin.

Later work has suggested that there are factors related to thromboplastin in the globulin fraction of normal plasma, and that it may be such factors, "plasma-thromboplastins", associated with platelets that normally initiate clotting. Probably both are needed.

Sequence of Changes. Thus far practically all workers on the subject are agreed. Coagulation of the blood is due finally to the interaction of thrombin and fibrinogen. Fibrinogen and prothrombin are present as such in the circulating plasma. Thrombin is not free in the circulating blood, but is produced or liberated after the blood has been shed. For the production of thrombin from prothrombin the presence of thromboplastin and of calcium ions is necessary.

It is therefore concluded that when blood leaves the vessels there is a disintegration of the blood platelets, with the liberation of thromboplastin. This acts upon prothrombin in the presence of calcium ions and produces thrombin. By the intermediation of the thrombin, the fibrinogen present as a colloidal solution in the plasma is converted into a quasi-crystalline gel of fibrin. The changes occurring in shed blood and resulting in the production of a clot are therefore mainly concerned with the production of thrombin.

This view of the essential character of coagulation is borne out by observations on other forms of plasma, especially of that of birds' blood. This, when obtained with scrupulous cleanliness, so as to avoid any contamination with dust or with the tissues, remains permanently uncoagulable. In the plasma got by centrifuging the blood, no blood platelets are to be seen, and no precipitate is produced by exposure to a temperature of 0° C. We may say, therefore, that blood platelets with their contained thromboplastin have been removed from the plasma, and with them the property of spontaneous coagulability. Since it contains prothrombin as well as soluble calcium salts, it is only necessary to add thromboplastin, *i.e.* a tissue extract, in order to cause immediate clotting.

In every case the initiation of the act of clotting would seem to depend on the addition of thromboplastin to the plasma. In mammalian blood there is no appreciable disintegration of the red or white corpuscles when the blood leaves the vessels, and the first act in coagulation is probably the disintegration of the blood platelets, with the setting free of thromboplastin.

Clotting in Arrest of Hæmorrhage. The part played by the platelets in coagulation is of great importance in maintaining the integrity of the vascular system. If an injury be made to the wall of a blood-vessel which is kept under observation by the microscope, it will be seen that the blood, as it flows past the injured spot, deposits blood platelets on the site of the puncture. These aggregate to form a white thrombus as a plug closely adherent to the wall of the vessel, and effectively preventing any escape of its contents. The white thrombus is almost entirely composed of agglutinated platelets, held together by fibrin. The stickiness of platelets is increased after hæmorrhage or surgical trauma. Another important factor in hæmostasis is *clot retraction* or shrinkage : this also depends on the presence and numbers of platelets. Retraction will draw together and seal off the walls of cut vessels. Later, by the growth of the adjacent endothelial cells, the thrombus is organised and covered with a layer of endothelium continuous with the rest of the vessel. The same process occurs when any part of the lining membrane of a large vessel is injured or when the blood is brought into contact with foreign matter, *e.g.* if a glass or cellophane tube is inserted in the course of a blood-vessel ; if a fine scratch is made inside the tube, platelets congregate speedily in the scratch, and then spread beyond it. Thus, destruction of a patch of endothelium in a vein leads to the deposition of blood platelets over the patch, and the formation of a " white thrombus " adherent to the wall and tending to spread down stream.* Under healthy conditions the thrombus serves simply to cover the bare area in the wall of the vein, and is grown over later by endothelium, so restoring the integrity of the vessel wall. The formation of the white thrombi can be prevented by adequate slow injections of heparin (Best, *et al.*).

---

* EAGLE. *J. Gen. Phys.*, 1937, **20,** 543.

† FULLERTON. *Lancet,* 1940, *ii,* 195.

An important factor in the arrest of hæmorrhage is the increased coagulability of the blood, which clots more rapidly after a considerable fraction of the circulating blood has been withdrawn. Several causes contribute to this, but the most important is probably an increase in the fibrinogen content of the blood. We have seen that fibrinogen is manufactured in the liver, and it would appear that the rate at which the liver adds fibrinogen to the blood is accelerated after a large hæmorrhage. One factor in producing this effect is stated to be the presence of an increased amount of adrenaline in the circulating blood ; as soon as the arterial pressure begins to fall owing to loss of blood the suprarenals discharge adrenaline into the circulation, and this is said to accelerate the coagulation rate of the blood by an action on the liver.† If the liver is excluded from circulation the injection of adrenaline is without influence on the coagulability of the blood, and it also has no effect on it *in vitro.*

Why does Blood not Clot in the Vessels ? No theory of coagulation can be satisfactory which does not account for this. One factor, at any rate, must be the nature of the surfaces with which the blood comes in contact. Blood can for a time be prevented from clotting if it be kept from contact with any foreign substance which is wetted by it, as, for instance, when it is received into paraffined vessels. On the other hand, free contact with such substances hastens coagulation. One must therefore conclude that mere contact with a foreign body has a direct destructive action on the blood platelets. In birds, the platelets are more stable than in mammals, so that coagulation is held in abeyance if contamination with thromboplastin from the juices of damaged tissues is avoided. But birds' blood can be made to clot without the addition of tissue juice if, by violent whipping, or addition of water or chloroform, we destroy the formed elements, so leading to the liberation of their contained thromboplastin.

The modern tendency has, however, been to attribute the fluidity of blood in the vessels to the operation of an anti-coagulation factor, such as the presence of heparin, in the blood.

The blood contains an antithrombin, present in the albumin fraction. Hence thrombin, when incubated with serum or plasma, is partly inactivated. It is not clear what the function of this antithrombin may be ; one suggestion is that it neutralises the small amounts of thrombin formed in the circulating blood.

HEPARIN, when tried on pure constituents (prothrombin, fibrinogen, thrombin), *in vitro*, has no anticoagulant action : it neither inhibits the conversion of prothrombin to thrombin, nor neutralises thrombin or thromboplastin. Yet in blood it acts as a powerful anticoagulant, prevents the conversion of prothrombin into thrombin, and also acts as an antithrombin.‡ For the exercise of these properties, a co-factor, which appears to be a serum albumin fraction, is essential.

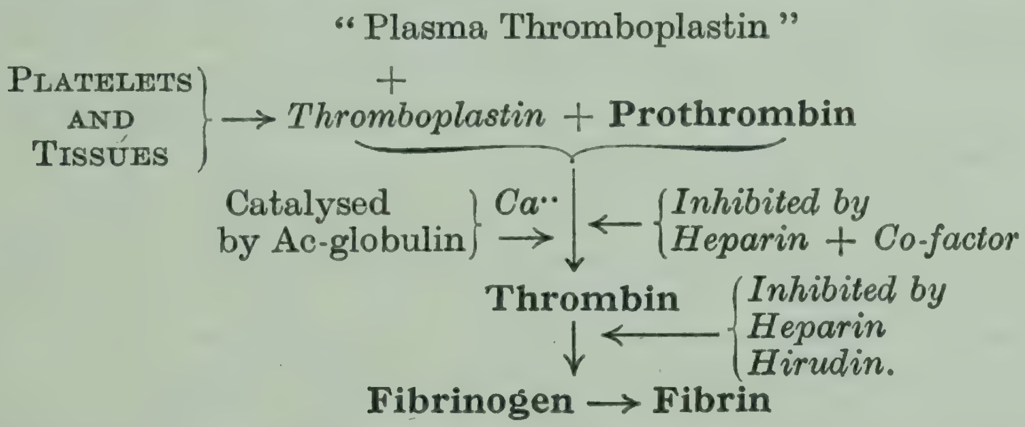
By reason of its sulphuric and carboxyl groups, heparin is a fairly strong acid, and combines with proteins to form salts, which are less dissociable the more basic the protein. Some such loose compound may be the real antagonist to the clotting changes in blood: it may even be that the normal blood antithrombin, which, like the co-factor, is an albumin, is the only inhibitor concerned, and that heparin catalytically accelerates its action, though not itself an anticoagulant.

It is doubtful whether heparin is present in normal blood, but there is good evidence that it is formed in the Ehrlich's mast cells, which are found abundantly along the course of many blood vessels. These cells contain granules which stain purple with toluidine blue, a dye that precipitates heparin, and the intima of blood vessels yields, on extraction, quantities of heparin, which are proportional to the abundance of the Ehrlich cells. Under certain conditions the heparin is rapidly poured out into the blood stream, *e.g.* when peptone or small amounts of thrombin or thromboplastin are injected intravenously. In these circumstances not only does no coagulation take place, but the blood obtained after the injection will not clot. Agglutination of platelets is also inhibited by heparin.

Heparin, if injected, is rapidly excreted in the urine, and destroyed in the tissues. Incoagulability *in vivo* can therefore only be maintained by continuous, or frequent, administration.

The following scheme summarises the occurrences in clotting:—



INTRAVASCULAR CLOTTING. Intravascular clotting can be produced by the intravenous injection of small amounts of thrombin: thus 1 mg. of the solid precipitated from the thrombin solution made by Mellanby's method, when quickly injected into the cat's circulation, causes extensive clotting of blood in the vessels and immediate death. Intravascular clotting is still more easily caused by the injection of thromboplastin, *e.g.* of normal saline extracts of tissues rich in cells, such as the thymus, lymph glands or testis.*

A curious result follows from injecting small amounts of these tissue extracts, or larger amounts very slowly. A minute quantity produces, not intravascular clotting, but a *delay* in the coagulation time. Repeated injections of small doses may absolutely annul the coagulability of the blood. The same double effect may be observed even with a larger dose. In rabbits, and in dogs after a full meal, the intravascular coagulation which occurs is complete, extending through the whole vascular system. If the injection be made into a fasting dog the thrombosis produced is limited to the portal vein. These two effects, namely the coagulation and the loss of coagulability, have been called the *positive* and *negative phases* respectively.

At least two different explanations have been given for the occurrence of the negative phase. Since it has not been observed *in vitro* it must be due to a reaction on the part of the living cells and probably to a secretion of heparin into the blood from the mast cells of the blood vessel walls, particularly in such organs as liver or lung. Another explanation has been suggested by Mellanby,† namely, that when small or slow injections of thromboplastin are given, intravascular coagulation actually does occur; the fibrin formed is, however, taken up by tissue cells or slowly deposited on the walls of the blood vessels, so that these are not obliterated; the blood then is really defibrinated blood, and so, of course, will not coagulate. Further evidence in support of this opinion has been given by the observation that slow injections of thrombin give exactly the same results * ; here also the slow injection causes slow continuous coagulation, but the fibrin so formed is safely deposited in places where it can do no harm. There is no reason why both these explanations may not be true in part.

---

* WOOLDRIDGE. "Chemistry of the Blood," 1893. (Kegan Paul, London.)

† MELLANBY. *J. Physiol.*, 1909, **38**, 474.

Fate of the Thrombin. The substances which interact for the production of thrombin and thrombin itself, are not entirely used up in the process of clotting. Blood serum contains traces of thrombokinase (which can be precipitated by the addition of dilute acetic acid) and prothrombin, as well as a fairly strong solution of thrombin. Thrombin, however, rapidly disappears from serum, which in two or three days may be almost free from it. It has been suggested that the thrombin undergoes a modification into an inactive form, called *metathrombin*. According to Rettger the disappearance of thrombin from serum is due to its combination with some of the proteins of the serum. This combination, like that of thrombin with fibrinogen to form fibrin, is unstable and can be broken up by the action of alkalies, acids, or by putrefaction.

We are now in a position to explain the behaviour of the various kinds of plasma.

Cooled Plasma contains the thromboplastin in the blood platelets. These can be separated by centrifuging at a low temperature, or by filtration. The remaining plasma contains only prothrombin, calcium salts and fibrinogen, and can be made to clot by the addition of tissue extracts or of thrombin, but not by warming.

In Sodium Sulphate Plasma the protein factors, or some of them, are precipitated. It is therefore sufficient merely to dilute the plasma in order to produce clotting.

Magnesium Sulphate Plasma if centrifuged while still warm will clot on simple dilution. If the blood be left for twenty-four hours before centrifuging, the plasma will not clot on dilution nor on addition of tissue extracts, because magnesium sulphate slowly precipitates the prothrombin and thrombin.

Sodium Fluoride Plasma might be expected to act like oxalate plasma, but fluoride also causes fixation of the blood platelets. If it be thoroughly centrifuged so that the plasma is obtained free from these constituents, it will no longer clot with calcium salts nor even with calcium salts *plus* tissue extracts, but will clot readily on addition of thrombin. Although it still contains a certain amount of prothrombin, this is adsorbed on the precipitate of calcium fluoride which is produced by the addition of calcium salts, so that the thromboplastin has nothing on which to exercise its effect. Sodium fluoride plasma is therefore useful as a test for the presence of thrombin. If water be added to the sodium fluoride blood, so as to destroy some of the formed elements and liberate their constituents into the plasma, it is possible to produce clotting by the simple addition of calcium salts.

Hirudin Plasma. Hirudin apparently combines with and neutralises thrombin. Hirudin plasma can therefore be made to clot by the addition of thrombin in sufficiently large quantities to over-neutralise all the hirudin.

Heparin Plasma remains fluid because the conversion of prothrombin to thrombin is inhibited. It clots on dilution, or on treatment with carbon dioxide. It also clots on addition of toluidine blue or protamine ; these basic substances withdraw the acidic heparin from its co-factor and precipitate it.

Dicoumarin Plasma is deficient in prothrombin, but not in the labile factor (Prothrombin A or factor 5).

Peptone Plasma. If blood be received into peptone blood, obtained by the injection of large doses of peptone into the veins of another animal, the mixture does not clot. This is because the peptone blood contains an excess of heparin, which can in fact be extracted from it.† It has been shown by Delezenne and others that the seat of its formation is in the liver. In anaphylactic shock also the blood is incoagulable because of the presence in it of an excess of heparin.‡

The Transudations. The earlier work on coagulation was largely carried out on the fluids obtained from the pericardial or pleural cavities, or on hydrocele fluid from the *tunica vaginalis*. These as a rule can be kept indefinitely without clotting, but will clot readily on addition of a few drops of blood or of thrombin. They will not clot on the addition of tissue extracts. Their behaviour is readily explained by the assumption that they contain fibrinogen, but are free from thromboplastin and prothrombin. In order to produce coagulation it is therefore necessary to add both these factors, as happens when we add blood, or else to add thrombin.

THEORIES OF COAGULATION. The incompleteness of our knowledge of what really happens in clotting is reflected in the great variety of theories which have been advanced to explain it. Any theory should have regard to the following facts : (1) Plasma contains all the substances necessary for clotting. (2) Blood does not clot in normal

* Mellanby. *Proc. Roy. Soc.*, 1933, **113B**, 93.

† Wilander. *Skand. Arch. Physiol.*, 1938, **81**, Suppl. XV.

‡ Jaques and Waters. *J. Physiol.*, 1941, **99**, 454.

blood vessels. (3) Coagulation is closely related to the properties of the colloids concerned in it. (4) Essential factors in clotting are primarily fibrinogen and thrombin; secondary factors which govern the formation of thrombin are prothrombin, calcium salts and thromboplastin. (5) In hæmophilia the blood is only slowly coagulable or even incoagulable. Thus far, though with different nomenclatures, most workers are now agreed.

Morawitz called the thromboplastic factor thrombokinase and considered that this substance, liberated by platelets or damaged tissues in presence of calcium salts, converted a precursor, prothrombin, in the plasma, into thrombin.

According to Nolf the essential factors are three proteins : fibrinogen, thrombogen and thrombozym. The two former are produced in the liver, while the thrombozym is formed from the leucocytes. The clotting depends on a mutual interaction and precipitation of colloids with, as a result, either fibrin or thrombin. Thrombin differs from fibrin merely in containing less fibrinogen. For this reaction to take place, the presence of calcium is necessary as well as certain thromboplastic substances which act as centres of precipitation. Thrombin, according to him, is merely an unsaturated compound which is capable of taking up or uniting with more fibrinogen to form fibrin. He compares these actions to the actions of digestive enzymes on proteins ; fibrinogen is first precipitated as fibrin by union with thrombozym and thrombogen. This fibrin is then hydrolysed and dissolved by the further action of the thrombozym, which he regards as essentially proteolytic in character. That the blood does not coagulate within the vessels he explains by assuming that the cells of the blood and tissues are covered normally with an ultra-microscopic layer of fibrin which has no thromboplastic effect upon the plasma.

Howell's theory assumes that the thromboplastic material (cephalin) liberated by platelets or by other damaged tissue cells neutralises heparin, which normally maintains the fluidity of the blood *in vivo*, so that calcium salts can then convert prothrombin to thrombin.

It seems certain that complex physico-chemical processes connected with electric charges on colloids or high-molecular substances play an important part, since many anti-coagulants are strongly acidic or basic substances of large molecular weight. For instance, the lignine sulphonic acids (Liquoid Roche), Germanin and heparin are acidic ; Janus green is basic.

HÆMORRHAGIC STATES. In some pathological states the bleeding from a wound is abnormally prolonged. This may be due to one or more of many causes. One of these conditions is called *hæmophilia.*

In this condition the blood clots, if at all, with extreme slowness ; hence subjects suffering from the complaint may die of hæmorrhage as a result of trivial injuries. Yet their blood undoubtedly contains prothrombin and fibrinogen, so that if thromboplastin solution is added it clots normally. The most probable explanation is that the platelets of hæmophilic blood are less readily made to yield sufficient thromboplastin than those of normal blood, either because of their small number or their relative stability.

Platelet-free plasma, normal or hæmophilic, does not coagulate on contact with glass ; adding normal platelets to hæmophilic blood does not induce clotting either ; but if *normal* plasma is also added, together with *either* normal or hæmophilic platelets, the hæmophilic plasma then clots in glass.* It appears, therefore, that the plasma thromboplastin is lacking, and hence transfusions of normal blood greatly shorten the clotting time in hæmophilic cases. Local application of certain snake venoms to the wound accelerates clotting. The disorder is of further interest because it is hereditary and is transmitted through the females, who are not affected by it, to the male descendants through many generations.

In other cases there is a lack of prothrombin, as in jaundice, or some days after administration of " dicoumarin " or of salicylates, and in certain nutritional disorders due to lack of vitamin K ; or there may be lack of fibrinogen, as in gross liver damage or in the hereditary pseudohæmophilia. Very rarely, if ever, is excessive bleeding due to calcium deficit, because for this to occur the $Ca^{\cdot\cdot}$ would have to be reduced to a level incompatible with life. A primary lack of some clotting factor is, however, not the only cause of excessive bleeding. For instance, in anaphylactic shock the blood is incoagulable because of the presence of an excess of heparin.

Often the hæmorrhagic state is associated with the occurrence of purple or livid spots on the skin—a symptom called purpura—which is due to fragility of the capillary walls. This may be associated with reduced blood coagulability, as in the purpura due to lack of vitamin K, but often the coagulation time is normal and there is no detectable lack of any coagulation factor in the blood. The most outstanding of such examples is scurvy, due to lack of vitamin C ; another may be due to lack of another vitamin, called vitamin P (flavone) so raising the permeability of the blood capillaries. Again, some states of purpura (idiopathic thrombocytopenic purpura) are distinguished by a reduction in the number of blood platelets. Whether this is due to sluggish production or accelerated destruction of platelets is unknown, and the condition is often relieved by removal of the spleen. Platelet deficiency is also present in the purpuras of aplastic anæmia and lymphatic leukæmia. Some believe that the primary fault is in the capillary endothelium, which is excessively vulnerable;

hence, many platelets are used up to repair the breaches, with consequent lowering of the circulating platelets.

THE CIRCULATION

CHAPTER XXX

GENERAL FEATURES OF THE CIRCULATION

In the tissues, the blood is passing continuously through a close meshwork of capillaries, minute vessels with walls consisting of a single layer of delicate endothelial cells, which permit of a free interchange of material by diffusion between the blood within and the tissue fluid outside the vessel. The movement of the blood is maintained by the heart, which acts as a pump, transferring the blood it receives at the low pressure of the veins, to the arteries at a high pressure, the blood being taken from the heart to the tissues by the arteries, and carried back from the tissues to the heart by the veins.

In all the vertebrates the vascular system is closed, *i.e.* communicates at no point with the tissue spaces or cœlomic cavity. It is found in its simplest form in fishes (Fig. 338, A), where the heart consists of one auricle and one ventricle. The blood is received from the great veins into the auricle. The walls of both auricle and ventricle contract rhythmically. By the contraction of the auricle the blood is forced into the ventricle and this, when it contracts, sends the blood on into the bulbus arteriosus. From the bulbus the blood passes through the branchial arteries into the gills, where it takes up oxygen from the surrounding water, and then flows on into the aorta, by which it is distributed to the various organs of the body. From the capillaries of these organs the blood is collected by the veins and is carried once more back to the auricle. The fish heart is thus entirely on the venous side of the vascular system.

A. Aorta.
c. Systemic capillaries.
L. Lung capillaries.
r, *l*. Right and left auricles.
rV, *lV*. Right and left ventricles.

In amphibia, such as the frog (Fig. 338, B), the heart consists of two auricles and one ventricle. The right auricle receives venous blood from the body by means of the venæ cavæ and forces it by its contraction into the ventricle. From the ventricle the blood passes into the aorta, whence it is carried partly by the pulmonary artery to the lungs, partly by arteries to the different organs of the body. The blood, which has passed through the lungs and been oxygenated, flows through the pulmonary veins to the left auricle, whence it passes into the ventricle and mixes with the venous blood which is arriving from the right auricle. The pulmonary circulation is thus merely a branch of the general or systemic circulation. The bulbus aortæ in the frog is divided into two parts by means of a spiral valve, by which a partial separation of the blood coming from the right and left auricles is effected, and the venous blood from the right auricle directed especially into the pulmonary artery.

In birds and mammals the heart has become entirely divided into two halves, right and left, which have no communication with one another except by way of the blood vessels and capillaries. The right auricle receives the venous blood from all parts of the body and sends it on to the right ventricle, whence it is forced into the lungs along the pulmonary artery. In the lungs it takes up oxygen and so becomes " arterial " and is returned by the pulmonary veins to the left auricle and on to the left ventricle. The rhythmic contractions of the left ventricle then force the blood into the aorta, whence by the branching arteries it is carried to all parts of the body (Fig. 338, c).

The whole vascular system is distensible and elastic, so that its capacity will increase with the pressure of the blood contained in it. Since the driving force is furnished by the heart, the pressure which causes the flow of blood through the system must decline as we pass from the arterial to the venous side (Fig. 339). In the arteries the pressure is high, *e.g.* about 120 mm. Hg in the large arteries of man ; it is somewhat lower in the smallest arteries. The chief function of the large arteries is to serve as elastic conduits, whereas the small arteries and arterioles leading from the arteries to the capillaries have in addition the function of regulating the amount of blood flowing through the capillary area of the organs which they supply. In the capillaries the pressure is much lower, say, 30 to 50 mm. Hg. The veins have the function of conducting blood at a low pressure (not usually greater than 1 mm. Hg) from capillaries to heart and of holding any excess of blood which is not immediately taken up by the heart.

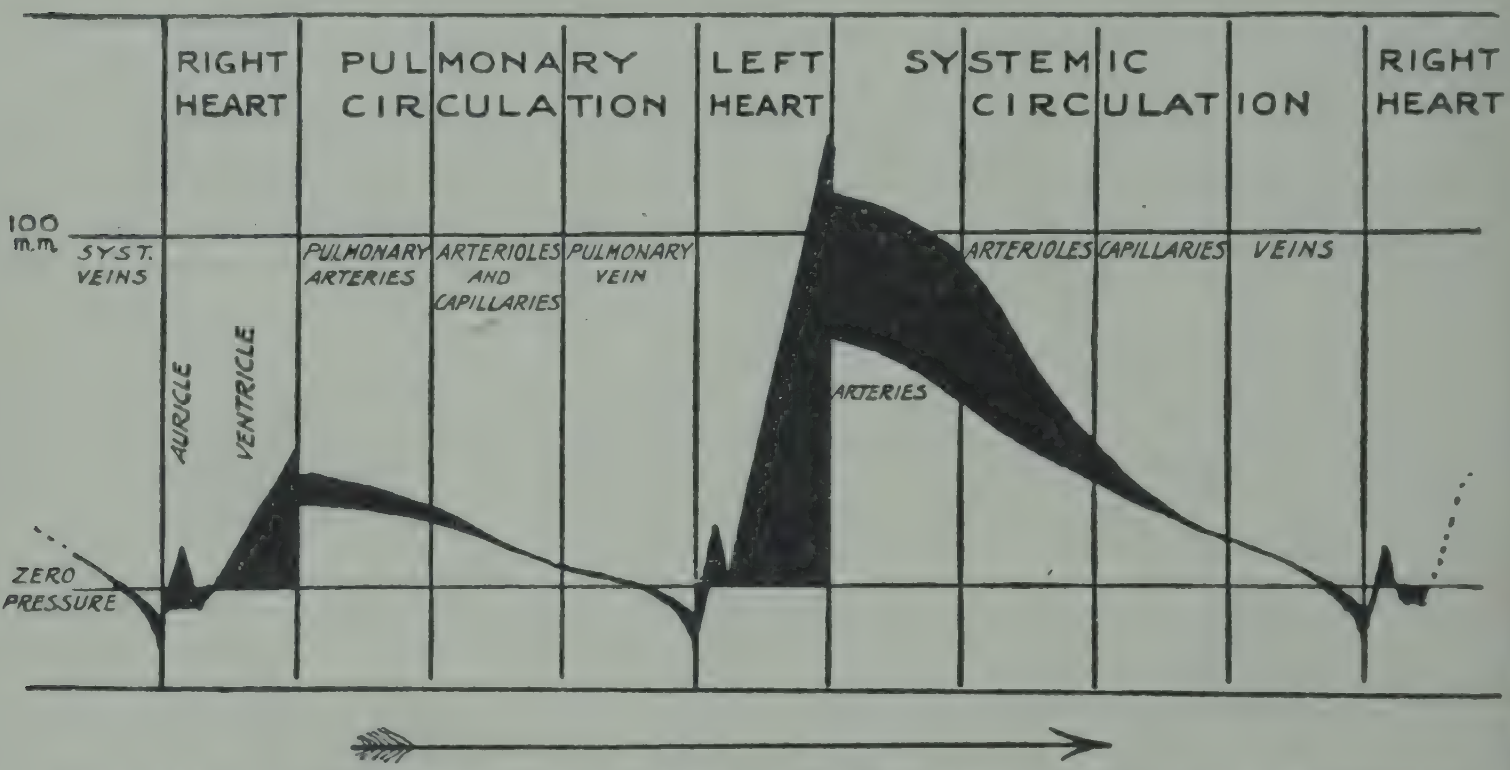

FIG. 339. Diagram to illustrate the pressures in different parts of the vascular circuit. The circulation proceeds in the direction of the arrow. Lines of " zero " (= atmospheric) pressure and of 100 mm. Hg pressure are shown. The pressures are shown as a graph of varying breadth ; the breadth at any point indicates the approximate magnitude of the pressure fluctuations caused by the heart beats. These fluctuations are at a maximum in the ventricles and at a minimum in the smallest capillaries and veins, in which the pressure is almost constant. (The fluctuation in the pulmonary arteries is probably much greater than is here shown.)

Corresponding to this difference in function we find variations in the structure of the blood vessels according to their situation in the circuit. The arteries are thick-walled and contain an abundance of muscular and elastic elements in their walls. The typical medium-sized artery is described as consisting of three coats (Fig. 340): an *intima* lined by a continuous layer of flattened endothelial cells, which rest on a well-marked lamina of yellow elastic tissue; a *media* composed of unstriated muscular fibres arranged mainly circularly; and an external coat or *adventitia* of fibrous tissue, with a number of longitudinal elastic fibres. Near the heart, in the great vessels such as the aorta and its larger branches, there is a preponderance of elastic tissue as compared to the muscular; and we find in the media alternate layers of muscle fibres and fenestrated elastic membranes.

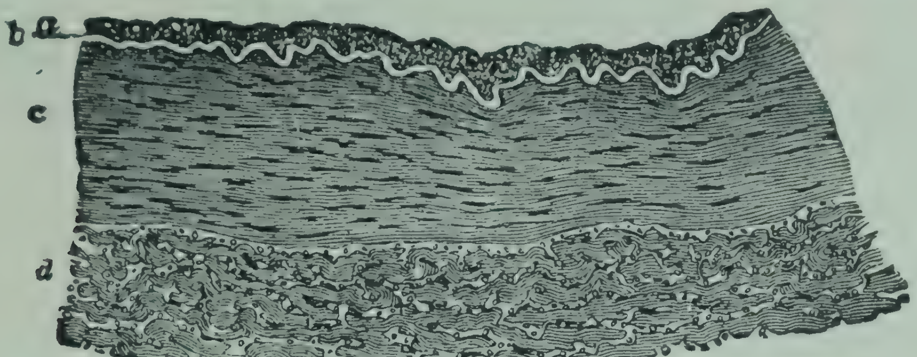

FIG. 340. Transverse Section of Part of the Wall of the Posterior Tibial Artery (× 75). (SCHAFER.)

a. Endothelial and sub-endothelial layers. of intima.
b. Lamina of elastic tissue.
c. Media consisting of muscle fibres.
d. Adventitia.

Arteries are of two types, the "elastic" and the "muscular." The aortic arch and its main branches are of the "elastic" type; they constitute a large elastic reservoir which lightens the work of the heart and converts the intermittent output into a continuous flow. The smaller arteries, such as radial and lingual, are of "muscular" type; they serve to regulate the supply of blood to the various organs as their needs require it. In the smallest arteries, the *arterioles*, the elastic element entirely disappears, so that the wall consists of muscle fibres, chiefly circular, lined by the endothelium. In these vessels a contraction of their walls may result in an entire obliteration of the lumen, so shutting off altogether the supply of blood to the capillaries beyond. The capillaries, though formed merely of a single layer of endothelial cells, also possess the power of contracting and relaxing, and so admitting of a larger or smaller flow of blood to the tissues according to their local needs. In the veins the same three coats can be distinguished as in the typical artery, but the wall of the vessel is much thinner in proportion to the lumen. In the vein, moreover, there is a preponderance of the fibrous tissue elements, the muscular and elastic tissue being but little marked. On this account the vein collapses unless it is distended by some internal pressure.

The histological difference between veins and arteries is of importance for the understanding of the distribution of pressures in the vascular system, since the distensibility of these vessels is conditioned by their structure. In Fig. 341 is represented the distensibility, *i.e.* the increase in capacity, of a vein under gradually increasing internal pressure. It will be seen that the capacity, which is negligible at zero pressure, becomes considerable on raising the pressure to

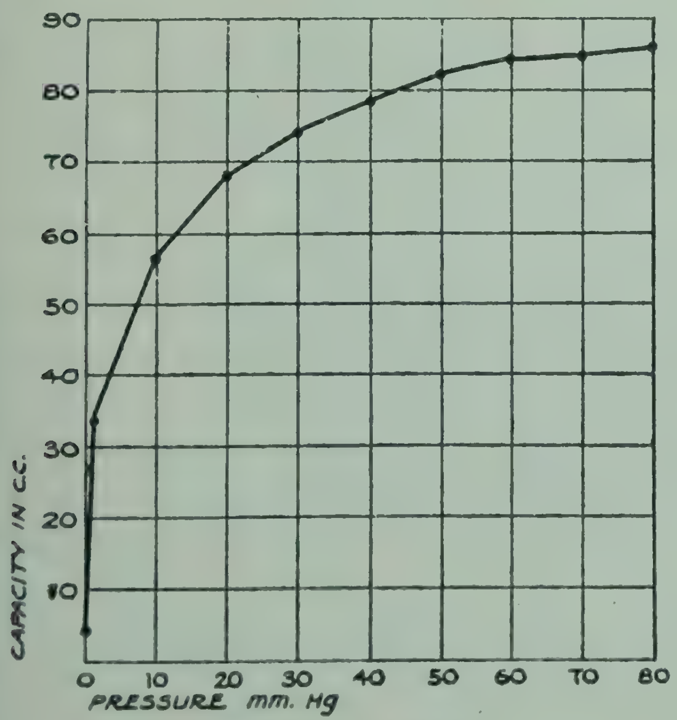

FIG. 341. Vein.

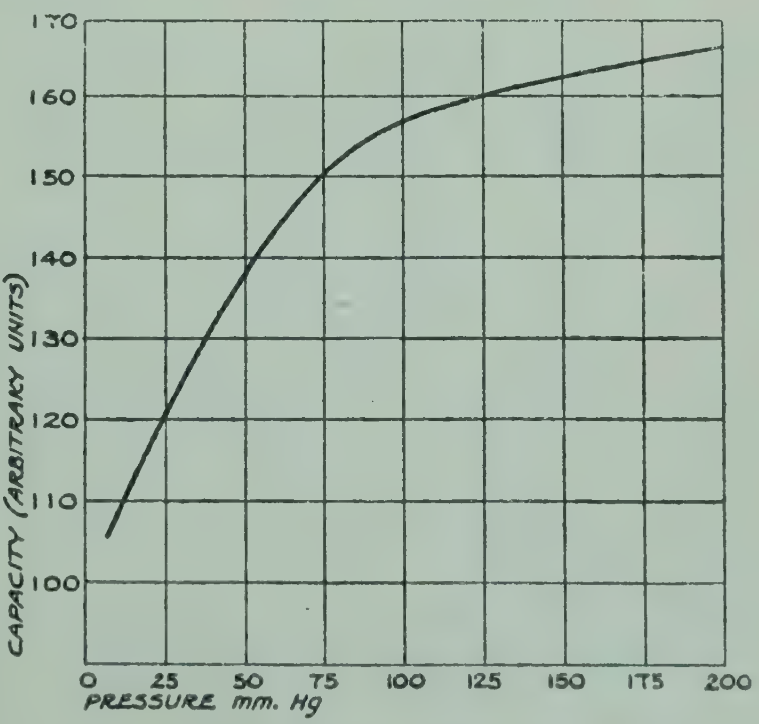

FIG. 342. Artery.

1 mm. Hg. A further rise of pressure to 10 mm. Hg causes a very large increase in volume, but from this point the increments of volume with rising pressure rapidly diminish. On the other hand, the artery, which has a certain capacity at zero pressure, increases its capacity much more slowly with rise of pressure, and the increment of capacity becomes gradually less as the internal pressure rises. In Fig. 342 is shown the distensibility of an artery to sudden alterations of pressure such as occur with each heart beat. It indicates that the arterial wall becomes more rigid with increasing distension. In the thoracic aorta of young subjects the curve is S-shaped, the most rapid distension taking place at about 100 mm. Hg. pressure.* The aorta is thus well suited to expand at each systole.

As the arteries branch, although each branch is smaller than the parent vessel, the total area of the two branches into which the vessel divides is greater. Thus there is a continual increase in the cross area of the bed of the blood stream as we pass from the heart towards the periphery. This increase is especially marked at the junction between the capillaries and the arterioles on one side and the venules on the other, so that the total area of the bed in the region of the capillaries can be taken as about 800 times that of the area of the aorta where the blood leaves the heart.

This figure would apply only to normal conditions, under which but a portion of the capillaries are open and pervious to the blood current. By the opening up of previously closed capillaries, the capacity of the capillaries in active muscle may be increased to many times that of these vessels in a resting muscle. In fact, a general and simultaneous dilatation of all the capillaries of the body may increase the capacity of the stream bed to such an extent that there is an insufficient return of the blood to the heart, and a condition of "shock" is brought about.

Arterio-venous Anastomoses. Although the bulk of the circulating blood has to pass through capillaries in order to travel from the arterial to the venous system, this is not invariably the case, for in certain parts of the body there are direct channels leading from arteries to veins. These are called arterio-venous anastomoses. In them the arterial twig, after a more or less tortuous course, opens directly into a relatively wide, thin-walled vein. The structures are often collected together in groups in certain situations, or may be scattered singly. They occur especially in erectile tissue, such as the penis, in the skin of the balls of the fingers, in the nail bed, and to a remarkable degree in the rabbit's ear skin. The openings of these anastomoses are capable of being closed by the contraction of a thick muscular wall; when this is relaxed the arterial blood is short-circuited directly into the vein.

CHAPTER XXXI

PHYSIOLOGY OF THE HEART

CARDIAC MUSCLE

In the ordinary span of a man's life his heart performs about 2,600 million beats, pumping at least some 155 million litres (say about 150,000 tons) of blood from each ventricle: at the lowest estimate the work done amounts to 241 million kg.-m., enough to raise a weight of 10 tons to a height of ten miles. In all this performance scarcely a beat is misplaced, and there is no rest longer than about three-quarters of a second throughout. It must be admitted that this is a remarkable performance for an organ weighing only about 300 grm., even when spread over seventy years.

If the heart be cut out of the body of a cold-blooded animal it will continue to beat with the normal sequence of its different chambers for hours, or even days, provided that it be kept cool and moist. In the case of a warm-blooded animal, the heart is similarly capable under proper conditions of continuing its rhythmic contractions for many hours after excision. The fact that the heart will continue to beat after removal from the body shows that the causation of the beat is to be sought in the walls of the heart itself. The heart wall consists of cardiac muscular tissue; it presents longitudinal and transverse striations and is capable of contracting both "spontaneously" and in response to direct stimulation. The histological unit is a muscle cell, roughly quadrilateral when

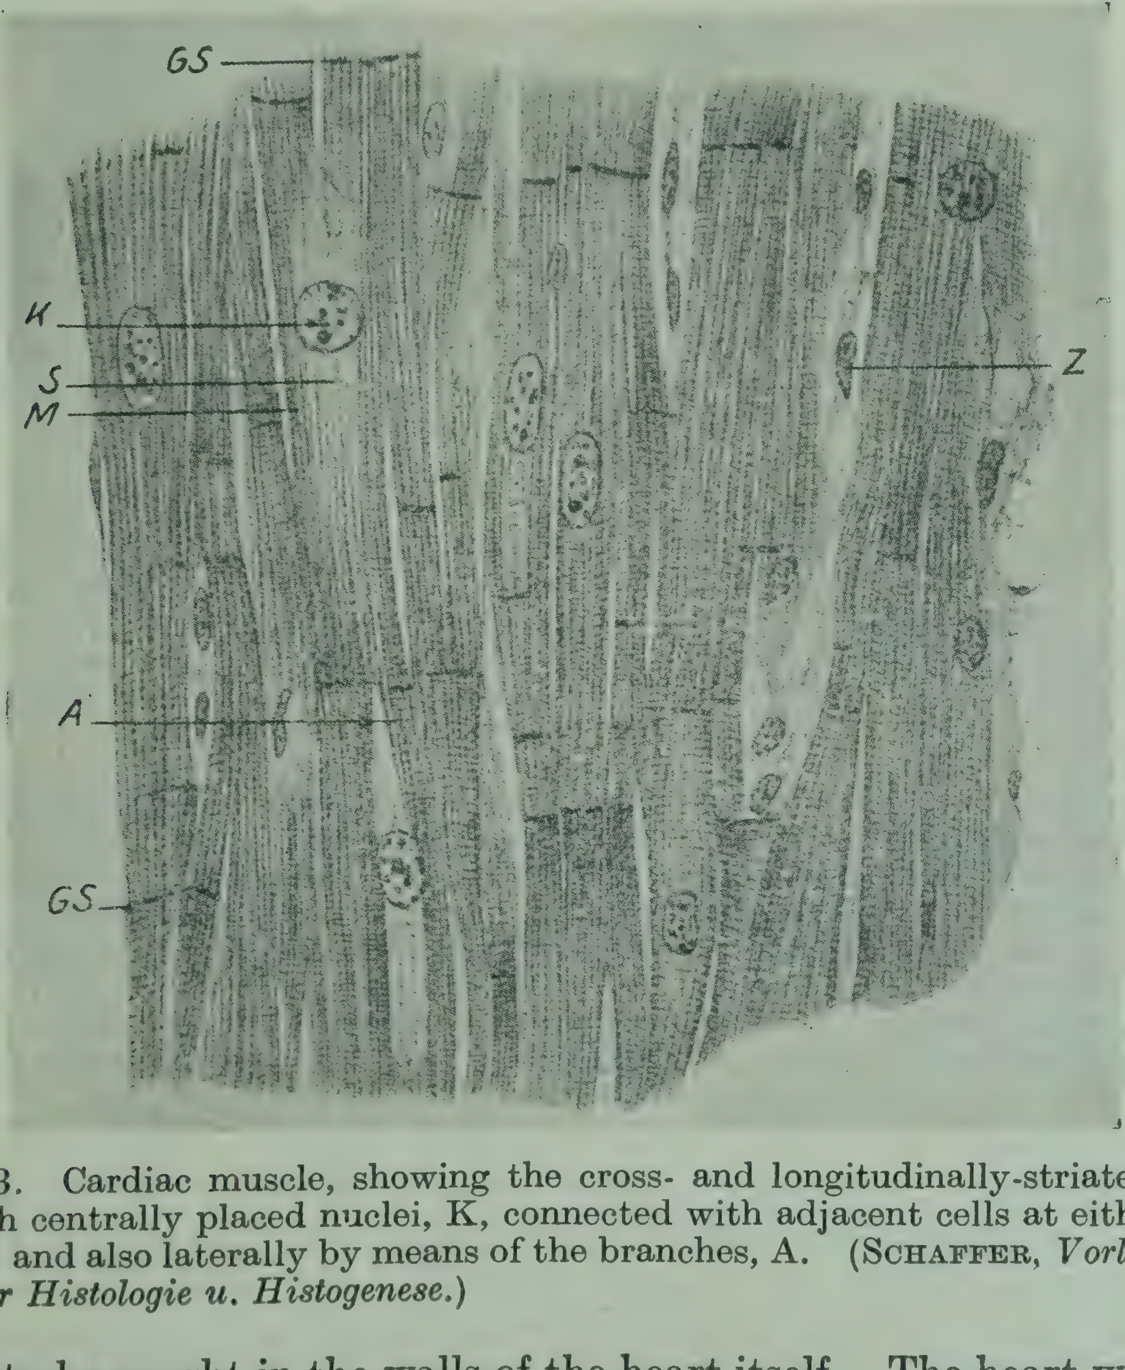

FIG. 343. Cardiac muscle, showing the cross- and longitudinally-striated cells, with centrally placed nuclei, K, connected with adjacent cells at either end, GS, and also laterally by means of the branches, A. (SCHAFFER, *Vorlesungen über Histologie u. Histogenese.*)

viewed from the surface. Each cell has a nucleus near its centre, and is joined to adjacent cells to form fibres. No sarcolemma is present, and the fibres lying side by side are connected at frequent intervals by short bridges (Fig. 343). The contractile units are thus not separate, as in voluntary muscle, but are in protoplasmic and functional continuity, *i.e.* they form a *syncytium*.

ANATOMY OF THE HEART IN THE FROG AND TORTOISE. The hearts of the frog and of the tortoise have figured largely in the researches on the causation of the heart beat.

The frog's heart (Fig. 344) consists of the sinus venosus, which receives the anterior and posterior venæ cavæ, two auricles, one ventricle, and the bulbus arteriosus which opens into the two aortæ. The venous blood from the body flows into the sinus venosus by the three venæ cavæ, and thence into the right auricle, while the left auricle receives the blood from the lungs. The ventricle thus receives mixed arterial and venous blood, the arterial blood being directed by the spiral valve of the bulbus aortæ so as to flow chiefly towards the head.

The muscular fibres of the frog's heart are less highly developed than those of the mammalian heart. They are spindle-shaped, and only dimly cross-striated. The cross-striation becomes more distinctly marked as we proceed from sinus to ventricle, the sinus muscle fibre representing the most primitive condition. There is complete muscular continuity between all the cavities of the heart. The circular ring of muscle at the junction of sinus with auricles and of auricles with ventricle presents only slight traces of cross-striation.

The heart is well supplied with nerve fibres and ganglion cells. The two vagi enter the sinus venosus and branch just under the pericardium. Here they become connected with a collection of nerve cells, known as Remak's ganglion. From the sinus the two vagi, now called septal nerves, pass down in the interauricular septum, one in front and the other behind. Near the auriculo-ventricular groove they enter two collections of ganglion cells, called Bidder's ganglia. From these ganglia non-medullated fibres are distributed to surrounding parts of the auricle and to the whole of the ventricle. In the upper third of the ventricle occur scattered ganglion cells attached to the nerve fibres. These are quite absent in the lower half or two-thirds.

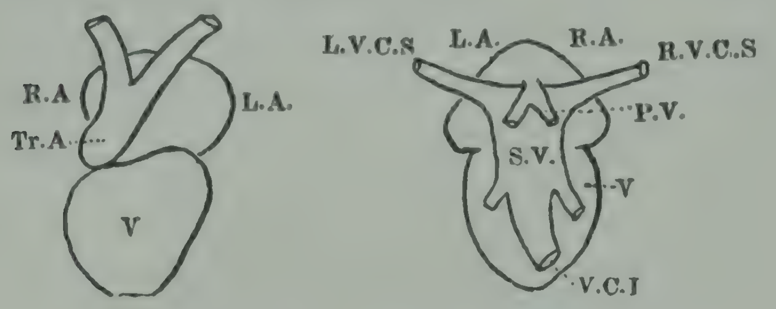

FIG. 344. Diagram of Frog's Heart. (After CYON.)

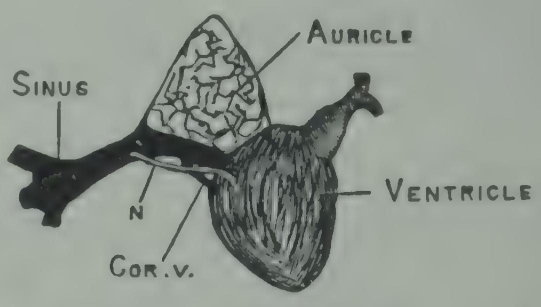

FIG. 345. Tortoise's Heart (after GASKELL) as it appears when Suspended for Registering the Auricular and Ventricular Contractions. N, nerve trunk with fibres connecting Remak's and Bidder's ganglia; COR. V., coronary vein.

In the tortoise (Fig. 345) the two auricles are bound together by a flat band of tissue, which serves also to connect the sinus with the ventricle. The septum between the auricles arises from the central line of this junction wall. The two vagus nerves pass into a large accumulation of ganglion cells in the sinus, and thence along the basal wall to the auriculo-ventricular groove, lying just under the pericardium. In the groove they pass into a collection of ganglion cells, whence fibres are given off to both auricles and ventricle. As they leave the sinus, a branch of the right nerve runs along the coronary vein, which conveys blood from the ventricular wall to the sinus.

The Contraction of the Cold-blooded Heart. THE STANNIUS LIGATURES. The frog's heart beats regularly, the contraction starting in the sinus, then travelling to auricles, ventricle and bulbus. If, however, the auricles be functionally separated from the sinus by a ligature round this junction (first Stannius ligature), the auricles and ventricle stop in an uncontracted condition (diastole), while the sinus goes on beating regularly. After the lapse of a period varying from five minutes to half an hour, the detached part of the heart begins to beat, at first slowly and then more rapidly, but never attaining the rate of the sinus. The auricles beat first and then the ventricle. If now the ventricle be separated from the auricles by a ligature at the auriculo-ventricular groove (second Stannius ligature), the auricles continue to beat, while the ventricle, after a few beats due to the excitation of the ligature, stops beating, though after a considerable time it may begin again to contract very slowly. But the lower two-thirds of the ventricle, if separated from the rest of the heart, never beats again, under normal circumstances. To single stimuli it responds with a single beat, not with a series of beats as the whole heart does. It can be made to beat rhythmically, however, by raising the pressure within its cavity.

There is thus a descending scale of automatic power in the different parts of the frog's heart—from the sinus, where it is highest, to the lower parts of the ventricle, where it is very slight. The normal sequence of events—*i.e.* the subordination of the ventricle to auricles, and auricles to sinus, so that the beat always follows in the order, sinus, auricles, ventricle, bulbus—can be ascribed to the difference between the natural rhythms of these different cavities. It is possible to record the contractions of each of these parts of the heart separately, after having divided them, either functionally by crushing the intervening tissue, or by actual section. Under such conditions it is found that there is a descending scale of rhythm from sinus to bulbus, the contractions of the sinus being most frequent, those of the ventricle and bulbus the least frequent. Thus in the entire heart, it is impossible for the ventricle to function at its own rhythm, since before it is ready to beat again spontaneously, it receives an impulse from the auricles which induces a beat. That the normal sequence of contractions is dependent on the domination by the sinus, is shown by the fact that, by exciting the ventricle by means of induction shocks repeated at a rhythm slightly quicker than that of the sinus, it is possible to induce a reverse rhythm, the order of the beat being now ventricle, auricles, sinus venosus. It is clear, therefore, that the portion of the heart which beats most rapidly dominates the rest, and it is therefore called the *pace-maker*.

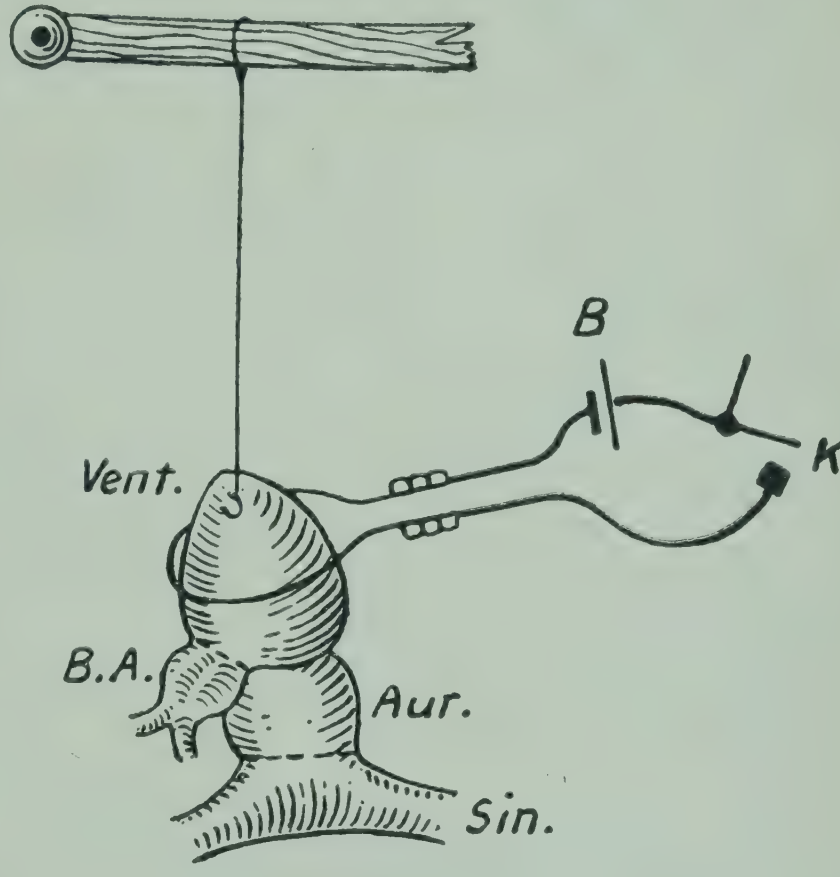

FIG. 346.

That the sinus is the pace-maker in the frog's heart may be shown by a simple experiment. The ventricle is connected with a recording lever, and a platinum loop, which can be heated by passing a current, is put round the heart (Fig. 346). When the ventricle alone is warmed the rhythm is unaltered. On lowering the loop so as to warm the sinus, the rhythm of the whole heart is quickened.

The different rhythmic power of these parts of the heart is apparently connected with the histological characters of the muscle fibres at each part. The lowly differentiated sinus cell has well-marked rhythmic power and a quick rhythm of beat, but is not able to exert much force in its contraction. The more highly differentiated ventricle cell has only a slight rhythmic power, but beats forcibly.

NEUROGENIC THEORY OF HEART BEAT. It was formerly thought that the ganglia (Remak's and Bidder's ganglia) were responsible for the initiation and co-ordination of the beats. This theory has been abandoned since it was shown by Gaskell and by Engelmann that—

(*a*) These ganglia may be excised in the frog and tortoise without altering the contractions or normal sequence of beat.

(*b*) Remak's ganglia are merely distributing ganglia for the vagus nerves to the heart. They may be paralysed by nicotine without disturbing the beat.

(*c*) A portion of cardiac muscle, free from ganglion cells, can contract rhythmically.

(*d*) The heart in the developing chick begins to contract at a date prior to the growth into it of nerve cells.

Finally it has been shown that cardiac muscle cells in tissue culture show rhythmic contractions.

THE PROPAGATION OF THE WAVE OF CONTRACTION. The normal contraction is started in the sinus venosus, propagated to the auricles, thence to the ventricle, and finally to the bulbus aortæ. Between the contractions of each of these cavities there is a slight pause, whereas the contraction spreads so rapidly over each cavity that all parts, say of the auricles or ventricle, appear to contract simultaneously. Cardiac muscle forms a syncytium, and the excitatory wave is propagated through the heart from one muscle cell to another, and not by means of nerve fibres.

That the propagation cannot be due to any nerve trunks running from sinus to ventricle is shown by various experiments of Engelmann and Gaskell.* Thus, if the auricle is slit up by a series of inter-digitating cuts, the contraction wave starting from the sinus travels along the auricular muscle around the end of each section and finally, on arrival at the ventricle, causes a contraction of this cavity. In the heart of the tortoise, the nerve trunks run in the band of tissue joining the sinus to the ventricle ; this band, with all its contained nerves, can be excised without interfering in any way with the normal sequence of contractions.

By the methylene blue method it is possible to demonstrate a close network of non-medullated fibres surrounding all the muscle cells of the heart. It is obvious that some known facts would not exclude the possibility of propagation occurring through such a nerve network, but the properties of the network would have to differ from those of any of the nerve tissues with which we are acquainted ; for example, the velocity with which the excitation is forwarded is much slower than that in nerve.

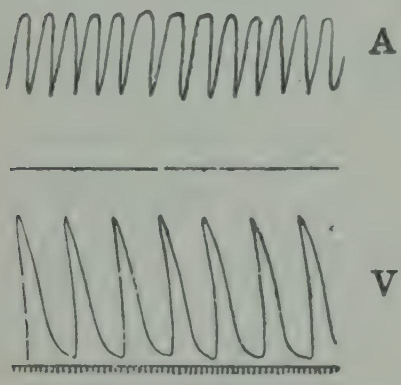

FIG. 347. Contraction of Auricles and Ventricle of Tortoise Heart. The auriculo-ventricular groove has been clamped so as to produce a partial block allowing only every second contraction to pass. (GASKELL.)

The pause between the contractions of auricles and ventricle, according to the more modern opinion, first advanced by Erlanger, is due to a latency in response of the junctional tissue to the action potentials reaching it from the auricle.† A similar retardation of the wave can be produced at any point, in either auricles or ventricle, by compression, or by cutting away the conducting muscular tissue to a sufficiently small amount. If the normal auriculo-ventricular " block " be increased, as for instance by compression of the auriculo-ventricular groove, it may be that only one out of every two or more auricular contractions passes across to the ventricle (Fig. 347), and further increase in the resistance to the propagation of the wave may lead to the block becoming complete.

The progress of the excitatory wave is well seen if a record be taken of the electrical changes resulting in the frog's heart from a single stimulation. A series of electrical changes occurs, which can be interpreted as due to the passage of a wave of excitation from the base to the apex of the heart.

THE PROPERTIES OF CARDIAC MUSCLE

Rhythmicity. The cause of the spontaneous rhythm of the various portions of the heart, and of the higher rhythm of the sinus tissue, is not known. It is evident that some stimulating agent is present in the cardiac cells themselves, and attention has been given to the possibility that this stimulus is a chemical one, as in the " heart hormone " of Haberlandt ‡ or the

---

† GIBSON. *Amer. J. Physiol.*, 1942, **138**, 113.

‡ HABERLANDT. " Das Hormon der Herzbewegung." 1927.

" active substance " of Demoor.* The higher rhythmic activity of the sinus is, according to these views, due to the more rapid production of the " hormone " in that region. According to others it is the outcome of a more vigorous metabolism.

Response to Direct Excitation. The curve of contraction of cardiac muscle resembles that of voluntary muscle, except that it occupies a longer time ; the contraction of the mammalian ventricular muscle lasts three-tenths of a second, of the frog's ventricle about half a second, and of the tortoise ventricle about two seconds. The contractile process originates at a stimulated point and travels thence to all other points.

All-or-none Contraction. When a ventricle strip is stimulated with a single induction shock, if it responds at all it will respond with a maximal contraction, no increase being obtainable, however the stimulus may be increased.† There is thus no proportionality in the heart between strength of stimulus and force of contraction. We have seen that the response to a minimal stimulus in a skeletal muscle is smaller than the response to a maximal stimulus, because in the former case only a small proportion of the muscle fibres is active, so that increasing the strength of the stimulus merely increases the number of fibres thrown into contraction, and a maximal contraction of skeletal muscle is one involving all the fibres. In the heart muscle all the muscle fibres are functionally continuous, so that a stimulus, if it excites at all, must excite all the fibres, and every contraction must be analogous to the maximal contraction of a skeletal muscle. The " all-or-none " law is therefore demonstrable without special methods in heart muscle.

Summation of Stimuli. If an isolated frog's ventricle which is not beating be stimulated with inadequate shocks, it may be found, on repeating these shocks at short intervals of time, that they culminate to cause a contraction of the ventricle. Stimuli which are subminimal may therefore summate.

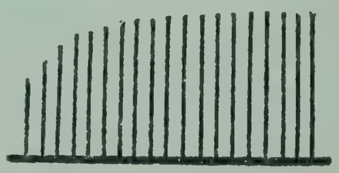

Fig. 348. Group of Contractions showing " Staircase " character.

Staircase. An improving effect of previous stimulation on the condition of heart muscle may be observed on the contractions themselves. Thus in a " Stannius preparation," if the ventricle be excited with single induction shocks once in every ten seconds, the first four or five contractions form an ascending series, each contraction being rather higher than the preceding one. This is often spoken of as the " staircase phenomenon " (Fig. 348). Each of the contractions represents a maximal contraction, but this maximum effort is at first not so great as it becomes after a few previous contractions. The phenomenon appears to be due to the accumulation of products of contraction which are beneficial.‡

The Refractory Period. When two stimuli are applied to any tissue at a sufficiently short interval of time, the second stimulus is without effect. In skeletal muscle the refractory period has passed away long before the muscle begins to respond, so that the stimulus applied after recovery from the refractory stage excites a second response, and wave-summation is produced.

In heart muscle the refractory period is extremely prolonged, *lasting as long as the contraction*, whether this occurs spontaneously or is evoked by a single stimulus. Hence, during the whole time that the muscle is contracted, any stimulus, however strong, applied to it remains without effect. Heart muscle therefore cannot be tetanised. As the contraction passes away the excitability once more rises and, as in the case of nerve, passes through a super-normal phase before it returns to normal. Directly after the contraction the excitability is so depressed that a very strong stimulus is required to produce excitation, but the strength necessary for this purpose gradually diminishes as the excitability returns. We may thus distinguish two phases : (*a*) an *absolute* refractory period during which no stimulus, however strong, can produce excitation ; (*b*) *a relative* refractory period, during which a second contraction is evoked by making the stimulus strong enough. The relation of these two phases in the excitability of cardiac muscle to the contraction produced by a single stimulus is shown in the accompanying diagram (Fig. 349). Directly after an effective stimulus is applied, the excitability of the preparation drops to zero and remains at this level during the phase of contraction. As relaxation of the cardiac muscle begins, excitability commences to rise, but some time elapses before it reaches normal. During this relative refractory period a second contraction of the muscle can be induced, the stimulus required becoming less as the absolute refractory period is left behind.

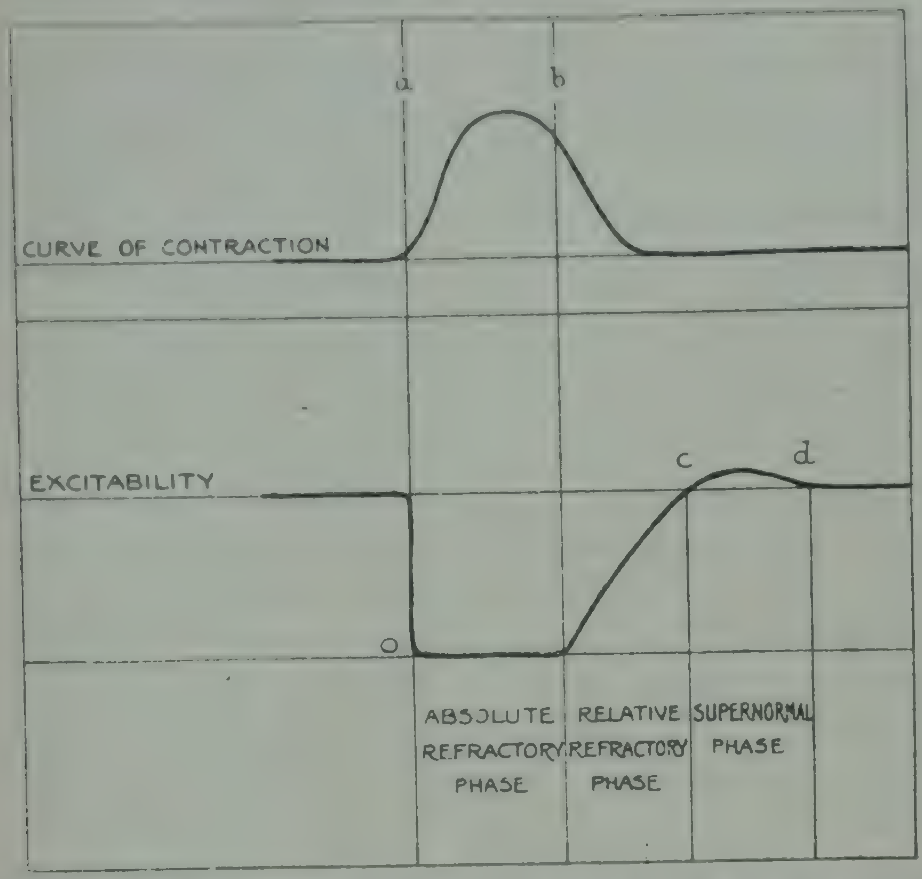

Fig. 349. Diagram showing changes in the excitability of heart muscle accompanying and following a single contraction.

A chemical explanation would seem to be applicable to these facts. Heart muscle, like skeletal muscle, contains adenosine tri-phosphate and creatine phosphate. As with skeletal muscle, part of these are broken down when contraction occurs, and probably provide the energy for the contraction.* After the contraction the material is resynthesised. We may suppose that, just after the sudden breakdown of the labile substances has taken place, any further breakdown becomes for a time impossible ; this time would be that of the absolute refractory period. As the store of labile material is regenerated, however, the excitability and contractility begin to return again, so that the tissue can respond to feebler and feebler stimuli, and at a certain point this store is great enough to enable the heart to respond to its normal " spontaneous " stimulus to contract. Just before this spontaneous contraction the heart muscle would respond to a minimal stimulus.

We should therefore expect the length of the refractory period to depend on the duration of the excitatory process : the smaller the breakdown as the result of excitation, the shorter will be the subsequent absolute refractory period. A contraction excited during the relative refractory period will be shorter than normal, because there has been less time for the accumulation of irritable material. Hence if the heart is stimulated to beat more frequently, the absolute refractory period following each beat is shortened, and we find that the length of the refractory period is inversely proportional to the frequency of the beat.

Thus Lewis found the following duration of the absolute refractory phase in mammalian auricular muscle under different rates of excitation :—

Rate per sec.	Refractory phase duration.
100	0·2 sec.
130–140	0·15 to 0·17 sec.
290	0·08 to 0·11 sec.

The refractory period is also shortened by stimulation of the vagus. This also will have the effect of diminishing the extent of the discharge at each beat. Thus the length of the refractory period seems to be determined by the amount of energy liberated or by the extent of the breakdown of irritable material in the previous contraction.

Under certain conditions the refractory period appears to be abnormally prolonged owing to the fact that a contraction is initiated by the second stimulus, but does not spread to the whole of the muscle, and hence is concealed (Drury and Love). This increase of the *effective* refractory period is seen when the muscle is subjected to cold, pressure, acid solutions, veratrine or quinidine, some of which, *e.g.* veratrine, do not alter the absolute refractory period at all, while others, *e.g.* quinidine, increase the absolute refractory period, but not to such an extent as might be supposed from estimations of the effective refractory period.

Premature Contractions. When a ventricle is beating at its normal rhythm in consequence of the stimuli communicated to it from the sinus venosus, the application of a single shock to the ventricle early in its diastole, is followed by the appearance of a ventricular contraction some while before the normal one would be due. It is called a *premature contraction* (or, less accurately, an " extra systole "), and is followed by a " compensatory pause " (Fig. 350). This is due to the fact that one of the impulses travelling from the sinus arrives at the ventricle during the refractory period ensuing on the application of the artificial stimulus ; hence it produces no effect and the ventricle has to wait for the arrival of the next succeeding excitatory wave from the sinus before it gives its next beat. In certain cases the first contraction after the pause is considerably augmented. The compensatory pause, of course, does not occur when we are testing the effects of artificial stimuli on the sinus venosus.

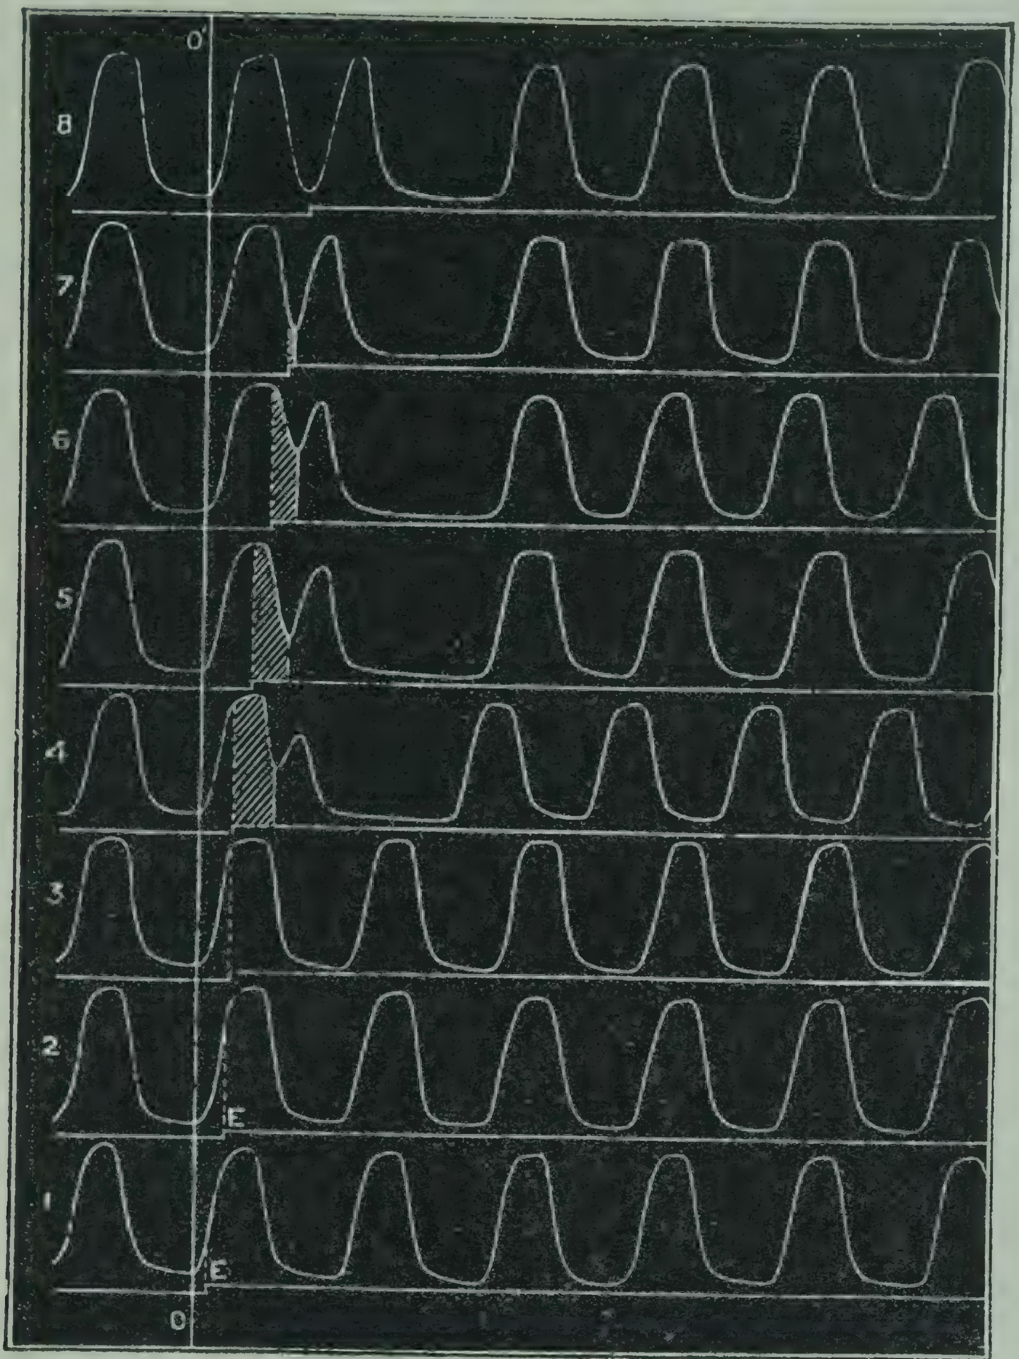

Fig. 350. Tracings of Spontaneous Contractions of Frog's Ventricle, to show Refractory Period. (Marey, *La méthode graphique,* 1885, p. 417 (Paris, Masson).)

In each series the ventricle was stimulated by an induction shock at E, as indicated by the tracing of the signal. In 1, 2 and 3, this stimulus had absolutely no effect, since it fell during the refractory period. In 4, 5, 6, 7 the effect of the shock was to interpolate a premature contraction in the series, the latent period (shaded part) gradually diminishing from 4 to 7. In 8 the irritability of the preparation was already considerable, and the latent period inappreciable. The " compensatory pause " after the premature contraction is also well shown in 4, 5, 6, 7, 8.

INVERTEBRATE HEARTS. The hearts of invertebrates are often very different in structure and properties from those of the higher animals. In *Limulus*, which has been extensively studied by Carlson,* the heart forms a segmented tube of ordinary striated muscular fibres, which has a local system of ganglion cells, so situated that they can be cut away entirely from the muscular portions of the organ. Extirpation of the nerve cord abolishes spontaneous contractions. It is possible to make a nerve-muscle preparation of the anterior part of the heart, consisting of the muscle of the first two segments with a longer stretch of the lateral nerves. Stimulation of the lateral nerves with a single shock causes a single beat of the anterior segments; tetanising shocks cause a tetanus. The beat of the heart is originated and co-ordinated by the action of the local ganglionic centres. It would, for these and similar reasons, be wrong to transfer the results obtained on the heart of Limulus, or other invertebrates, to the explanation of the phenomena exhibited by the hearts of vertebrates.

THE MAMMALIAN HEART

In the mammal each side of the heart consists of an auricle into which the veins open, and a ventricle which receives the blood from the auricle and discharges it into the arterial trunk—either aorta or pulmonary artery. Since the auricles have to act merely as a receptacle for *part* of the blood which enters during the relaxation or diastole of the heart, their cavities are smaller than those of the ventricles, and their walls are thin, corresponding to the small amount of work thrown on them in propelling blood into the relaxed ventricle. The ventricles have the office of carrying on the main work of the circulation, viz. of forcing blood through the peripheral resistance. Their walls are much thicker than those of the auricles. The right ventricle has a wall which is only

* Carlson. *Amer. J. Physiol.*, 1904, **12**, 67.

about one-fourth the thickness of the left ventricle, in conformity with the much heavier work to be done by the latter. The capacity of both ventricles is approximately equal.

The auricles are separated from the ventricles by a fibro-tendinous ring. From this ring take origin most of the muscular fibres of the heart walls.

The muscular fibres of the auricles run in both circular and longitudinal directions (Fig. 351), the circular fibres being continued round both auricles and special rings of circular fibres surrounding the openings of the great veins. From the fibro-tendinous ring between the auricle and the left ventricle and from the sides of the aorta, the muscular fibres forming the superficial layer of the ventricular wall pass obliquely downwards to the left towards the apex of the ventricle. Here they loop round into the interior of the ventricle and pass up near its inner surface to end either in the papillary muscles or in the auriculo-ventricular ring of fibrous tissue. Between these two layers we find a third median layer of muscular fibres which is in the form of a muscular cone. The fibres of this layer form complete loops round the left ventricle. The middle layer is connected by many strands of muscular fibres with both inner and outer layers.*

As Harvey showed, the normal direction of the blood flow through the heart is determined mainly by the valves. The auriculo-ventricular valves are membranes attached round the entire circumference of the auriculo-ventricular ring (Fig. 352). They are composed of fibrous and elastic tissue covered on each

side with endocardium, and project downwards into the cavities of the ventricles. On each side the membrane is divided by deep incisions into large flaps, three in number on the right side (the tricuspid valve) and two in number on the left side (the mitral valve). The sail-like margins of these valves are connected by thin tendinous cords to the papillary muscles, which are projections of the muscular walls of the ventricles. By this means the edges of the valves are kept close together and prevented from eversion under the strong pressure exerted by the blood in the contracting ventricle. By the downward pull of the papillary muscles on the valves during the contraction of the ventricles, closure is rendered more complete, the inner surface of the valves being apposed over a considerable area. The action of the valves is aided by the contraction of the fibres surrounding the base of the heart, so that the auriculo-ventricular orifice is much smaller during systole than during diastole.

Each arterial orifice is provided with three valves, semilunar in shape and each attached by its convex borders to the arterial wall, and presenting in the middle of its free border a small nodule, the *corpus Arantii*, from which fine elastic fibres pass to all parts of the valve. The extreme margin of the valve, the *lunula* on each side of the corpus Arantii, is very thin. Whenever the pressure in the arteries is greater than that in the ventricles, these valves are closed, and the thin margins come in contact with similar portions of the adjacent valves, so preventing any reflux of blood. The borders of the valves under these circumstances come together in the form of a star composed of three lines at angles of 120°, the three corpora Arantii being pressed together at the centre of the star.

No valves are found at the orifices of the great veins into the auricles, and so a reflux of blood occurs during contraction of the heart, but it is limited by the contraction of the muscular rings round the veins, which slightly precedes the main auricular contraction.

The heart and the roots of the great vessels lie almost free inside the pericardium. This is attached below to the central tendon of the diaphragm, and above to the arterial trunks. It is lined by a layer of mesothelium continuous with a similar layer covering the surface of the heart. The two surfaces are kept continually moist by the pericardial fluid, so that the heart can move freely within the pericardium without friction. One of the chief functions of the pericardium appears to be to check an excessive dilatation of the heart.

THE CONTRACTION OF THE MAMMALIAN HEART

A perfectly rhythmic activity of the mammalian heart may be maintained for hours after its removal from the body by perfusing the coronary arteries with blood, or with a suitable warm oxygenated perfusion fluid.

It is possible to sever all the nervous and muscular connections between auricles and ventricles without stopping the contractions of the ventricles which, after a pause, recommence beating at a rhythm which is independent of and slower than that of the auricles. A piece of an auricular appendix, suspended in warm oxygenated Ringer's solution, will continue to beat for hours, and a fragment of the ventricular wall, free from ganglion cells, will similarly contract if fed by an artificial circulation through a branch of the coronary artery. We may therefore conclude that in the mammalian, as in the amphibian, heart every part of the heart muscle possesses the power of rhythmic activity, the normal sequence of transmission being determined by the greater frequency of the natural rhythm at the venous end of the heart.

Conduction of Excitatory Wave. The excitatory condition started at one point in the muscle spreads through it in all directions, and the spread is independent of nerve fibres. As in the frog, the excitatory process may, in exceptional circumstances, be made to travel in a direction the reverse of normal, as, for instance, when the ventricles are excited at a rhythm of

higher frequency than the natural one starting at the venous end of the heart.* The phenomena are easily explained on the assumption that the whole of the musculature of the heart acts in many respects as a single muscle fibre, along which an excitatory process may be propagated in any direction. But in the mammalian heart the muscle fibres of both auricles and ventricles are seen to arise from a fibro-tendinous ring at the auriculo-ventricular junction, leaving apparently no muscular continuity between the two cavities. The discovery by Kent,† and then by His ‡ of a distinct band of modified muscle fibres passing, in the septum, from the auricles to the ventricles, the "*auriculo-ventricular bundle*," furnished an anatomical basis for the conduction of the wave.§

In the adult heart, *e.g.* of man, the anatomical relations of the different cavities have become considerably modified from their primitive form (Fig. 353) in the course of development. The sinus venosus, *i.e.* the part where in the lower vertebrates the contraction wave takes its origin, is now represented merely by the termination of the superior vena cava and of the coronary sinus in the right auricle, in a small amount of tissue underlying the *sulcus terminalis* of the right auricle, as well as by the remains of the Eustachian and venous valves. The auricular canal gives rise to the auricular septum and to the auricular ring surrounding the auriculo-ventricular orifice, and in some hearts it is prolonged into the ventricle as the intraventricular or invaginated part of the auricular canal.

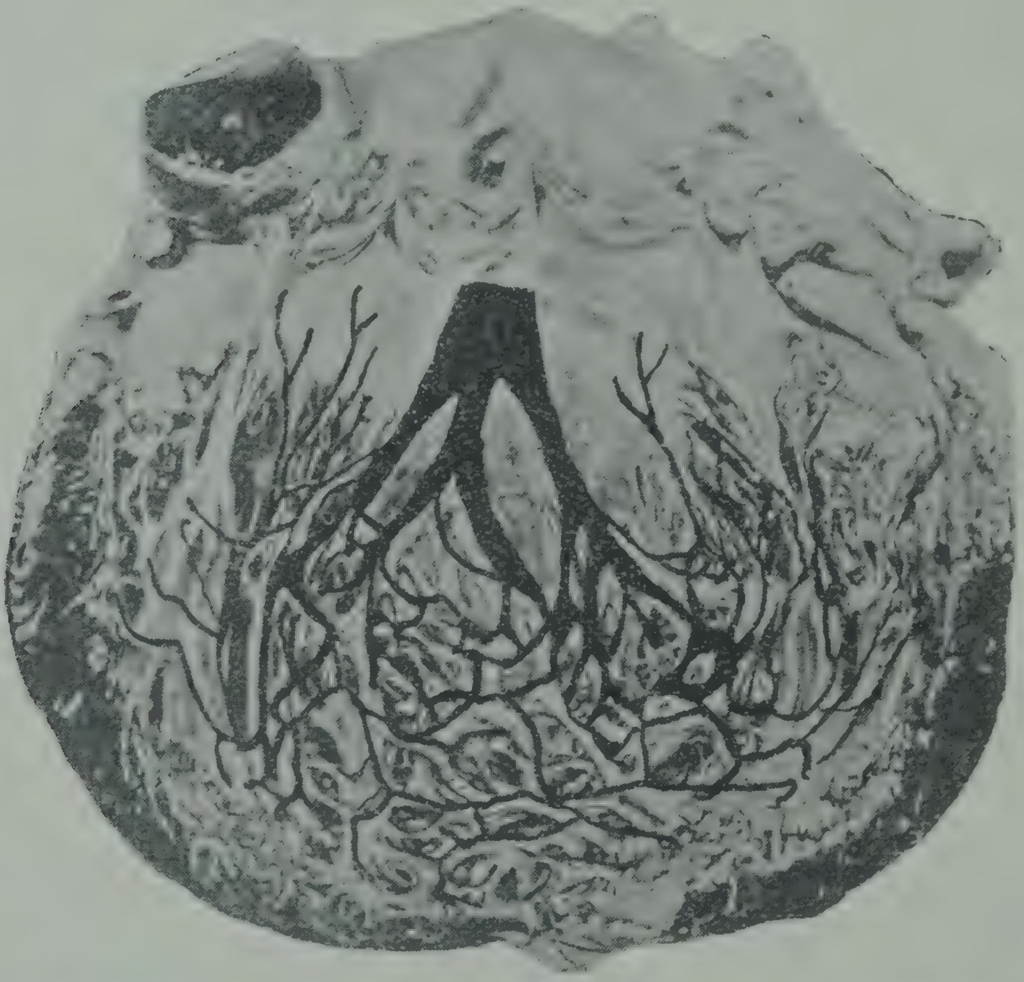

FIG. 355. Left Ventricle, laid open to display the Interventricular Septum, on which the Course of the Left Division of the Auriculo-ventricular Bundle and its Ramifications are shown in black. (After TAWARA.)

In the adult heart two accumulations of more primitive tissue are found in the region corresponding to the sinus venosus of the embryo, and these are known as the *sino-auricular node* ‖ and the *auriculo-ventricular node*. They are composed of delicate interlacing fusiform fibres, faintly striated and embedded in dense connective tissue. The fibres contain very little glycogen. The sino-auricular node (Fig. 354) lies in the groove between the superior vena cava and the right auricle.¶ The auriculo-ventricular node lies at the base of the auricular septum on the right side, below and to the right of the opening of the coronary sinus (Fig. 355).

Continuous with the A–V node, a bundle of muscular fibres (the auriculo-ventricular or A.V. bundle) runs along the interventricular septum and then divides into the right and left septal divisions, which pass down in each ventricle on the interventricular septum. Each division gives off branches which break up, finally forming a reticulated sheet of tissue over the greater part of the interior of the ventricles just below the endocardium, with branches that penetrate to end beneath the epicardium, and in the papillary muscles. (Figs. 354 and 355). The fibres composing this tissue are more primitive in character than the rest of the cardiac musculature and have long been distinguished as the "fibres of Purkinje." In them the striation is confined to the periphery of the muscle cell (Fig. 356). They are distinguished by a high glycogen content. The course of the system of Purkinje tissue in the heart may be demonstrated by the injection of coloured materials into the sheaths which enclose the main strands.*

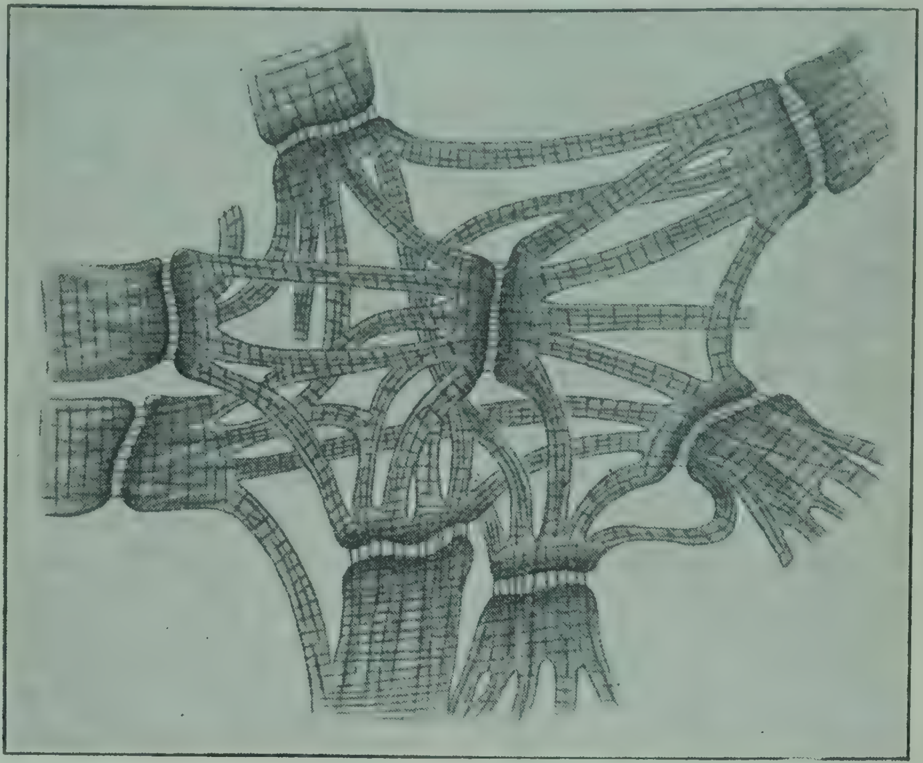

Fig. 356. Fibres of Purkinje, from the Sub-endocardial Network. (Tawara.)

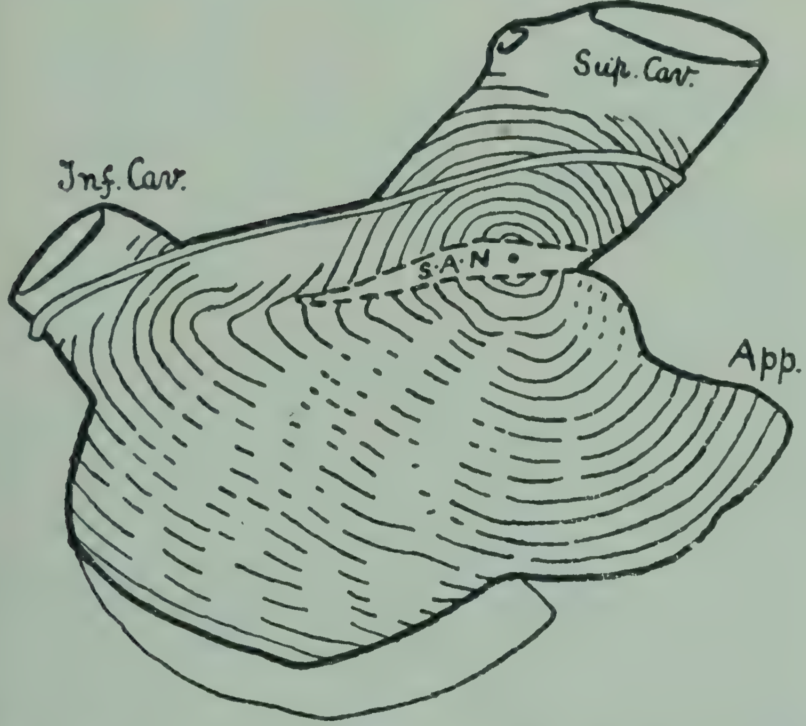

Fig. 357. Diagram showing the manner in which the Excitatory Process spreads from the Sino-auricular Node over the Auricles and along the great Veins. (T. Lewis.)

There are plexuses of nerves on the outer surface of the heart and beneath the endocardium, and ganglion cells around the openings of the great veins, along the interauricular septum, in the auriculo-ventricular groove and in the basal parts of the ventricles. Numerous nerve fibres and ganglion cells accompany the muscle fibres of the auriculo-ventricular bundle. We have, however, no reasons for regarding the nervous structures as primarily concerned in the initiation or propagation of the excitatory wave.

The auriculo-ventricular bundle forms the only continuous muscular tissue between the auricles and ventricles, and destruction of it causes complete abolition of the normal sequence of beat between auricles and ventricles.

By leading off different parts of the heart to the string galvanometer, it is possible to follow the progress of the excitatory process. It is then found that the sino-auricular node is normally the starting-point of the excitatory process concerned in each heart beat. It is therefore spoken of as the "*pace-maker*" of the heart. At each beat an excitation starts at the sino-auricular node, spreads a short way up the great veins, and along the auricular muscle in all directions at a speed of about 1 m.p.sec. (Fig. 357). When it arrives at the auriculo-ventricular node, this in turn is excited; it conducts slowly (0·2 m.p.sec.) and so there is some delay in transmission here. The impulse is then carried on to the ventricles along the auriculo-ventricular bundle, spreading along the branches of this bundle to almost all parts of the ventricular muscle. Although normally the sino-auricular node initiates each heart beat, this node can be put out of action by injury or by cooling without stopping the rhythmic sequence of the heart beat, the office of pace-maker being now taken up by the auriculo-ventricular node. A specialisation of function accompanies the differentiation in structure which we find in the auriculo-ventricular bundle and its branches. The conduction of the excitatory process along the auriculo-ventricular bundle, *i.e.* Purkinje tissue, occurs about ten times as fast as the conduction through the ordinary muscular tissue of the heart, the rates being about 5 m. and 1 m. per second respectively.

---

* Lhamon. *Amer. J. Anat.*, 1912, **13**, 55; Cohn. *Heart*, 1912, **4**, 225.

The limitation of the muscular continuity to a single narrow bundle, which is endowed with greatly increased conducting powers and ends in a network of similar tissue, ensures that all parts of the ventricles contract almost simultaneously. If this were not the case, the sudden contraction of the muscle fibres near the base of the ventricles would simply bulge out the still uncontracted portion near the apex, and there would be a risk of injury to the uncontracted part of the ventricle.

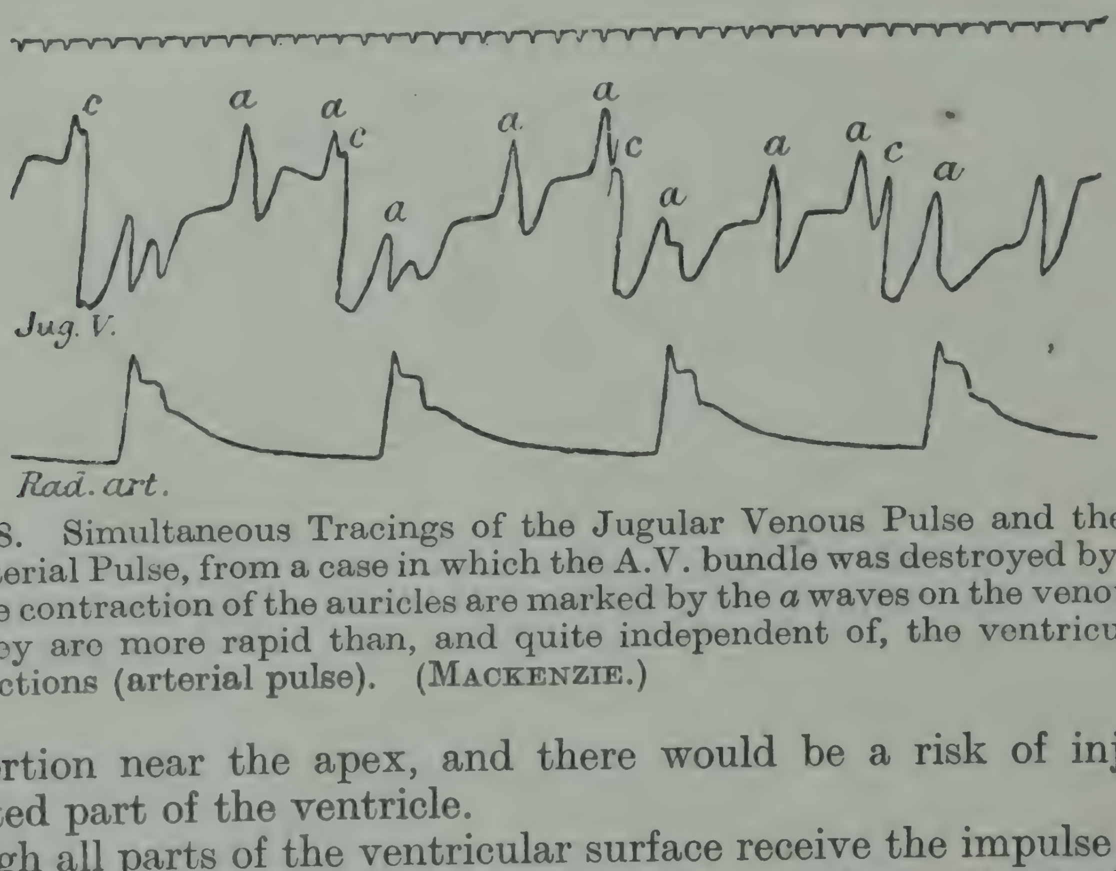

FIG. 358. Simultaneous Tracings of the Jugular Venous Pulse and the Radial Arterial Pulse, from a case in which the A.V. bundle was destroyed by disease. The contraction of the auricles are marked by the *a* waves on the venous pulse. They are more rapid than, and quite independent of, the ventricular contractions (arterial pulse). (MACKENZIE.)

Although all parts of the ventricular surface receive the impulse to contract almost simultaneously, *i.e.* within 8 msec. of one another in the dog's heart, the whole ventricle being involved within 0·07 sec., the contraction wave is found to commence 10–17 msec. earlier at the surface overlying the interventricular septum. On the other hand, the conus of the pulmonary artery is the last part of the heart to begin contracting.

The conductivity of the A.V. node and bundle, the former never high, may be impaired by disease. In such cases we get a series of phenomena known as *heart block*, the main characteristic of which is the slow rhythm of the ventricle, accompanied by a normally rapid auricular rhythm, seen in the venous pulse to be entirely independent of the ventricular pulse. The automatic activities of auricle and ventricle are, in fact, dissociated. At certain intervals or at earlier stages of the disease, the fibres of the bundle may present only a partial block, so that the ventricle responds once to every second contraction of the auricle. The existence of this condition is shown at once on the electrocardiogram (or venous pulse, see Fig. 358) by the dissociation of the normal relation between the auricular and ventricular components.

Fibrillation. If a strong faradic stimulus is applied during the latter part of systole to the ventricle of a heart beating normally, a premature contraction results and then the rhythmic contraction of the chamber stimulated sometimes ceases instantaneously; the chamber dilates and its walls are seen to be the seat of vermicular movements, each muscle fibre or fasciculus seeming to be contracting independently of the fibres around it, so that the whole surface is affected with a writhing movement.* The same condition of fibrillation may sometimes be produced in the mammalian ventricle by obstruction of one coronary artery, and may account for the sudden death which frequently occurs as a result of occlusive disease of the coronary arteries. It seems probable that a similar condition is sometimes responsible for the sudden death which may occur during the induction of chloroform anæsthesia.†

Fibrillation in the ventricles is usually irreversible and causes death.

When fibrillation is induced in the auricles, it often passes off after a variable time and the ordinary rhythmic contractions recommence. Fibrillation of the auricles is a frequent complication of heart disease, where the myocardium has been injured by some previous infective process, such as rheumatic fever. The fibrillation is at the rate of about 450 per minute, and does not spread to the ventricles, but sets up frequent and irregular excitations which travel along the A.V. bundle and cause a rapid and irregular ventricular rhythm. The smaller contractions in this rhythm may be ineffective for the expulsion of blood from the ventricles, and merely promote the exhaustion of the heart.

In some instances the auricular fibrillation is not general, and the effect of the local fibrillation is to impart a very rapid, but regular, rhythm to the auricles, while the ventricles have a regular rate one-half or a quarter that of the auricles. This is called *auricular flutter*.

The clue to the causation of fibrillation was given by observations of Mines ‡ and of Garrey. Mines found that under certain conditions a ring of frog's ventricular muscle might respond to a single stimulus by a wave of contraction passing continuously round and round the ring, and Garrey observed the same phenomenon in a ring cut from the contractile tissue of the umbrella of the jelly fish. The way in which this circus movement is brought about has been elucidated by T. Lewis. In Fig. 359 is represented a ring of auricular tissue. If it is excited rhythmically at X, the wave of excitation will travel in both directions round the ring and finish at Y. If, however, the rate of stimulation be continually increased, the refractory period gets steadily shorter, and a time will arrive at which any slight difference in the duration of the refractory stage at *a* and *b* becomes important. Let us suppose it is shorter at *b*. The wave due to the second stimulus may therefore be able to pass *b* but not *a*. The wave will thus pass in one direction only (anti-clockwise), and will travel right round the ring. By the time it has travelled past Y and arrived at *a*, the refractory stage may have passed off, so that the muscle at *a* can now contract. Whether the circus movement continues indefinitely will depend on (1) the rate of conduction, (2) the length of the ring, and (3) the duration of the refractory period. Anything which diminishes the rate of conduction and the duration of the refractory period (and both these changes result from frequent stimulation) will tend to set up a circus movement. When fibrillation is present, there is a circus movement in a ring of tissue round the mouths of the great veins. This ring is not, however, separated from the rest of the auricle, so that the wave of excitation in its course round the ring will excite in turn the adjacent portions of the auricular muscle, so that these will contract at all intervals after the passage of the wave past X. All co-ordinated movements will then be abolished and the auricle will continue in a state of fibrillation. This explanation is supported by the fact that it is possible to set the auricle into fibrillation by the application of two shocks at such an interval that the second falls just outside the absolute refractory period of the auricular muscle, and the same thing doubtless occurs when the auricle or ventricle is set

into fibrillation by the application of strong faradic currents. Administration of quinidine may put a stop to auricular fibrillation owing to the fact that it increases the effective refractory period.

THE SEQUENCE OF EVENTS IN THE CARDIAC CYCLE

The heart beats about seventy times a minute in normal resting human adults. Each beat begins by a simultaneous contraction of both auricles, and of the auricular appendages, which become pale and bloodless. The contraction of the auricles is followed by that of the ventricles, as a result of which blood is thrown out into the large arteries. In clinical terminology, the term "systolic" refers to the ventricular systole, so that "*pre-systolic*" events occur during auricular systole. The duration of ventricular systole in man is given by the interval between the commencement of the first and second heart sounds, or by the interval between the upstroke of the R wave and end of T wave on the electrocardiogram. The contraction of the auricle lasts about a tenth of a second, that of the ventricles about three-tenths of a second. The period of total relaxation or diastole lasts about four-tenths of a second. During this cycle of changes the following events are taking place within the heart :

In the diastolic period the aortic valves are closed, and the auriculo-ventricular valves open. There is a continuous flow of blood from veins, through auricles into ventricles and, as the walls of both these cavities are relaxed, there is no impediment to the inflow of the blood until the heart is quite full and begins to stretch the pericardium. Under normal circumstances the diastole comes to an end before such restraining influence of the pericardium can be effective.

The contraction of the auricles drives some of their contents into the ventricles and so still further increases their filling, no resistance being offered by the flaccid wall of the ventricles. The amount of blood propelled into the ventricle by the auricular contraction has been variously estimated as from 18 to 60 per cent. of the total ventricular filling. In fact it is a variable quantity, depending on complex dynamical factors, chief of which is the time relation between auricular and ventricular systoles.* But even when the auricle is fibrillating, and non-functional, ventricular filling may still be adequate. As the blood rushes from auricle into ventricle through the funnel-shaped opening of the membranous tube formed by the valves, eddies are set up in the ventricle tending to close the valves, so that they are held, by the resultant of the two opposing currents, in a condition midway between closure and opening.

The onset of the ventricular contraction is extremely sudden. There is a quick rise of pressure in the ventricle, which presses together the flaps of the mitral or tricuspid valve, while the bases of these valves are approximated by the contraction of the circular fibres at the base of the ventricles. As the heart shortens in systole the papillary muscles also shorten, so that the valves are prevented from being everted into the auricles, while the blood is pressed, so to speak, between the cone of the ventricular wall and the cone formed by the closed valves.

The outflow of blood from the ventricles, however, does not commence instantly, and for a very short time, therefore, the ventricle is contracting on a closed cavity, and is thus performing an *isometric* contraction (isometric phase), during which the pressure within it must rise abruptly. Before the beginning of systole the pressure in the ventricular cavity is quite small (only 2 or 3 mm. Hg), while the pressure in the aorta is 70 to 90 mm. Hg. Before the aortic valves can be opened, the pressure in the left ventricle must rise to a point which is greater than that in the aorta, and similarly on the right side of the heart. As soon as this happens the valves open and the outflow of blood (ejection phase) commences, and continues so long as the pressure in the ventricles is higher than that in the great arteries.

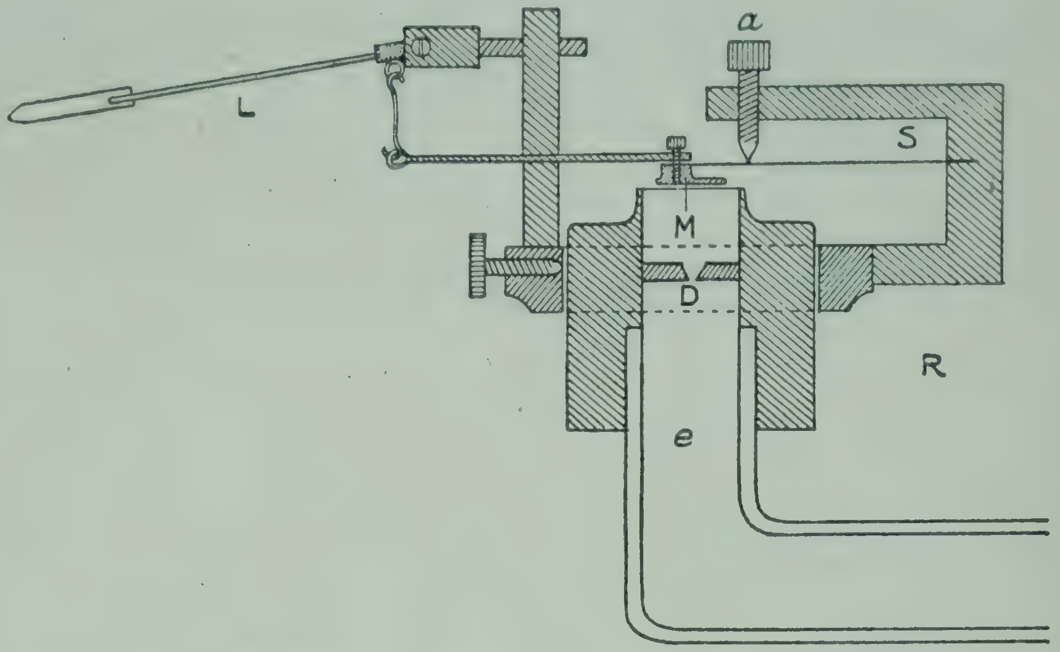

FIG. 360. Diagram to show the principle of the membrane manometer. M, the rubber membrane; S, the spring; *e*, connecting tube to artery; D, damping diaphragm; L, the lever. (FRANK.)

Even in extreme contraction the cavities of the ventricles are never entirely obliterated, though the right ventricle is reduced to a narrow slit widening out slightly in the neighbourhood of the auriculo-ventricular orifices, while in the left ventricle a distinct cavity is left between the mitral valves and the free ends of the papillary muscles. During normal activity the emptying of the cavities rarely proceeds to so great an extent. Directly the ventricular pressure falls below the arterial pressure, the arterial valves must close again and the output of blood come to an end.

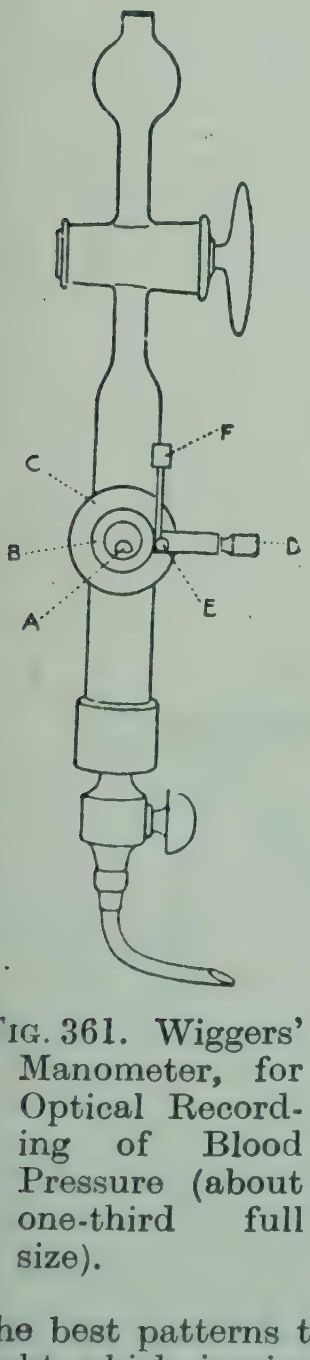

FIG. 361. Wiggers' Manometer, for Optical Recording of Blood Pressure (about one-third full size).

In order to obtain an accurate idea of the progress and duration of each of these events in the cardiac cycle, it is necessary to study the changes occurring in the pressure within the auricles and ventricles during the various phases of the heart beat.

The Endocardiac Pressure. A manometer which shall register accurately the changes in the pressure within the heart must be capable of responding faithfully to very rapid changes without entering into oscillations of its own. Thus in the left ventricle at the beginning of the systole, there may be a rise of 130 mm. Hg in 0·06 sec., *i.e.* at the rate of nearly 3 atmospheres per sec. In a heart beating rapidly and forcibly, the rise may be as rapid as 8 atm./sec. A mercurial manometer would be quite unsuitable.

A study of the theory of recording instruments by Otto Frank * showed that the fundamental requirements of such an instrument were that the mass of fluid and of parts of the instrument moved must be as small as possible: the ratio $\Delta P/\Delta V$, of pressure change per unit of volume change, must be high; also, in order to avoid vibrations of instrumental origin, the period of self-vibration of the mass moved must be as high as possible. This is accomplished, as in Hürthle's instrument, by using a very small tambour, covered with a strong, tightly stretched membrane connected, by as short and wide a tube as is feasible, with the heart or blood vessel where it is desired to register changes of pressure. The whole is filled with fluid. In the best patterns the oscillations of the membrane are recorded by means of a beam of light which impinges on a mirror attached to the membrane and is reflected on to a moving photographic surface.

---

* FRANK. *Z. f. Biol.*, 1903, **44**, 445; 1908, **50**, 309; 1925, **82**, 49.

Manometers on these principles have been designed by Frank (Fig. 360), Wiggers, and Piper. Wiggers' manometer * is shown in Fig. 361. At its lower end cannulæ of various forms and sizes can be attached. At the middle of the tube is a short lateral tube to which, by a ball and socket joint B, is attached a tiny "segment capsule" A. Over the capsule is stretched a thick rubber membrane, to which on the straight side of the segment a small mirror is affixed. The entire capsule and its mirror can be adjusted in any direction by the handle D. A second small mirror E serves to project a base line, and is adjustable by the handle F. Alterations in the pressure within the manometer cause minute oscillations of the membrane, which can be recorded and magnified to any desired extent by means of a beam of light reflected from the mirror on to a moving photographic plate or paper (Fig. 362). The "figure of merit" of this manometer, *i.e.*, its own period of vibration, when filled with fluid, and with a thick membrane, is about 450 per second so that it can record with accuracy such rapid changes of pressure as occur even in the left ventricle.

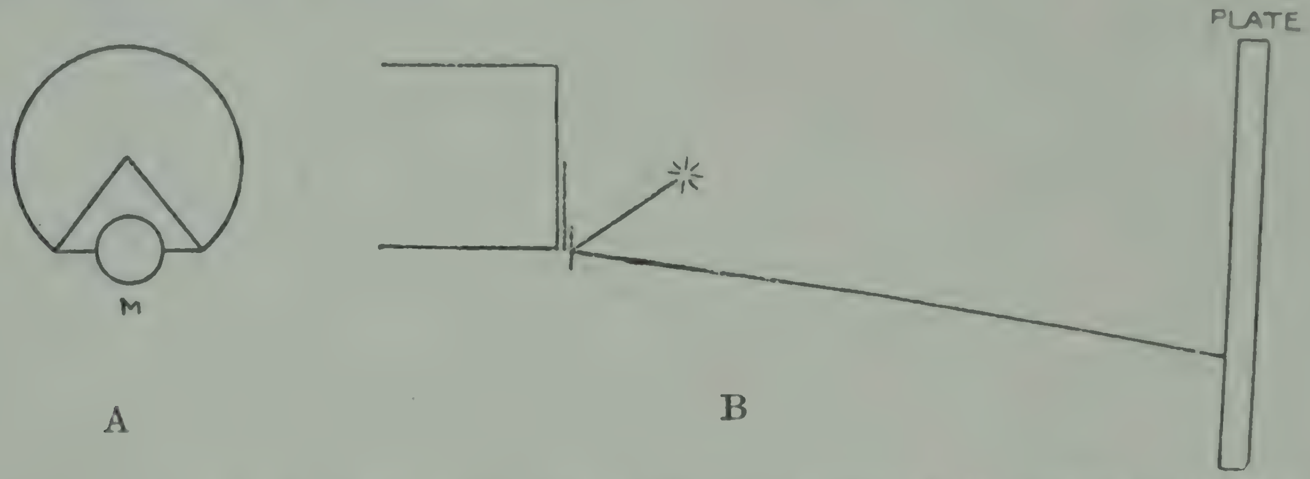

FIG 362. A, Magnified Diagram of a "Segment Recorder" covered with Membrane, to which is connected the minute Mirror M (front view).
B, Diagram showing how a Beam of Light is thrown on to the Mirror and then reflected on to a moving Photographic Plate.

In a further improvement a still more rigid membrane, in the form of a thin plate of beryllium copper, replaces the rubber one.†

INTRAVENTRICULAR PRESSURE CHANGES. In order to interpret these curves, we must have a simultaneous record of the pressures in the auricle and ventricle, or in the ventricle and aorta. Fig. 363 represents curves obtained from the

left ventricle and left auricle. On the up-stroke of the ventricular curve one or two elevations are usually visible, the most noticeable being the elevation marked S_1. This can be shown to correspond to the opening of the aortic valves.

The average course of the changes of pressure in the left heart during each beat is shown diagrammatically in Fig. 364. The cardiac cycle begins with the contraction of the auricle, which may cause a slight rise of pressure in the ventricle. As the auricular contraction dies away, the ventricular contraction begins at I. This causes a very rapid rise of pressure. Almost immediately after the beginning of the rise the auriculo-ventricular valves close, and the *isometric phase* begins. In this the pressure rises rapidly in the ventricular cavity without causing any change in its contents. Directly the pressure exceeds that in the aorta, the aortic valves open at the point marked II, where the *ejection phase* begins, and the aortic pressure now, from II to V, varies directly with the ventricular pressure. During the whole of this phase, the aortic pressure remains somewhat below the ventricular pressure, showing that blood is flowing continuously from ventricle into aorta. The ejection of blood is at first rapid, and the pressure in the ventricles continues to rise. As the heart empties, the amount of blood ejected into the aorta becomes less than that flowing away in unit time through the peripheral branches, so that the pressure begins to fall in the aorta and ventricle, even though ejection of blood is still going on. The ejection period may therefore be divided into two phases, that of *maximum ejection*, and that of *reduced ejection*. Usually this portion

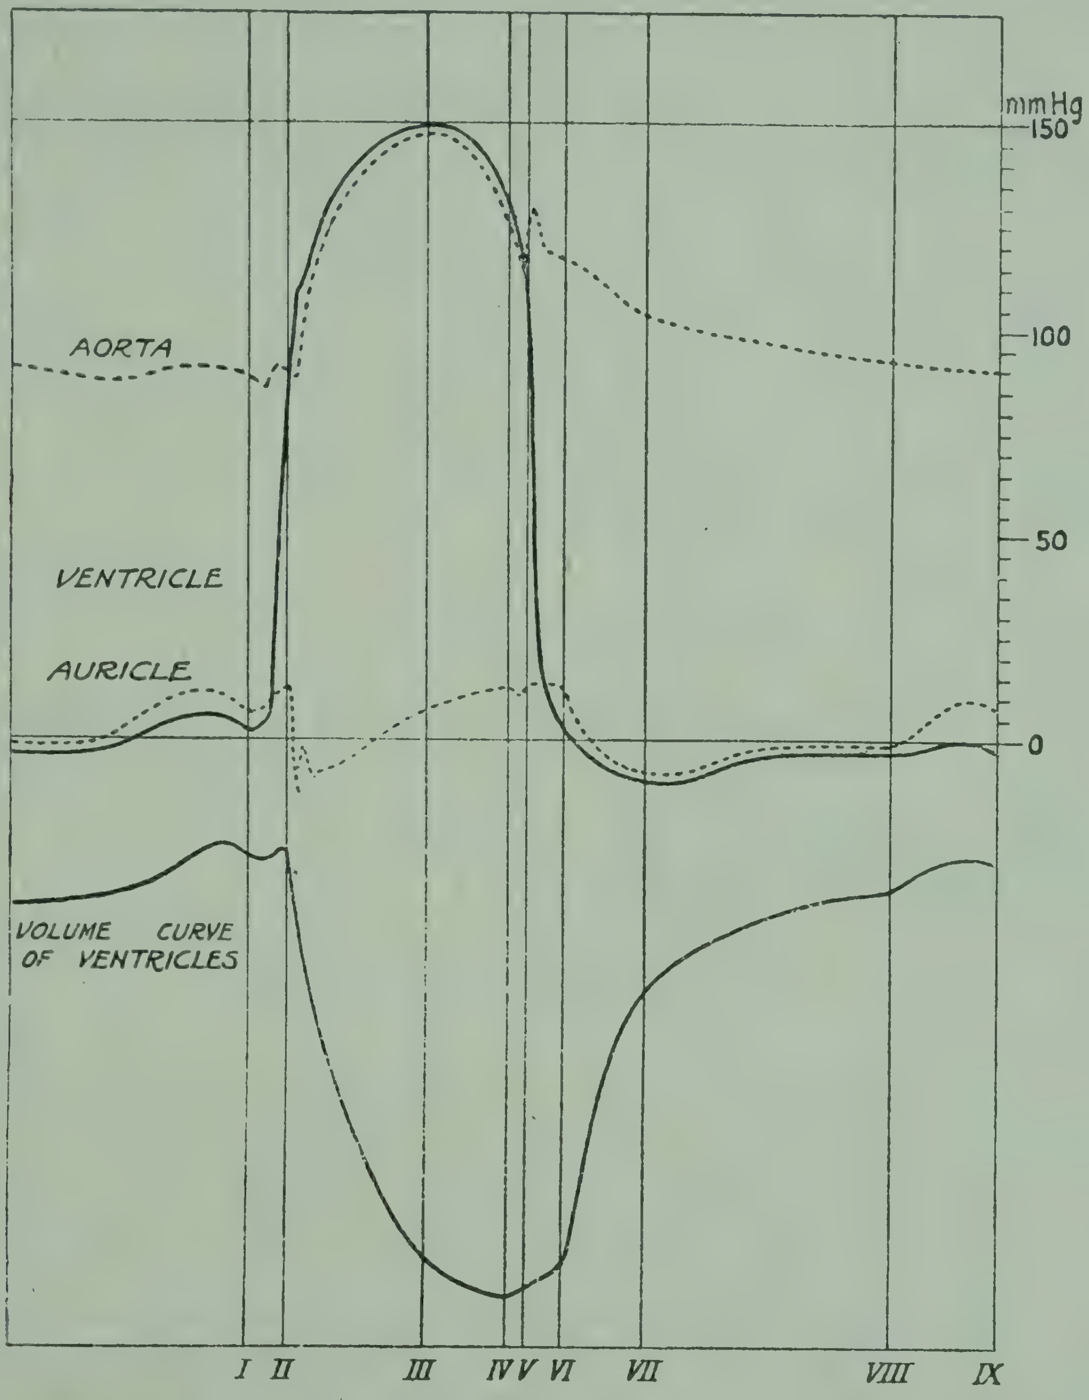

FIG. 364. Pressure Curves from Aorta, left Ventricle and left Auricle, together with Volume Curve of the two Ventricles during one complete Cardiac Cycle. (Modified from WIGGERS.)

of the curve forms a smooth arch, but under some conditions it may be flattened to form a plateau, of horizontal, ascending or descending slope. The ventricular muscle suddenly relaxes at the point marked IV, causing a sudden fall of pressure in the ventricle, and a slight fall in the aorta. This latter, however, is arrested almost at once by the closure of the aortic valves, marked by the sharp, depression, the *incisura* (V), in the aortic tracing. Between V and VI the relaxation is isometric, since all the valves guarding the orifices of the ventricle are closed. The pressure in the ventricle continues to fall, until at the point VI it drops below that in the auricle, and then the auriculo-ventricular valves open, allowing the inflow of blood from pulmonary veins and auricle. The pressure in the ventricles soon reaches zero and remains at or near this line during the greater part of diastole. With a big inflow there may be a slight rise towards the end of diastole, and a further rise on auricular contraction. If the chest is opened, the pressure in the ventricle never sinks below zero during any part of diastole. Naturally, under normal conditions, the pressure in the closed chest outside the heart is " negative " owing to the elastic retraction of the lungs, and may vary from — 3 to —30 mm. Hg, according as it is measured during normal expiration or during forced inspiration. This negative pressure may be transmitted to the interior of the heart ; hence, in the closed chest the pressure in the heart cavities during diastole may, as in Fig. 364, be negative, but never falls below the intra-pleural pressure which obtains outside them, *i.e.*, the heart does not actively exercise suction during diastole.

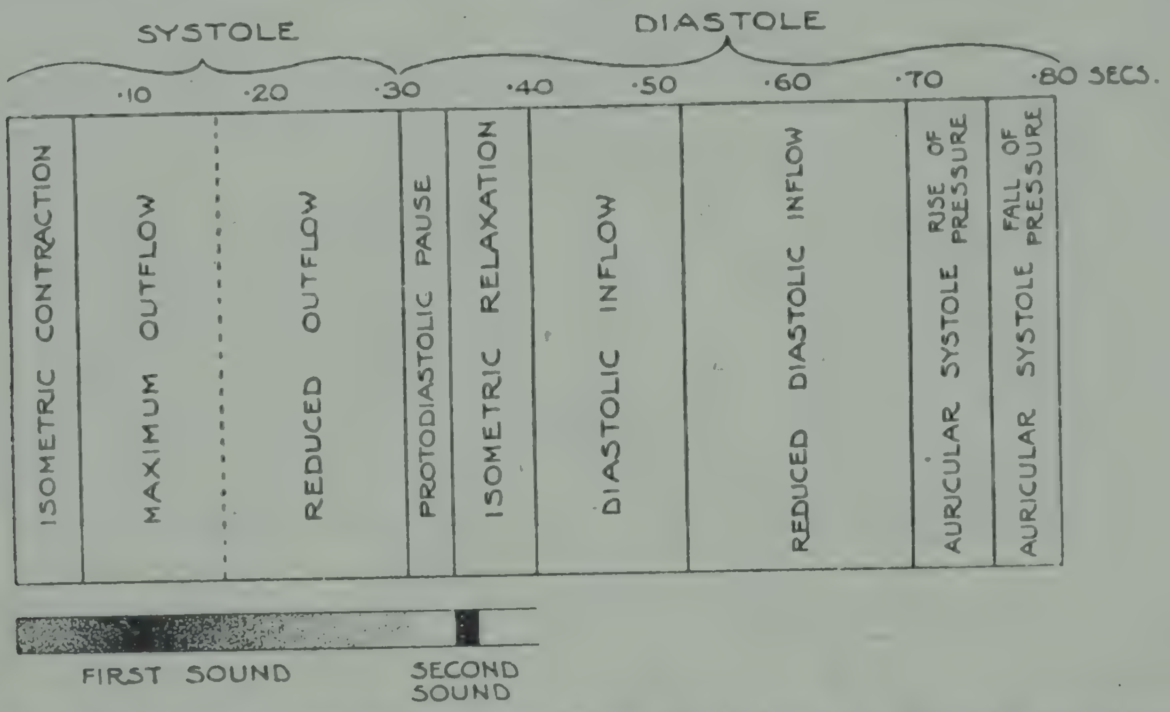

FIG. 365. Diagram showing average Time Relations of Events constituting Cardiac Cycle.

The time relations of these events naturally varies with the frequency of contraction of the heart. As a round figure, in a heart, beating 75 times p. m., a cardiac cycle will last 0·8 seconds. Based on this, the following may be taken as the average duration of the different phases in the left ventrclie (Wiggers) :—

(1) Last phase of ventricular diastole. A small rise of pressure due to contraction of the auricles, lasting 0·05 second. The whole auricular systole (rise and fall of intra-auricular pressure) takes about 0·11 second.

(2) The isometric phase, initiating systole, lasts 0·04 to 0·06 second. It varies but little with alteration in heart rate.

(3) The total duration of ventricular systole is about 0·3 second, varying from 0·33 to 0·23, as the heart rate quickens from 60 to 120 per minute.

(4) The diastolic phase may be divided into the following periods :—

(*a*) Protodiastolic phase (from beginning of relaxation to closure of aortic valves), 0·038 second.
(*b*) Isometric relaxation, 0·076 second.
(*c*) Rapid inflow phase, 0·113 second. } Joint diastole = 0·39 sec.
(*d*) Slow inflow phase, 0·163 second.

The relative durations of these last two phases will naturally vary according to the rate of the heart and the inflow of blood into the heart.

The average relation of these various phases of the heart cycle are represented diagrammatically in Fig. 365.

Similar but smaller pressure changes occur in the right side of the heart.

Intra-auricular Pressure Changes. Owing to the absence of valves between the right auricle and the venæ cavæ, changes of pressure within this cavity are transmitted along the veins. Observation shows that the jugular vein pulsates at least twice for each heart beat. The exact form of the pressure tracing in the auricles varies considerably, according to the inflow of blood and the state of filling of their cavities. A typical tracing with a moderate inflow of blood is given in Fig. 363, p. 558, and in this figure the relations of the different elevations in the auricular tracing to the intraventricular events can be made out ; in Fig. 366, the essential features of the curves are similar, and present the following features :

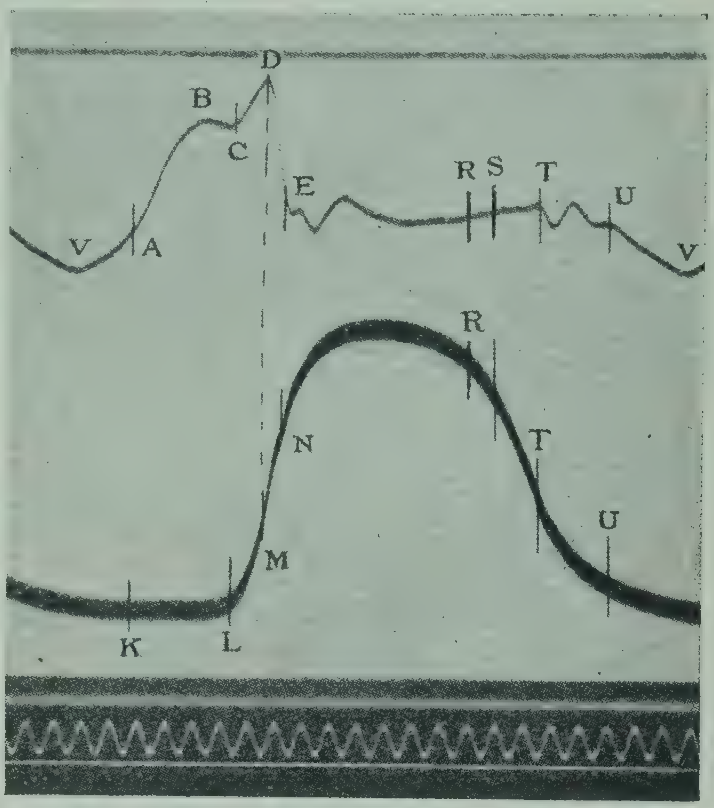

Fig. 366. Synchronous Left Auricular (upper) and Left Ventricular (lower) Pressure curves. (Wiggers.)

A, B, C = Auricular systole.
C, D = Second positive wave.
R = End of ventricular systole.
U, V = Rapid inflow phase.
Time = 0·02 second.

(1) The first positive wave, B (pre-systolic wave) corresponding to the auricular systole.

(2) The second positive wave D (first systolic wave) occupying the beginning of the ventricular systole. This is caused by the sharp closure of the A.V. valve.

(3) A negative wave of variable extent E largely due to the contracting ventricle pulling down the A.V. ring towards the apex, and so opening out the auricle " like a concertina."

(4) A third positive wave (second systolic wave) which may present secondary undulations. This rise of pressure is due to the gradual filling of the auricles while the auriculo-ventricular valves are still shut.

(5) A negative wave, not always well marked. At this point (U.V., Fig. 366) the ventricle is entirely relaxed and the auriculo-ventricular valves open, so allowing the blood to flow freely from the auricle into the ventricle.

The pressure rises in the left auricle somewhat higher than in the right auricle. In the latter the big veins act as a supplementary reservoir to the auricle, so that in no period of the cardiac cycle need the pressure in the latter chamber rise to any extent. In auricular tracings the heart sounds are often apparent as small oscillations in the curve (Fig. 363).

Changes in Form of the Heart. Under normal circumstances the heart in the unopened chest lies in the pericardium, and is also supported laterally by the lungs, which have very little influence on its shape. As the heart walls are flaccid during diastole, its shape will depend upon the position in which the heart is lying. Thus if the chest and the pericardium be opened and the animal be in the supine position, the heart during diastole will be flattened from before backwards. In this position, therefore, systole will be accompanied by a shortening in the lateral and vertical directions and a lengthening in the sagittal direction. During systole the heart, whatever its previous condition, takes the form of a truncated cone.

When the heart is freed from the pericardium, the obliquity of its fibres causes the apex to move forwards and to the right during systole ; this movement is normally prevented by the attachment of the pericardium to the central tendon of the diaphragm, so that the most movable part of the heart is then the base, which moves downwards towards the apex. This movement is determined partly by the shortening of the fibres of the ventricular wall partly by the lengthening of the great arteries as blood is forced into them from the ventricles. It was observed by Leonardo da Vinci that if three needles be passed through the chest wall so that their points lie, one in the base, one about the middle of the ventricles, and one in the apex of the ventricles, each ventricular systole is accompanied by a downward movement of the needle in the base of the heart, a slighter movement of the needle in the middle of the ventricles, and practically no movement at all of the needle which is thrust into the apex.

The Cardiac Impulse. Each ventricular systole causes a throb to be communicated to the chest wall, over a limited area of which it may be felt and seen, except in fat individuals. The region where the pulsation is most marked usually lies in the fifth intercostal space, a little to the median side of the left nipple. This position may shift with alterations in the work of the heart, as after exercise. The pulsation is spoken of as the *cardiac impulse* or "apex beat," though the apex of the heart is situated lower down. During diastole the ventricles form a flabby flattened cone lying against the chest wall and slightly deformed by the latter, especially when the subject leans forwards, or assumes the prone position. In systole the ventricles become rigid, assuming the form of a rounded cone. This sudden recovery of shape and hardening of the ventricular wall pushes out that part of the chest wall in immediate proximity to the ventricles, and so gives rise to the cardiac impulse. The cardiac impulse, by its characters of force, regularity, frequency and maintenance, gives valuable clinical information as to the occurrence and nature of the ventricular contraction.

The Heart Sounds. If we apply the ear, or listen with a stethoscope, to the front of a person's chest, we hear two distinct sounds accompanying each cardiac impulse, *i.e.* each systole, followed by a pause corresponding to the diastole. The sounds are often, though inadequately, compared to the syllables *lubb, dup*, the first sound being low-pitched and prolonged, the second sound higher and sharp. Thus the heart sounds may be represented: 1st, 2nd (pause), 1st, 2nd (pause), etc.

The *first sound* is best heard at the situation of the cardiac impulse. It is caused by the sudden closure of the auriculo-ventricular valves and the sudden increase in tension upon them and in the ventricular walls, whereby all these structures are caused to vibrate. It was formerly believed that the contraction of the ventricular muscle contributed a component to the first sound, but any such component is probably small, because little sound is produced if means are adopted to prevent alteration in tension of the ventricular walls and of the auriculo-ventricular valves.* The first sound is reduplicated if the two ventricles contract asynchronously (as in bundle branch block).†

The *second sound* is heard most loudly just over the second right costal cartilage, *i.e.* where the aorta lies nearest the surface. It comes at the end of ventricular systole, as determined by the cardiac impulse, and is synchronous with the closure of the aortic valves. It is, in fact, caused by the vibrations set up in the valves, and in the walls of the aorta near them, consequent upon their sudden shutting and stretching directly the heart ceases to contract and to force the blood into the aorta. If the valves be hooked back in an animal by means of a wire passed down a carotid artery, the second sound disappears and is replaced by a murmur caused by the blood rushing back into the ventricle at the end of the systole.

The pulmonary and aortic valves generally close simultaneously. In some cases, however, the aortic may close slightly before the pulmonary, giving rise to a " reduplicated second sound."

---

* Eckstein. *Amer. J. Physiol.*, 1937, **118,** 359; Lewis and Dock. *J. Amer. Med. Assoc.*, 1938, **110,** 271.

† Braun-Menéndez and Solari. *Arch. Int. Med.*, 1939, **63,** 830.

The distinctness with which the vibrations causing the heart sounds are heard, and also their character and duration, depends primarily on the physical conditions for conduction, such as the thickness of the chest wall, the properties of the stethoscope, etc., but other things being equal, the loudness of the first sound depends on the abruptness and force with which the ventricle contracts, while the loudness of the second sound varies with the force with which the aortic valve is closed. The slower vibrations of the sounds are suppressed by stethoscopes and also by the ear, and so tend to be lost.

THE GRAPHIC RECORD OF THE HEART SOUNDS. Various methods have been devised for graphically recording the heart sounds. They have been recorded directly by delicate membranes bearing mirrors. The usual method is to convey the heart sounds to a microphone, which is thus set into vibration. The alterations in current so produced are recorded by a string galvanometer, and a simultaneous record is usually made of the jugular pulse and E.C.G. A record of the heart sounds is shown in Fig. 367. It reveals vibrations which are usually inaudible. The first sound, as recorded, may last for as long as 0·165 of a second, though the audible part, using a stethoscope, may be less than half that duration. Its frequency ranges from 25 to 40 per second. Its early, slower vibrations (A) the "auricular sound," synchronise with auricular systole, and are normally inaudible. The readily audible vibrations correspond to the isometric and early ejection phases of ventricular systole.

The audible portions of the second sound correspond approximately to closure of the semilunar valves, at about the beginning of the V-wave of the venous pulse: the frequency is about 50 per second, and duration 0·08 to 0·14 second, according to conditions of recording.

THE THIRD HEART SOUND. A third heart sound is described * as occurring in certain individuals during diastole, shortly after the second sound. It may be mistaken for a reduplicated second sound. It is softer and of a lower pitch than the second sound, and is heard most distinctly over the apex beat. It is probably due to the vibrations set up in the fluid itself, or in the auriculo-ventricular valves, by the sudden inrush of blood from auricles to ventricles at the beginning of diastole.† The sound is shown in Fig. 367.

CARDIAC MURMURS. When a fluid escapes through a narrow orifice into a wider space, vibrations are set up in the fluid and may cause sound. The same sort of vibration may be set up in the large vessels or in the heart, whenever the blood passes rapidly through a narrow orifice into a wider space.

In the normal resting individual, sounds produced in this way, though detectable by delicate recorders, are so slight that they are inaudible; examples are seen in the third sound and in the auricular sound already mentioned; under abnormal conditions, as after diseases affecting the valvular orifices of the heart, or after exercise, they may be heard with ease. These murmurs, or *bruits* as they are called, are of paramount importance in enabling the medical man to form a judgment as to the condition of the different valves of the heart. Thus injury to an aortic valve, so as to allow of leakage during diastole, allows a small amount of fluid under high pressure to pass from the aorta into the relaxed ventricle. On listening to the chest of a man with such a lesion, this regurgitation during diastole is heard as a rushing sound occurring in the place of, or continuing, the second sound up to the beginning of the next first sound, which denotes the commencement of systole.

In many cases, the disease which occasions the incompetence of the aortic valve is followed by cicatrization, so that the orifices can never become thoroughly patent or properly closed. Under such circumstances vibrations will also be set up in the current of blood as it escapes through the narrow orifice into the aorta during systole; and on listening to the chest over the second right costal cartilage, a " to and fro " bruit is heard composed of a systolic immediately followed by a diastolic murmur. In the same way, incompetence of the mitral valve, or dilatation of the mitral orifice, gives rise to a murmur which lasts during the whole of the ventricular contraction and is therefore

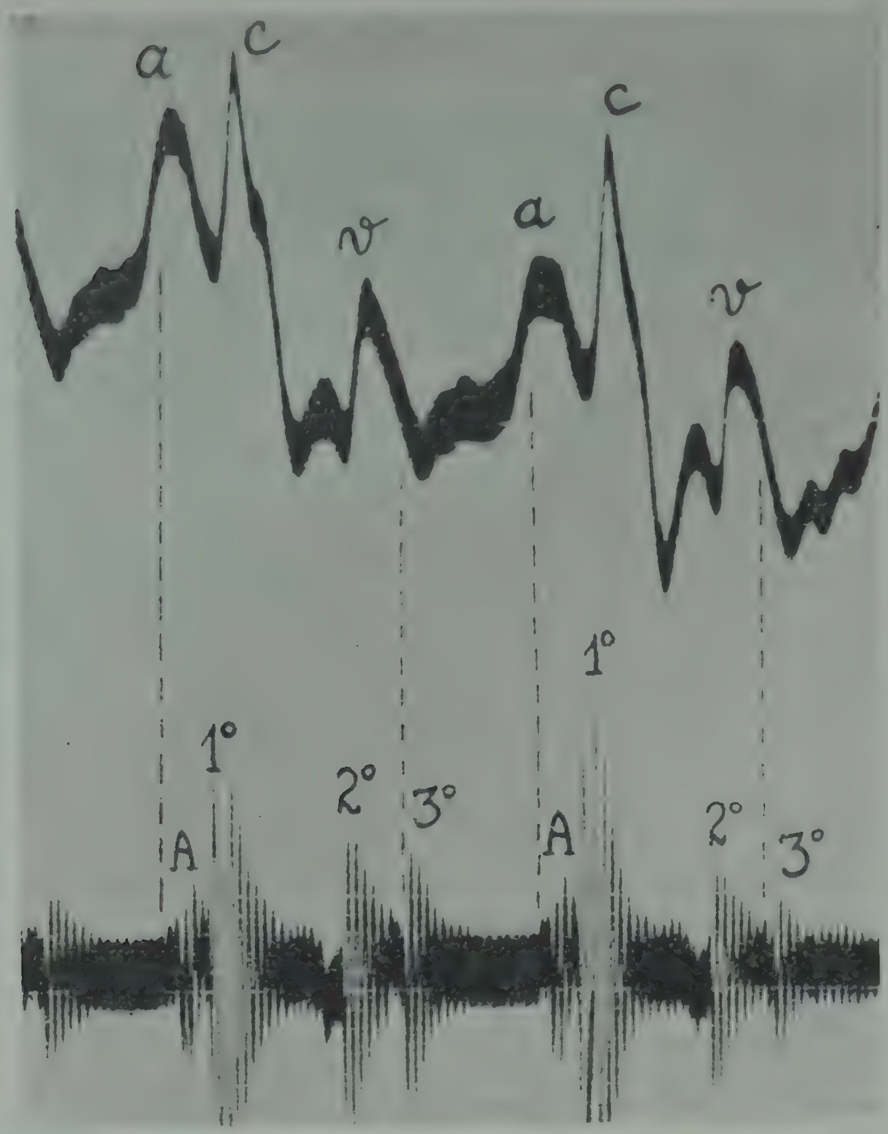

FIG. 367. Jugular vein pulse and heart sounds in man. In addition to the audible first and second sounds, the normally inaudible auricular sound (A) and the third sound are shown. (E. BRAUN-MENÉNDEZ and O. ORÍAS. *Rev. Argent. Cardiol.*, 1934, **1**, 101.)

systolic in relation. Such a murmur is heard best over the area of the cardiac impulse, and is also transmitted backwards, so that it can be heard on listening at the back of the patient. A narrowing of the mitral orifice in consequence of cicatrization of the valves will set up a resistance to the flow of blood from left auricle to left ventricle. The auricle becomes hypertrophied, its contraction prolonged, and the passage of blood through the contracted orifice gives rise to an auricular murmur which is heard on listening over the apex beat as a *presystolic bruit*. This bruit is easily distinguished from a systolic murmur by noticing that it runs up to and ends with the cardiac impulse, whereas a systolic murmur does not begin until the cardiac impulse commences.

ORÍAS and BRAUN-MENÉNDEZ (1939). The Heart Sounds in Normal and Pathological Conditions. (Oxford Med. Publ.).

The Human Electrocardiogram. When an excitable tissue is immersed in saline solution, the electrical changes led off during excitation are not of the simple diphasic or monophasic nature obtained when the tissue is in air.* Similarly, if we lead off any two parts of the heart's surface to an oscillograph, we record potential changes which are caused partly by events occurring in the muscle just underlying the electrode, partly by changes occurring at a distance and transmitted by the intervening muscle and blood acting simply as a moist conductor.† These two kinds of effect may be alluded to as direct and indirect. If we lead off, not from the heart itself, but from neighbouring tissues in contact with it, we shall still obtain the indirect effects of the electrical changes at each beat; and so in like manner these can be obtained when very various couples of points on the surface of the intact animal are led off to the galvanometer. In man, where the heart lies asymmetrically, with its electrical axis varying during systole, but roughly lying in an oblique direction pointing downwards towards the left, it is usual to start with the three classical "leads," viz. right arm—left arm (lead I); right arm—left leg (II); left arm—left leg (III). More recently, various other leads have been added to elicit further information, *e.g.* chest leads (IV) to right arm, left arm, or left foot (IV.R; IV.L; IV.F), or various precordial leads (C) (*e.g.* CR; CL; CF), or a CV lead ("unipolar lead"), the V lead being obtained by connecting R, L and F together as one lead.*

In all cases, each pair of leads, from suitable electrodes, are led to a string galvanometer or cathode ray oscillograph (Fig. 45, p. 118). In the record, or *electrocardiogram*, the time scale is uniform, and the electric potential scale always the same (1 cm./mv.): negativity of F or of C, is in a downward direction, and of R or L upward, *i.e.* excitation of the base of the heart, roughly speaking, gives an upward movement, and that of the apex a downward one. A typical electrocardiogram (E.C.G.) is shown in Fig. 368. The different points in the tracing are designated by the letters P, Q, R, S, T, first applied by Einthoven and retained because they do not commit us to theoretical interpretation of the curves, which, in view of the reasons given above, would be difficult; P, R and T are usually upward waves, Q and S, downwards. Such interpretation as we have is the result of direct experimental observation, which shows that the electrocardiogram is a composite picture of different events in the heart; that P is certainly due to the auricular excitation, and Q marks the beginning of the ventricular excitation. The P wave averages 0·08 sec. and precedes auricular contraction by 0·02 sec. Q, R, S varies normally, with heart rate, from 0·04–0·08 sec., and represents the spread of excitation in the ventricles. It precedes their contraction. Q—T (0·43 sec.) gives duration of systole. The A—V. interval is given by the distance between P and R

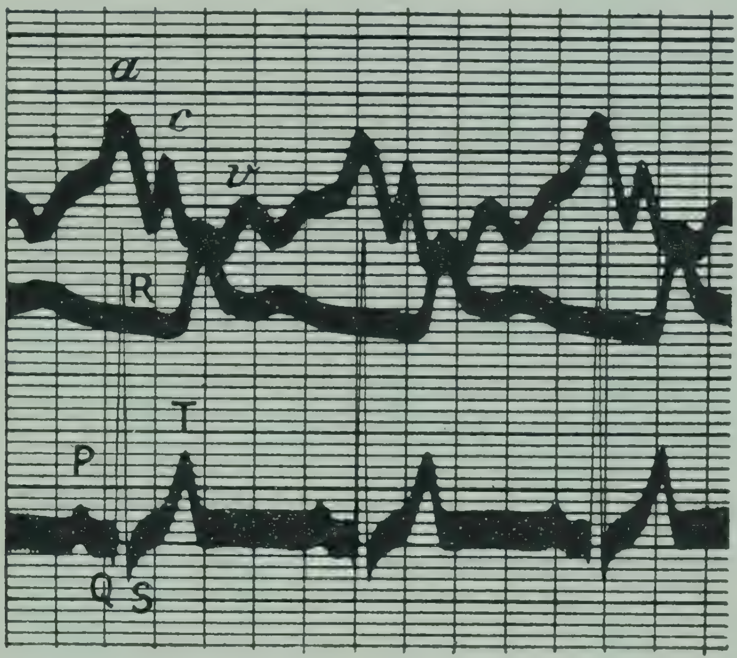

FIG. 368. Jugular venous pulse, radial arterial pulse and electrocardiogram in man. Vertical lines = 0·2 second: horizontal lines 0·1 mv. on E.C.G. The jugular waves *a*, *c*, *v* are marked; also the E.C.G. waves P, Q, R, S, T. Note that, due to delay in pulse transmission, the P precedes *a*, and *c* precedes the radial upstroke. The interval between auricular and ventricular systole, as measured by *a*—*c*, is slightly greater than that obtained from P—R (0·15 secs.). The summit of R is about 0·03 sec. before ventricular systole begins; the summit of T is at height of systole and end of T about 0·03 sec. before second sound. (LEWIS. *Diseases of the Heart*, 1933. Macmillan.)

(0·12–0·2 sec.), the total duration of the excitatory condition in the ventricle by the distance between Q and T. The highest wave, R, ranges normally from 0·7 to 1·8 mv. The T wave (0·27 sec.) ends at the termination of ventricular systole.

Quite apart from the objections outlined above, we should not expect, in view of the mechanism of the propagation of the excitatory wave in the ventricle, that the electrogram obtained in this indirect fashion would be easy of interpretation, at any rate so far as regards the course of the wave through the ventricular muscle. It must be remembered that the ventricular muscle is excited almost simultaneously at all points, in consequence of the rapid propagation of the wave of excitation along the branches of the A.V. bundle. The exact interval at which the excitatory process arrives at different points of the surface of the dog's ventricle after the upstroke of R in the whole electrocardiogram is shown, for example, in Fig. 369.

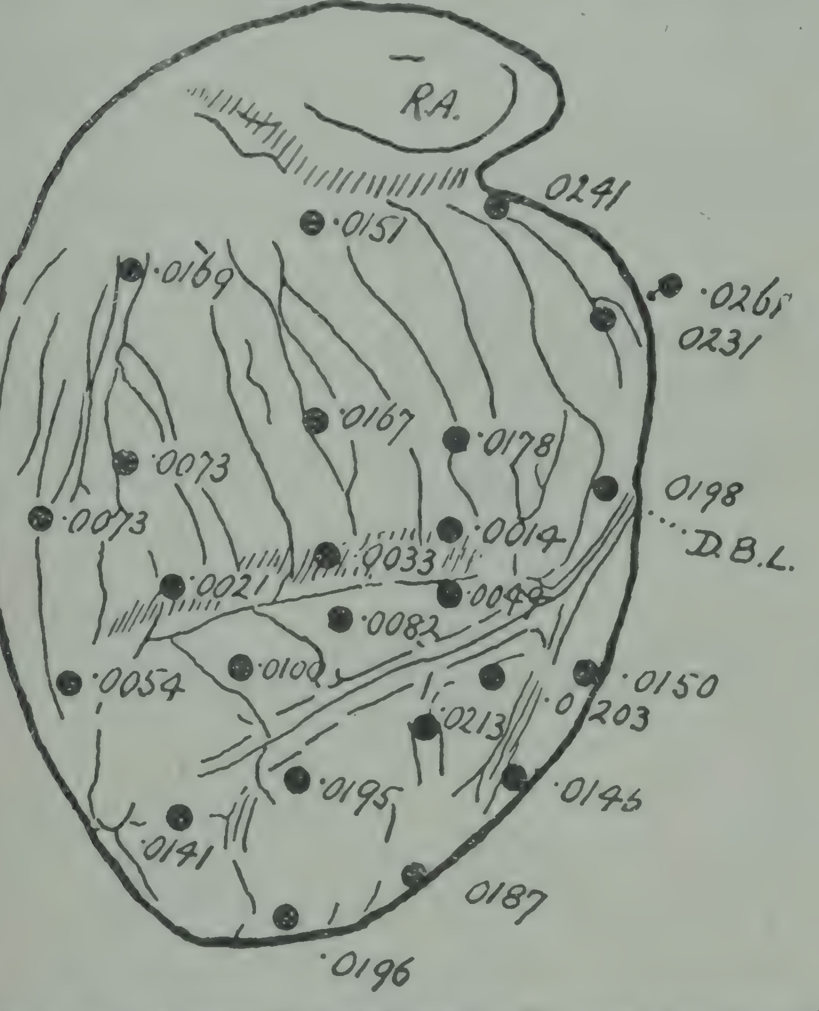

FIG. 369. Diagram showing the Time of Arrival of the Excitatory Wave at different points on the surface of the Ventricles in the Dog. (LEWIS and ROTHSCHILD, *Phil. Trans. Roy. Soc.*, 1915, **206B**, 181.)

The exact form and time relations of the ventricular part of the electrocardiogram may be altered in disease, or by interruption of one or other of the main branches of the A.V. bundle, because then the order of spread of the wave of excitation becomes different.

DEXTRO- AND LÆVOCARDIOGRAMS. When the right branch of the A.V. bundle is blocked or cut, the excitatory wave will reach the left ventricle first, and if the left branch is divided, then the right ventricle will contract first. In either case the normal composite electrocardiogram will be departed from, and the resulting record is called lævocardiogram (*i.e.* right branch blocked), or dextrocardiogram (left branch blocked) respectively, because it shows respectively the effect of an initial and preponderating contraction of left or right ventricles. A similar record will be obtained if a premature contraction is provoked by a stimulus applied to the appropriate ventricle. The results of direct stimulation of the ventricles in man * show that the two curves have the following characters :—

Dextrocardiogram. *Lead I*, initial deflection (R) upwards ; *Lead III*, initial deflection (R) downwards.

Lævocardiogram. *Lead I*, initial deflection (S) downwards ; *Lead III*, initial deflection (R) upwards.

(Owing to incorrect inferences from other species, the earlier investigators believed that the deflections were the opposite of those stated above.)

The electrocardiogram, moreover, is of considerable use clinically for the determination of the relation between the auricular and the ventricular contractions. Thus, in heart block there will be P waves independently of Q, R, S waves ; in a partial block there will be delayed conduction time, as shown by increased P—R interval (over 0·2 sec.) ; in auricular fibrillation the P waves are replaced by small rapid waves, etc.

Filling of the Heart in Diastole. The heart during diastole exerts no active suction on the blood in the veins. Its filling depends on the existence of a pressure within the veins greater than that in the auricles and ventricles * ; the greater the pressure within the large veins the more rapidly will the blood enter the heart during diastole. In this process an important part is played by the mechanical conditions existing in the thoracic cavity. Owing to the elasticity of the lungs and to the fact that they are constantly tending to contract, the pressure in the thorax is less than that of the external atmosphere. At the end of expiration this difference amounts to about 5 mm. Hg, rising to 9 mm. Hg at the end of inspiration and to 30 mm. Hg at the end of a forced inspiration. This " negative pressure " chiefly affects the thin-walled veins and auricles, and the right ventricle when it is relaxed. On the other hand, the veins outside the thorax are exposed to a pressure which is a little above that of the atmosphere. The respiratory movements, by causing an alternating suction on the walls of the great veins and heart, act like an accessory pump and cause an aspiration of blood into the heart with each inspiration.

If the pressure within the thorax be raised enough to cause a sufficient positive pressure on the big veins and auricles, the return flow of blood into the heart is suspended. Thus during extreme muscular effort with the glottis fixed a positive pressure is produced in the thorax. The impaired circulation is rendered evident by the engorgement of the superficial veins. Weber showed that, by a forcible expiration with the glottis closed, the pulse might disappear at the wrist and the circulation be brought to a standstill for such a time that loss of consciousness might supervene.

The whole heart is enclosed in the tough, fibrous, inextensible sac formed by the pericardium. Under normal circumstances the heart, even during diastole, does not entirely fill the sac, increased rate of filling being compensated by a reflex quickening of the heart rate. Under extreme stress, when both inflow and resistance to outflow are increased, or when the heart muscle is in a bad condition from fatigue or disease, the heart may expand during diastole so as entirely to fill the pericardium, which then prevents any further distension, and, by limiting inflow, limits also the stroke volume of the heart. Thus, the size of the pericardium determines the maximum possible output per beat. If the pericardium be removed, the heart may distend in diastole still further, the only limit to its filling being set by the resistance of the heart wall. Under these conditions the contraction may not empty the ventricle and the heart may fail.

The normal filling of the heart during diastole can be prevented by anything which hinders its expansion, such as the presence of fluid in the pericardial cavity. This happens in puncture of the left ventricle of the heart, as by rapier wounds. The same effect may be produced if oil be injected into the pericardium in a dog with the chest open ; when the pressure of the oil in the pericardial cavity is equal to that in the veins to the heart, the arterial blood pressure falls to zero and death ensues.†

It is under such conditions that the *pulsus paradoxus* may be observed, in which the pulse becomes small or absent during inspiration. This is due to the fact that, when the pericardial sac is filled with fluid under a positive pressure, the auricles and ventricles are much less affected by respiratory variations of intrathoracic pressure. The big veins, however, are still subject to these variations, so that during inspiration the blood tends to accumulate within them and not pass on into the heart. This organ therefore has less blood to discharge, and there is a diminution or absence of the pulse during inspiration. (Katz and Gauchat.)

Systolic Output of the Heart. The rate at which the blood circulates round the body depends on the quantity of blood which leaves the left heart per unit of time. In normal fasting men at rest the output is about 5 to 6 l. per minute, or 2·8 ± 0·3 l.per minute per sq. metre of body surface, this latter figure being called the *cardiac index*. It falls slightly with advancing age, from forty to fifty-five, and then more slowly.* It is not surprising that the output depends, among other things, on the body surface, being, in fact, for most mammals at rest, usually 2 to 3 l./sq.m./min. The output of the right ventricle must over any length of time be equal to that from the left ventricle, otherwise the blood would accumulate on one or other side of the heart. It must be remembered, however, that the coronary arteries, supplying the wall of the heart itself, leave the aorta at its very commencement, just beyond the aortic valves. The quantity of blood passing per unit of time along the aortic arch is therefore less than that leaving the left ventricle by the amount of blood which traverses the coronary vessels. The true output of each ventricle is therefore given, not by the flow through the aorta, but by the flow through the pulmonary artery.

Methods for experimentally determining the cardiac output fall into two classes. In the first the *stroke volume*, *i.e.* the volume changes in the ventricles at each beat of the heart is determined. A second method consists in the determination of the total volume of blood leaving the right or left ventricle in the course of a given time, say one minute—*the minute volume*. If this amount be divided by the number of heart beats in the same time, the stroke volume is obtained.

METHODS OF DETERMINING OUTPUT

(i.) **Cardiometric Method.** For recording the stroke volume in animals with opened thorax, a cardiometer † of the shape shown in Fig. 370, is slipped over the heart. To the margin of the opening is tied a rubber diaphragm with a hole in it, which accurately fits the heart and lies in the auriculo-ventricular groove. The tube of the cardiometer is connected with a piston recorder. During diastole the ventricles increase and during systole they diminish in volume. The change in volume at each beat gives the combined output of right and left ventricles, and must be divided by two in order to give the output of either ventricle separately. A cardiometer record is shown in Fig. 376. The disadvantages of this method are the open chest, and that the inertia and friction of the moving parts deform the curve.

(ii.) **Application of the Fick Principle.** If we know the difference between the oxygen content of the right heart and arterial bloods, a determination of the oxygen intake by the lungs over a given interval of time will tell us how much blood has passed through the lungs during that time. We thus get the *minute volume*. The mixed venous blood is drawn from the right ventricle. Thus ‡ in one case, in a horse weighing 360 kilos, 2,733 c.c. of oxygen were taken up in the lungs per minute, while the arterial blood contained 10·33 per cent. more oxygen than the venous blood. Since every 100 c.c. of blood that passed through the lungs had taken up 10·33 c.c. of oxygen, and 2,733 c.c. had been taken up in the course of a minute, it follows that

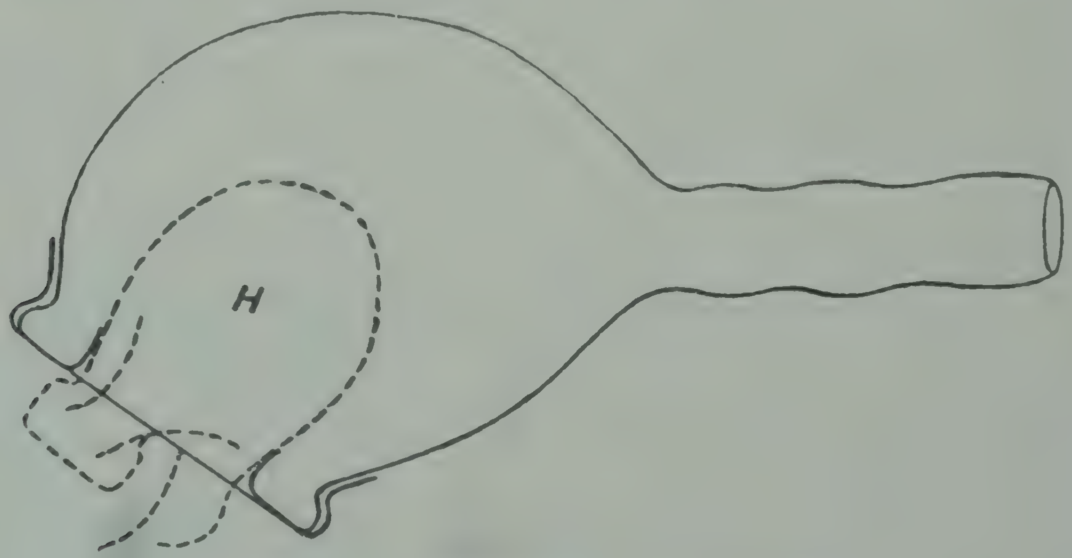

FIG. 370. Henderson's Cardiometer.

$$\frac{100 \times 2{,}733}{10{\cdot}33} = 26{,}457 \text{ c.c.}$$

of blood must have passed through the lungs in the time. Instead of oxygen differences, CO_2 differences may be taken, and the total output of CO_2 by the lungs determined.

DETERMINATION OF CARDIAC OUTPUT IN MAN. The direct Fick principle can be applied to man. It involves the passing of a catheter into the right auricle by way of an appropriate vein, usually in the bend of the elbow,* and is not difficult (Fig. 371).
